Chapter 1 Introduction to Programming and the Java Language
- Introduction
- 1.1 Basic Computer Concepts
  - 1.1.1 Hardware
  - 1.1.2 Operating Systems
  - 1.1.3 Application Software
  - 1.1.4 Computer Networks and the Internet
    - *Computer Networks*
    - *The Internet*
- 1.2 Practice Activity: Displaying System Configuration
  - 1.2.1 Displaying Windows Configuration Information
  - 1.2.2 Displaying Mac OS Configuration Information
- 1.3 Data Representation
  - 1.3.1 Binary Numbers
  - 1.3.2 Using Hexadecimal Numbers to Represent Binary Numbers
  - 1.3.3 Representing Characters with the Unicode Character Set
- 1.4 Programming Languages
  - 1.4.1 High- and Low-Level Languages
  - 1.4.2 An Introduction to Object-Oriented Programming
  - 1.4.3 The Java Language
- 1.5 An Introduction to Programming

- 1.5.1 Programming Basics
- 1.5.2 Program Design with Pseudocode
- 1.5.3 Developing a Java Application
- 1.5.4 Programming Activity 1: Writing a First Java Application
  - *Debugging Techniques*
  - *Testing Techniques*
- 1.5.5 Making a JAR File
- 1.6 Chapter Summary
- 1.7 Exercises, Problems, and Projects
  - 1.7.1 Multiple Choice Exercises
  - 1.7.2 Converting Numbers
  - 1.7.3 General Questions
  - 1.7.4 Technical Writing
  - 1.7.5 Group Project (for a group of 1, 2, or 3 students)

Chapter 2 Programming Building Blocks— Java Basics
- Introduction
- 2.1 Java Application Structure
- 2.2 Data Types, Variables, and Constants
  - 2.2.1 Declaring Variables
  - 2.2.2 Integer Data Types
  - 2.2.3 Floating-Point Data Types
  - 2.2.4 Character Data Type
  - 2.2.5 Boolean Data Type
  - 2.2.6 The Assignment Operator, Initial Values, and Literals
  - 2.2.7 *String* Literals and Escape Sequences
  - 2.2.8 Text Blocks
  - 2.2.9 Constants
- 2.3 Expressions and Arithmetic Operators
  - 2.3.1 The Assignment Operator and Expressions
  - 2.3.2 Arithmetic Operators
  - 2.3.3 Operator Precedence
  - 2.3.4 Programming Activity 1: Converting Inches to Centimeters
  - 2.3.5 Integer Division and Modulus

- 2.3.6 Division by Zero
- 2.3.7 Mixed-Type Arithmetic and Type Casting
- 2.3.8 Shortcut Operators

2.4 Programming Activity 2: Temperature Conversion

2.5 Chapter Summary

2.6 Exercises, Problems, and Projects

- 2.6.1 Multiple Choice Exercises
- 2.6.2 Reading and Understanding Code
- 2.6.3 Fill In the Code
- 2.6.4 Identifying Errors in Code
- 2.6.5 Debugging Area—Using Messages from the Java Compiler and Java JVM
- 2.6.6 Write a Short Program
- 2.6.7 Programming Projects
- 2.6.8 Technical Writing

Chapter 3 Object-Oriented Programming, Part 1: Using Classes

Introduction

3.1 Class Basics and Benefits

3.2 Creating Objects Using Constructors

3.3 Calling Methods

3.4 Using Object References

3.5 More on the *String* Class

- *The length Method*
- *The charAt Method*
- *The indexOf Methods*
- *The substring Methods*
- *The isBlank and strip Methods*
- *String Processing*

3.6 Programming Activity 1: Calling Methods

3.7 The Java Class Library

3.8 Formatting Output with the *DecimalFormat* Class

3.9 Generating Random Numbers with the *Random* Class

3.10 Input from the Console Using the *Scanner* Class

3.11 Calling *Static* Methods and Using *Static* Class Variables

3.12 Using *System.in* and *System.out*

- 3.13 The *Math* Class
    - *The pow Method*
    - *The round Method*
    - *The min and max Methods*
- 3.14 Formatting Output with the *NumberFormat* Class
- 3.15 The *Integer, Double, Character,* and Other Wrapper Classes
- 3.16 Programming Activity 2: Using Predefined Classes
- 3.17 Chapter Summary
- 3.18 Exercises, Problems, and Projects
    - 3.18.1 Multiple Choice Exercises
    - 3.18.2 Reading and Understanding Code
    - 3.18.3 Fill In the Code
    - 3.18.4 Identifying Errors in Code
    - 3.18.5 Debugging Area—Using Messages from the Java Compiler and Java JVM
    - 3.18.6 Write a Short Program
    - 3.18.7 Programming Projects
    - 3.18.8 Technical Writing
    - 3.18.9 Group Project (for a group of 1, 2, or 3 students)

Chapter 4 Introduction to Graphical Applications

- Introduction
- 4.1 JavaFX Application Structure
- 4.2 The Graphics Coordinate System and Color
- 4.3 Drawing Shapes and Text
- 4.4 Drawing Custom Shapes
- 4.5 Programming Activity 1: Writing an Application with Graphics
- 4.6 Chapter Summary
- 4.7 Exercises, Problems, and Projects
    - 4.7.1 Multiple Choice Exercises
    - 4.7.2 Reading and Understanding Code
    - 4.7.3 Fill In the Code
    - 4.7.4 Identifying Errors in Code
    - 4.7.5 Debugging Area—Using Messages from the Java Compiler and Java JVM
    - 4.7.6 Write a Short Program

- 4.7.7 Programming Projects
- 4.7.8 Technical Writing
- 4.7.9 Group Project (for a group of 1, 2, or 3 students)

Chapter 5 Flow of Control, Part 1: Selection

- Introduction
- 5.1 Forming Conditions
  - 5.1.1 Equality Operators
  - 5.1.2 Relational Operators
  - 5.1.3 Logical Operators
    - *DeMorgan's Laws*
- 5.2 Simple Selection with *if*
- 5.3 Selection Using *if/else*
    - *Block Scope*
- 5.4 Selection Using *if/else if*
- 5.5 Sequential and Nested *if/else* Statements
  - 5.5.1 Sequential *if/else* Statements
    - *Finding the Minimum or Maximum Values*
  - 5.5.2 Nested *if/else* Statements
    - *Dangling else*
- 5.6 Testing Techniques for *if/else* Statements
- 5.7 Programming Activity 1: Working with *if/else*
- 5.8 Comparing Floating-Point Numbers
- 5.9 Comparing Objects
  - 5.9.1 The *equals* Method
  - 5.9.2 *String* Comparison Methods
- 5.10 The Conditional Operator (?:)
- 5.11 The *switch* Statement
- 5.12 Programming Activity 2: Using the *switch* Statement
- 5.13 Chapter Summary
- 5.14 Exercises, Problems, and Projects
  - 5.14.1 Multiple Choice Exercises
  - 5.14.2 Reading and Understanding Code
  - 5.14.3 Fill In the Code
  - 5.14.4 Identifying Errors in Code
  - 5.14.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

        - 5.14.6 Write a Short Program
        - 5.14.7 Programming Projects
        - 5.14.8 Technical Writing
        - 5.14.9 Group Project (for a group of 1, 2, or 3 students)

Chapter 6 Flow of Control, Part 2: Looping

- Introduction
- 6.1 Event-Controlled Loops Using *while*
- 6.2 General Form for *while* Loops
- 6.3 Event-Controlled Looping
    - 6.3.1 Reading Data from the User
    - 6.3.2 Reading Data from a Text File
- 6.4 Looping Techniques
    - 6.4.1 Accumulation
    - 6.4.2 Counting Items
    - 6.4.3 Calculating an Average
    - 6.4.4 Finding Maximum or Minimum Values
- 6.5 Type-Safe Input Using *Scanner*
- 6.6 Constructing Loop Conditions
- 6.7 Testing Techniques for *while* Loops
- 6.8 Event-Controlled Loops Using *do/while*
- 6.9 Programming Activity 1: Using *while* Loops
    - *Task Instructions*
    - *Troubleshooting*
- 6.10 Count-Controlled Loops Using *for*
    - 6.10.1 Basic Structure of *for* Loops
    - 6.10.2 Constructing *for* Loops
    - 6.10.3 Testing Techniques for *for* Loops
- 6.11 Nested Loops
- 6.12 Programming Activity 2: Using *for* Loops
    - *Instructions*
    - *Troubleshooting*
- 6.13 Chapter Summary
- 6.14 Exercises, Problems, and Projects
    - 6.14.1 Multiple Choice Exercises
    - 6.14.2 Reading and Understanding Code
    - 6.14.3 Fill In the Code

        - 6.14.4 Identifying Errors in Code
        - 6.14.5 Debugging Area—Using Messages from the Java Compiler and Java JVM
        - 6.14.6 Write a Short Program
        - 6.14.7 Programming Projects
        - 6.14.8 Technical Writing
        - 6.14.9 Group Project (for a group of 1, 2, or 3 students)

Chapter 7 Object-Oriented Programming, Part 2: User-Defined Classes

    - Introduction
    - 7.1 Defining a Class
    - 7.2 Defining Instance Variables
    - 7.3 Writing Class Methods
    - 7.4 Writing Constructors
    - 7.5 Writing Accessor Methods
    - 7.6 Writing Mutator Methods
    - 7.7 Writing Data Manipulation Methods
    - 7.8 Programming Activity 1: Writing a Class Definition, Part 1
    - 7.9 The Object Reference *this*
    - 7.10 The *toString* and *equals* Methods
    - 7.11 *Static* Class Members
    - 7.12 Another Example: The *Rational* Class
    - 7.13 Graphical Objects
    - 7.14 Enumeration Types
    - 7.15 Programming Activity 2: Writing a Class Definition, Part 2
    - 7.16 Creating Packages
    - 7.17 Generating Web-Style Documentation with Javadoc
    - 7.18 Chapter Summary
    - 7.19 Exercises, Problems, and Projects
        - 7.19.1 Multiple Choice Exercises
        - 7.19.2 Reading and Understanding Code
        - 7.19.3 Fill In the Code
        - 7.19.4 Identifying Errors in Code
        - 7.19.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

- 7.19.6 Write a Short Program
- 7.19.7 Programming Projects
- 7.19.8 Technical Writing
- 7.19.9 Group Project (for a group of 1, 2, or 3 students)

Chapter 8 Single-Dimensional Arrays

- Introduction
- 8.1 Declaring and Instantiating Arrays
  - 8.1.1 Declaring Arrays
  - 8.1.2 Instantiating Arrays
  - 8.1.3 Combining the Declaration and Instantiation of Arrays
  - 8.1.4 Assigning Initial Values to Arrays
- 8.2 Accessing Array Elements
- 8.3 Aggregate Array Operations
  - 8.3.1 Printing Array Elements
  - 8.3.2 Reading Data into an Array
  - 8.3.3 Summing the Elements of an Array
  - 8.3.4 Finding Maximum or Minimum Values
  - 8.3.5 Copying Arrays
  - 8.3.6 Changing the Size of an Array
  - 8.3.7 Comparing Arrays for Equality
  - 8.3.8 Displaying Array Data as a Bar Chart
- 8.4 Programming Activity 1: Working with Arrays
    - *Instructions*
    - *Troubleshooting*
- 8.5 Using Arrays in Classes
  - 8.5.1 Using Arrays in User-Defined Classes
  - 8.5.2 Retrieving Command Line Arguments
- 8.6 Searching and Sorting Arrays
  - 8.6.1 Sequential Search of an Unsorted Array
  - 8.6.2 Selection Sort
  - 8.6.3 Insertion Sort
  - 8.6.4 Sorting Arrays of Objects
  - 8.6.5 Sequential Search of a Sorted Array
  - 8.6.6 Binary Search of a Sorted Array
- 8.7 Programming Activity 2: Searching and Sorting Arrays

        - *Instructions*
        - *Troubleshooting*
    - 8.8 Using Arrays as Counters
    - 8.9 Methods Accepting a Variable Number of Arguments
    - 8.10 Chapter Summary
    - 8.11 Exercises, Problems, and Projects
        - 8.11.1 Multiple Choice Exercises
        - 8.11.2 Reading and Understanding Code
        - 8.11.3 Fill In the Code
        - 8.11.4 Identifying Errors in Code
        - 8.11.5 Debugging Area—Using Messages from the Java Compiler and Java JVM
        - 8.11.6 Write a Short Program
        - 8.11.7 Programming Projects
        - 8.11.8 Technical Writing
        - 8.11.9 Group Project (for a group of 1, 2, or 3 students)

Chapter 9 Multidimensional Arrays and the *ArrayList* and *HashMap* Classes
- Introduction
- 9.1 Declaring and Instantiating Multidimensional Arrays
    - 9.1.1 Declaring Multidimensional Arrays
    - 9.1.2 Instantiating Multidimensional Arrays
    - 9.1.3 Combining the Declaration and Instantiation of Multidimensional Arrays
    - 9.1.4 Assigning Initial Values to Multidimensional Arrays
- 9.2 Accessing Multidimensional Array Elements
- 9.3 Aggregate Two-Dimensional Array Operations
    - 9.3.1 Processing All the Elements of a Two-Dimensional Array
    - 9.3.2 Processing a Given Row of a Two-Dimensional Array
    - 9.3.3 Processing a Given Column of a Two-Dimensional Array
    - 9.3.4 Processing a Two-Dimensional Array One Row at a Time
    - 9.3.5 Processing a Two-Dimensional Array One Column at a Time

  - 9.3.6 Displaying Two-Dimensional Array Data as a Bar Chart
- 9.4 Two-Dimensional Arrays Passed to and Returned from Methods
- 9.5 Programming Activity 1: Working with Two-Dimensional Arrays
    - *Instructions*
    - *Troubleshooting*
- 9.6 Other Multidimensional Arrays
- 9.7 The *ArrayList* Class
  - 9.7.1 Declaring and Instantiating *ArrayList* Objects
  - 9.7.2 Methods of the *ArrayList* Class
  - 9.7.3 Looping Through an *ArrayList* Using an Enhanced *for* Loop
  - 9.7.4 Using the *ArrayList* Class in a Program
- 9.8 Programming Activity 2: Working with the *ArrayList* Class
    - *Instructions*
    - *Troubleshooting*
- 9.9 The *HashMap* Class
  - 9.9.1 Declaring and Instantiating *HashMap* Objects
  - 9.9.2 Methods of the *HashMap* Class
  - 9.9.3 Using the *HashMap* in a Program
- 9.10 Chapter Summary
- 9.11 Exercises, Problems, and Projects
  - 9.11.1 Multiple Choice Exercises
  - 9.11.2 Reading and Understanding Code
  - 9.11.3 Fill In the Code
  - 9.11.4 Identifying Errors in Code
  - 9.11.5 Debugging Area—Using Messages from the Java Compiler and Java JVM
  - 9.11.6 Write a Short Program
  - 9.11.7 Programming Projects
  - 9.11.8 Technical Writing
  - 9.11.9 Group Project (for a group of 1, 2, or 3 students)

Chapter 10 Object-Oriented Programming, Part 3: Inheritance, Polymorphism, and Interfaces

Introduction
10.1 Inheritance
10.2 Inheritance Design
  10.2.1 Inherited Members of a Class
  10.2.2 Subclass Constructors
  10.2.3 Adding Specialization to the Subclass
  10.2.4 Overriding Inherited Methods
10.3 The *protected* Access Modifier
10.4 Programming Activity 1: Using Inheritance
    Instructions
10.5 *Abstract* Classes and Methods
10.6 Polymorphism
10.7 Programming Activity 2: Using Polymorphism
    Instructions
10.8 Interfaces
10.9 Chapter Summary
10.10 Exercises, Problems, and Projects
  10.10.1 Multiple Choice Exercises
  10.10.2 Reading and Understanding Code
  10.10.3 Fill In the Code
  10.10.4 Identifying Errors in Code
  10.10.5 Debugging Area—Using Messages from the Java Compiler and Java JVM
  10.10.6 Write a Short Program
  10.10.7 Programming Projects
  10.10.8 Technical Writing
  10.10.9 Group Project (for a group of 1, 2, or 3 students)

Chapter 11 Exceptions and Input/Output Operations
Introduction
11.1 Simple Exception Handling
11.2 Catching Multiple Exceptions
11.3 Reading Text Files Using *Scanner*
11.4 The *java.io* Package
11.5 Recovering from an Exception
11.6 Writing and Appending to Text Files

  - 11.6.1 Writing to Text Files
  - 11.6.2 Appending to Text Files
- 11.7 Reading Structured Text Files
  - 11.7.1 Parsing a *String* Using *Scanner*
  - 11.7.2 Reading Structured Data Using *Scanner*
- 11.8 Programming Activity 1: Reading from a Structured Text File
    - *Instructions*
    - *If you have time*
    - *Troubleshooting*
- 11.9 Streams
- 11.10 Reading Formatted Open Data from a Remote Location
  - 11.10.1 Accessing Remote Data
  - 11.10.2 JSON Formatting and Parsing
  - 11.10.3 Reading, Parsing, Streaming, and Processing Remote Data
- 11.11 Reading and Writing Objects to a File
  - 11.11.1 Writing Objects to Files
  - 11.11.2 Reading Objects from Files
- 11.12 Programming Activity 2: Reading Objects from a File
    - *Task Instructions: Reading from the transactions.obj File*
    - *If you have time*
    - *Troubleshooting*
- 11.13 User-Defined Exceptions
- 11.14 Chapter Summary
- 11.15 Exercises, Problems, and Projects
  - 11.15.1 Multiple Choice Exercises
  - 11.15.2 Reading and Understanding Code
  - 11.15.3 Fill In the Code
  - 11.15.4 Identifying Errors in Code
  - 11.15.5 Debugging Area—Using Messages from the Java Compiler and Java JVM
  - 11.15.6 Write a Short Program
  - 11.15.7 Programming Projects
  - 11.15.8 Technical Writing
  - 11.15.9 Group Project (for groups of 2, 3, or more

students)

Chapter 12 Recursion
- Introduction
- 12.1 Simple Recursion: Identifying the General and Base Cases
- 12.2 Recursion with a Return Value
  - 12.2.1 Computing the Factorial of a Number
  - 12.2.2 Computing the Greatest Common Divisor
- 12.3 Recursion with Two Base Cases
- 12.4 Programming Activity 1: Checking for a Palindrome
    - *Instructions*
    - *Task Instructions*
    - *Troubleshooting*
- 12.5 Simple Recursion on an Array
- 12.6 Binary Search: A Recursive Solution
- 12.7 Programming Activity 2: The Towers of Hanoi
    - *Instructions*
    - *Task Instructions*
    - *Troubleshooting*
- 12.8 Merge Sort
- 12.9 Quick Sort
- 12.10 Recursion Versus Iteration
- 12.11 Chapter Summary
- 12.12 Exercises, Problems, and Projects
  - 12.12.1 Multiple Choice Exercises
  - 12.12.2 Reading and Understanding Code
  - 12.12.3 Fill In the Code
  - 12.12.4 Identifying Errors in Code
  - 12.12.5 Debugging Area—Using Messages from the Java Compiler and Java JVM
  - 12.12.6 Write a Short Program
  - 12.12.7 Programming Projects
  - 12.12.8 Technical Writing
  - 12.12.9 Group Projects (for a group of 1, 2, or 3 students)

Chapter 13 An Introduction to Data Structures
- Introduction
- 13.1 Linked Lists
  - 13.1.1 Linked-List Concepts and Structure
  - 13.1.2 Linked-List Basics
  - 13.1.3 Methods of a Linked List
  - 13.1.4 Testing a Linked-List Class
- 13.2 Linked Lists of Objects
  - 13.2.1 A Linked-List Shell
  - 13.2.2 Generating an Exception
  - 13.2.3 Other Methods of a Linked List
  - 13.2.4 Testing a Linked-List Class
- 13.3 Implementing a Stack Using a Linked List
- 13.4 Implementing a Queue Using a Linked List
- 13.5 Array Representation of Stacks
- 13.6 Programming Activity 1: Writing Methods for a Stack Class
    - *Instructions*
    - *Troubleshooting*
- 13.7 Array Representation of Queues
- 13.8 Sorted Linked Lists
- 13.9 Programming Activity 2: Writing *Insert* and *Delete* Methods for a Sorted Linked List
    - *Instructions*
    - *Troubleshooting*
- 13.10 Doubly Linked Lists
- 13.11 Linked Lists Using Generic Types
- 13.12 Recursively Defined Linked Lists
- 13.13 Chapter Summary
- 13.14 Exercises, Problems, and Projects
  - 13.14.1 Multiple Choice Exercises
  - 13.14.2 Reading and Understanding Code
  - 13.14.3 Fill In the Code
  - 13.14.4 Identifying Errors in Code
  - 13.14.5 Debugging Area—Using Messages from the Java Compiler and Java JVM
  - 13.14.6 Write a Short Program

13.14.7 Programming Projects
13.14.8 Technical Writing
13.14.9 Group Project (for a group of 1, 2, or 3 students)

Chapter 14 Running Time Analysis
Introduction
14.1 Orders of Magnitude and Big-Oh Notation
14.2 Running Time Analysis of Algorithms: Counting Statements
14.3 Running Time Analysis of Algorithms and Impact of Coding: Evaluating Recursive Methods
Handwaving Method
Iterative Method
Proof by Induction Method
Other Methods
14.4 Programming Activity: Tracking How Many Statements Are Executed by a Method
Instructions
Troubleshooting
14.5 Running Time Analysis of Searching and Sorting Algorithms
14.6 Simulation of Various Sorting Algorithms
14.7 Chapter Summary
14.8 Exercises, Problems, and Projects
14.8.1 Multiple Choice Exercises
14.8.2 Compute the Running Time of a Method
14.8.3 Programming Projects
14.8.4 Technical Writing
14.8.5 Group Project (for a group of 1, 2, or 3 students)

Chapter 15 General Trees, Binary Trees, and Binary Search Trees
Introduction
15.1 Trees
15.2 Binary Trees
15.3 Binary Tree Implementation
15.4 Programming Activity 1: Working with Binary Trees

Instructions

Troubleshooting

15.5 Binary Search Trees

15.5.1 Searching in a Binary Search Tree

15.5.2 Inserting in a Binary Search Tree

15.5.3 Deleting from a Binary Search Tree

15.6 Binary Search Tree Implementation

15.7 Rebalancing a Binary Search Tree

15.8 Programming Activity 2: Working with Binary Search Trees

Instructions

Troubleshooting

15.9 Chapter Summary

15.10 Exercises, Problems, and Projects

15.10.1 Multiple Choice Exercises

15.10.2 Reading and Understanding Code

15.10.3 Fill In the Code

15.10.4 Identifying Errors in Code

15.10.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

15.10.6 Write a Short Program

15.10.7 Programming Projects

15.10.8 Technical Writing

15.10.9 Group Project (for a group of 1,2, or 3 students)

Chapter 16 Graphical User Interfaces (available online in the eBook)

Chapter 17 Graphical User Interfaces Using JavaFX (available online in the eBook)

Appendix A Java Reserved Words and Keywords

Appendix B Operator Precedence

Appendix C The Unicode Character Set

Appendix D Representing Negative Integers

Appendix E Representing Floating-Point Numbers (available online in the eBook)

Appendix F Solutions to Selected Exercises (available online in the

eBook)

Python

is used for single line comments

```python
# This is a comment
```

Java

// is used for single line comments

```java
// This is a comment
```

Python

''' and ''' are used to delimit multiple line comments

```python
''' This is a
    comment that spans over several
   lines
'''
```

Java

/* and */ are used to delimit multiple line comments

```java
/* This is a
    comment that spans over several lines
*/
```

Python

There is no need to end a statement with a semicolon (;).

Data types are implicit. We do not need to declare a variable, we just use it.

```python
age = 18
gpa = 3.7
```

Java

Every statement ends with a semicolon (;).

Data types are explicit. A variable must be declared before using it.

```java
int age;
age = 18;
double gpa = 3.7;
```

Python

/ is used floating point division, // is used for integer division

```python
average = 373 / 4
# floating point division
quarters = 102 // 25
# integer division
```

Java

The type of division (floating point or integer) is based on the data types of the two operands.

```java
double average = 373.0 / 4;
// floating point division
int quarters = 102 / 25;
// integer division
```

Python

Single quotes and double quotes have the same meaning.

```python
grade = 'A'
city = "New York"
```

Java

Single quotes are used for characters, double quotes are used for Strings.

```java
char grade = 'A';
String city = "New York";
```

Python

There is no formal concept of a constant, but using uppercase for a variable is good practice to denote that we should not change its value.

```python
DAYS = 365
# Please do not change the
# value of DAYS
```

Java

The *final* keyword is used to declare constants. The value of a constant cannot be changed.

```java
final int DAYS = 365;
// DAYS' value cannot be
// changed
```

Python

Indentation counts. Parentheses around the condition are not needed, and a colon (:) precedes the indented statements.

```python
if age >= 18:
    print( "You can vote" )
    print( "Congratulations" )
```

Java

Indentation does not count, but we use it for style and readability. Parentheses are required around conditions. If there is more than one statement attached to a selection or looping construct, we use curly braces for the block.

```java
if ( age >= 18 )
{
    System.out.println( "You can vote" );
    System.out.println( "Congratulations" );
}
```

Python

The logical operators are *and*, *or*, and *not*.

```python
if age >= 18 and age <= 65:
    print( "Hi" )
```

Java

The logical operators are *&&* (for and), *//* (for or), and *!* (for not).

```java
if ( age >= 18 and age <= 65 )
    System.out.println( "Hi" );
```

Python

The keyword *def* is used for functions. The parameter list is a comma delimited list of variable names. The function header is followed by a colon (:). The body of the function is indented.

```python
def sum( a, b ):
   return a + b
```

Java

The parameter list of a function (called method in Java) is a comma delimited list of variable names and their respective data types. The method header includes the return data type (void if the method does not return anything). The body of the method is inside a set of curly braces. Indentation is optional but recommended for better readability.

```java
int sum( int a, int b )
{
  return a + b;
}
```

Preface

Purpose of This Text and Its Audience

Java Illuminated, Sixth Edition, covers all of the material required for the successful completion of an introductory course in Java. While the focus is on the material required for the Computer Science I (CS1) and Computer Science II (CS2) curricula, students enrolled in Information Systems, Information Technology, or self-directed study courses will find the text useful as well. It has been written to provide introductory computer science students with a comprehensive overview of the fundamentals of programming using Java as the teaching language. In addition, the text presents other topics of interest, including graphical user interfaces (GUI), data structures, file input and output, and graphical applications.

Throughout the text, we take an “active learning” approach to presenting the material. Instead of merely presenting the concepts to students in a one-sided, rote manner, we ask them to take an active role in their understanding of the concepts through the use of numerous interactive examples, exercises, and projects.

Coverage and Approach

Our approach is to teach object-oriented programming in a progressive manner. We start in Chapter 1 by presenting an overview of object-oriented programming. In Chapter 3, we delve a little deeper into the concepts of classes and objects and introduce the student to many of the useful classes in the Java Class Library. Our emphasis at this point is on using classes; we teach the student how to read APIs in order to determine how to instantiate objects and call methods of the classes. In Chapter 7, we move on to designing user-defined classes, and in Chapter 10, we present inheritance, polymorphism, and interfaces. Throughout the text, we present concepts in an object-oriented context.

Our philosophy is to emphasize good software engineering practices by focusing on designing and writing correct, maintainable programs. As such, we discuss pseudocode, testing techniques, design trade-offs, and other software engineering tips.

We teach the student basic programming techniques, such as accumulation, counting, calculating an average, finding maximum and minimum values, using flag and toggle variables, and basic searching and sorting algorithms. In doing so, we emphasize the patterns inherent in programming. Concepts are taught first, followed by fully implemented examples with source code. We promote Java standards, conventions, and methodologies.

What's New in *Java Illuminated*

In this edition, we have incorporated the latest Java features as they apply to this text: text blocks, the new *switch* statement syntax and *switch* expression, the new syntax for *instanceof*, and the *record* class. We have added coverage of merge sort, quick sort, and the *HashMap* class. We have also eliminated the *SimpleDate* class and incorporated more materials into our coverage of calling methods and building a class in Chapters 3 (using classes) and 7 (creating our own classes).

For students coming from Python, we have added a small section at the beginning of the book showing examples of Python syntax and its Java equivalent.

Throughout the text, we have updated, improved, or replaced examples accordingly.

In Chapter 1, we added how to run a program in one step, without compiling, and how to retrieve the version of *javac* and *java*.

In Chapter 2, we show how to use text blocks, for example, to display a menu.

In Chapter 3, we have eliminated the *SimpleDate* class. We use the *String* class to explain how to instantiate objects and call methods. We have added more examples using the *String* class, such as parsing an email address.

In Chapter 5, we explain the new *switch* syntax and how to use *switch* expressions.

In Chapter 7, in addition to the *Auto* class, we have added a new example: a *Rational* class. We added explanations showing how *this* is the object reference that called a method. We also cover the new syntax of the *instanceof* operator.

In Chapter 9, we include coverage of the *HashMap* class.

In Chapter 11, we have converted some of the examples to using the *record* class and explain how it works well if all we need is a class to store data (that we read from a file). We also changed the example reading data from a remote location to a simpler example.

In Chapter 12 (recursion, formerly Chapter 13), we have added merge sort and quick sort, including examples and explanations.

In Chapter 13 (linked lists, formerly Chapter 14), we are now using the *compareTo* method in the sorted linked list example.

In Chapter 14 (running time analysis, formerly Chapter 15), we have added simulation code counting comparison statements for insertion sort, merge sort, and quick sort, including when the array is already sorted.

Chapter 15 (binary trees and binary search trees) is a new chapter in this text, replacing the old Chapter 12 (graphical user interfaces), which has been moved online. We start with general trees and tree concepts (e.g., root, height, level, and leaves), then cover binary trees, including pre order, in order, and post order traversals. We discuss the motivation for binary search trees and cover binary search trees, including an analysis of running times for search, insert, and delete methods. We also cover the need to rebalance the tree and implement and discuss a rebalancing recursive method.

Learning Features

Recognizing today's students' growing interest in visualization, we distribute techniques for producing graphical output throughout the book, starting in Chapter 4 with graphical applications. An example using either animation or graphical output is included in most chapters. Instructors who are not interested in incorporating graphics into their curriculum can simply skip these sections. In addition, some of our examples are small games, which we find motivational for students.

In each chapter, we include one or two Programming Activities, which are designed to provide visual feedback to the students so that they can assess the correctness of their code. In most Programming Activities, we provide a framework, usually with a graphical user interface, to which the student adds code to complete the application. The student should be able to finish the Programming Activity in about 15 to 20 minutes; thus, these activities can be used in the classroom to reinforce the topics just presented. Each Programming Activity also includes several discussion questions that test the student's understanding of the concepts the activity illustrates. The Programming Activities are also appropriate for a closed or open laboratory environment. In short, this text can be used in a traditional lecture environment, a computer-equipped classroom, or a lab environment.

We also provide the instructor and students with an extensive variety of end-of-chapter material: multiple-choice questions, examples that ask the student to predict the output of prewritten code or to fill in missing code, debugging activities, short exercises, programming projects, technical writing assignments, one or more learning-to-learn exercises called Look It Up, and a higher-difficulty group project.

Chapter-by-Chapter Overview

The chapters are logically organized from simple to more difficult topics, while incorporating object orientation as needed, taking into account the specifics of the Java language. Here is a brief summary of the topics covered in each chapter.

Chapter 1: Introduction to Programming and the Java Language

We introduce the student to the concept of programming, first covering computer hardware and operating systems, and following with a brief evolution of programming languages, including an introduction to object-oriented programming. We explain programming basics and pseudocode as a program design technique. The student writes, compiles, and debugs their first program using an integrated development environment.

Chapter 2: Programming Building Blocks—Java Basics

In this chapter, we concentrate on working with variables and constants of primitive data types and composing arithmetic expressions. We illustrate the differences between integer and floating-point calculations and introduce operator precedence. We introduce jshell, the Java programming sandbox. We use a combination of jshell sessions and complete programs to demonstrate the concepts at hand.

Chapter 3: Object-Oriented Programming, Part 1: Using Classes

Chapter 3 introduces classes from the user, or client, standpoint and discusses the benefits of encapsulation and code reuse. The student learns how to instantiate objects and call methods. We also demonstrate useful Java classes for console input and output, formatting output, performing mathematical calculations, generating random numbers, and using methods of the Wrapper classes. We use methods of the *String* class to visually illustrate the passing of arguments and receiving of and use of return values.

Chapter 4: Introduction to Graphical Applications

Chapter 4 presents several methods of the JavaFX *GraphicsContext* class that can be used to create graphical output by drawing shapes, text, and sprites. The windowing graphics coordinate system is explained and using color is also explored. We demonstrate these graphics methods in JavaFX applications. Instructors wishing to postpone or skip graphics coverage altogether can use as little or as much of this chapter as they desire.

Chapter 5: Flow of Control, Part 1: Selection

Various forms of the *if, if/else*, and *if/else if* statements are presented, along with the appropriate situations in which to use each form. We also demonstrate nested *if/else* statements and testing techniques. We begin our coverage of scope by introducing block scope. Later chapters build upon this foundation. As part of our object-oriented programming coverage, we teach the importance of comparing objects using the *equals* method. This chapter also covers the conditional operator, the *switch* statement, and *switch* expressions.

Chapter 6: Flow of Control, Part 2: Looping

This is probably the most important chapter in the text. We have found that looping and repetition are the most difficult basic programming concepts for the average student to grasp. We try to ease the student's understanding of looping techniques by presenting patterns to follow in coding basic algorithms: accumulation, counting, calculating an average, and finding minimum and maximum values. Looping is further explored as a tool for validation of input values. We also introduce toggle variables and flag variables as tools to facilitate writing loops. We continue our coverage of scope by illustrating the scope of variables declared within the *while* loop body and *for* loop header. We concentrate on using the *while* loop *for* event-controlled and sentinel-controlled repetition and the *for* loop for count-controlled looping. A large section focuses on constructing loop conditions, which is often a challenging task for the student. Sections are also provided on testing techniques for loops. In this chapter, we also introduce reading data from a text file using the *Scanner* class.

Chapter 7: Object-Oriented Programming, Part 2: User-Defined Classes

In this chapter, we teach the student to write classes, as well as client applications that instantiate objects and call methods of the class. We present class design techniques and standard patterns for writing constructors, mutators and accessors, and the *toString, equals*, and other user-defined methods. We further explain scope in the context of class members and method parameters. We explain and show that *this* refers to the object reference calling an instance method of a class. We also explain how to write classes with *static* methods and *static* data. Additionally, we illustrate how to write methods so that the method calls can be chained. *Enum* is also covered as a user-defined class type. Finally, we teach the student how to use Javadoc.

Chapter 8: Single-Dimensional Arrays

This chapter begins with the declaration, instantiation, and initialization of single-dimensional arrays. From there, the student learns to perform the basic programming techniques (accumulation, counting, calculating an average, and finding maximum and minimum values) on array elements. We also cover arrays as instance variables of a class, and demonstrate maintaining encapsulation while accepting arrays as method parameters and returning arrays from methods. We demonstrate how to represent an array as a bar chart. Basic searching and sorting algorithms are also presented, including sequential and binary searches and Selection and Insertion sorts.

Chapter 9: Multidimensional Arrays and the *ArrayList* and *HashMap* Classes

We focus in this chapter on two-dimensional array processing, including techniques for processing the elements in the entire array, or the elements in a specific column or row. We also demonstrate the extra processing needed to handle arrays with rows of different lengths. Creating a bar chart of the data in the array is also demonstrated. In addition, we extrapolate the concepts from two-dimensional arrays to discuss multidimensional arrays.

We present the *ArrayList* class as an expandable array and demonstrate using classes with generic types, the enhanced *for* loop, and autoboxing and unboxing. We also cover the *HashMap* class.

Chapter 10: Object-Oriented Programming, Part 3: Inheritance, Polymorphism, and Interfaces

Continuing our object-oriented programming coverage, we discuss the important concepts and benefits of inheritance and the design of class hierarchies, including abstract classes. We cover inherited members of a class, constructing objects of a subclass, adding specialization to a subclass, overriding inherited methods, and calling methods of the superclass. We discuss the trade-offs of declaring members as *protected* versus *private*. We demonstrate polymorphism with a graphical example. We introduce the student to interfaces, emphasizing code reuse as the motivation for defining interfaces. We explain *default* methods and how we can use them in new versions of a program so that our old code does not break as we add new features. We also demonstrate polymorphism using interfaces. Interfaces are used extensively in Graphical User Interfaces (see online chapter). We introduce UML diagrams to help students visualize the inheritance hierarchy of the examples.

Chapter 11: Exceptions and Input/Output Operations

Recognizing that building robust applications requires error handling, we present exception handling as a tool for validating user input and recovering from errors at run time. We demonstrate handling predefined exceptions and writing user-defined exceptions.

With this knowledge, the student is ready to perform file input and output operations. We demonstrate reading and writing *Strings* and primitive data types to text files, and reading and writing objects directly to files. The *Scanner* class is used to read and parse input from text files and *Strings*. We use *record* classes to read data into objects of these *record* classes. We demonstrate how to read and place file contents into a *Stream* and how to filter and process that *Stream*. We use lambda expressions when processing the *Stream*. We use the *org.json* package to show how to parse JSON data. We demonstrate how to read data from a remote file located on the Internet, including parsing JSON data and converting that data into a *Stream* for filtering and processing.

Chapter 12: Recursion

Recursion is presented as a design technique, reducing the size of a problem until an easy-to-solve problem is reached. We demonstrate recursive methods with one base case and with multiple base cases, and with and without return values. Specific examples provided include computing the factorial of a number, finding the greatest common divisor, performing a binary search, determining if a phrase is a palindrome, calculating combinations, solving the Towers of Hanoi problem, merge sort, and quick sort. We use the *StackWalker* class to demonstrate how values are pushed onto and popped off the stack as recursive calls are executed. The benefits and trade-offs of recursion versus iteration are also discussed.

Chapter 13: An Introduction to Data Structures

In this chapter, we cover data structures by exploring the concepts and implementations of various types of linked lists, stacks, and queues. We demonstrate many types and uses of linked lists: a singly linked list, a linked list as a stack, a linked list as a queue, a doubly linked list, a sorted linked list, and a recursively defined linked list. Arrays as stacks and circular arrays as queues are also covered in detail.

We begin with a list of primitive types (*int*) and progress to a list consisting of objects of a user-defined *Player* class. Then we cover defining a class using generic types to demonstrate how a list can be defined to hold generic objects.

Chapter 14: Running Time Analysis

We explain how to evaluate the performance of an algorithm in this chapter. We explain the Big-Oh notation and orders of magnitude. Students learn various methods for deriving performance estimates: counting statements in loops, iterative, handwaving, and proof by induction analyses for recursive methods. We demonstrate how the coding of an algorithm influences its running time. Worst-case, best-case, and average-case performances are explained and illustrated. We show an example counting comparison statements for insertion sort, merge sort, and quick sort, included when the array is already sorted, and how that relates to the math analysis of the running times of these methods.

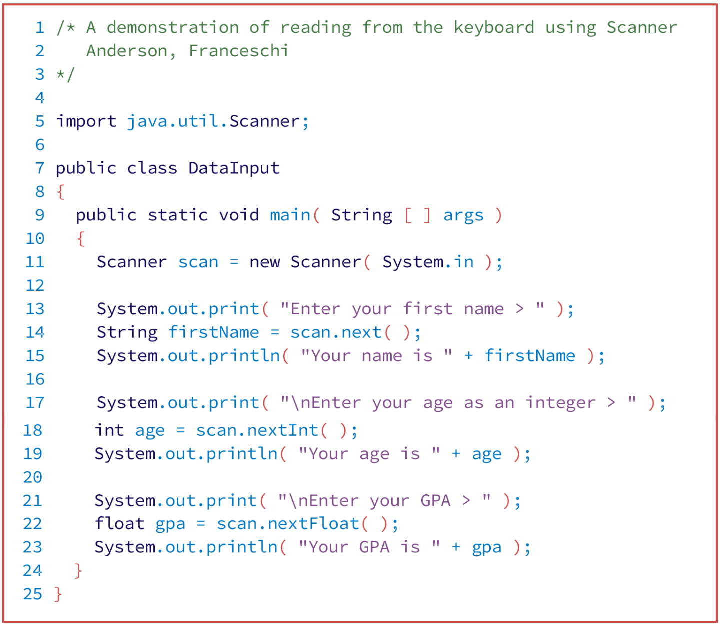
Chapter 15: General Trees, Binary Trees, and Binary Search Trees

We cover general trees and tree concepts (e.g., root, height, level, leaves, complete and full binary trees). Then, we cover binary trees, including pre order, in order, and post order traversals. We discuss the desirability of trees to be compact and compute the number of levels in a full binary tree as a function of the number of nodes in the tree. We discuss the motivation for binary search trees and cover binary search trees, including search, insert, and delete methods. Then, we analyze the running times of these methods. We also discuss the need to rebalance the tree and implement and discuss a rebalancing recursive method.

Pedagogy

Concepts are always taught first, followed by complete, executable examples illustrating these concepts. Most examples demonstrate real-life applications so that the student can understand the need for the concept at hand. The example code is colored to better illustrate the syntax of the code and to reflect the use of colors in today's IDE tools, as shown in this example from Chapter 3:

Example 3.9 Reading from the Keyboard Using *Scanner*



```java
/* A demonstration of reading from the keyboard using Scanner
   Anderson, Franceschi
*/

import java.util.Scanner;

public class DataInput
{
  public static void main( String [ ] args )
  {
    Scanner scan = new Scanner( System.in );

    System.out.print( "Enter your first name > " );
    String firstName = scan.next( );
    System.out.println( "Your name is " + firstName );

    System.out.print( "\nEnter your age as an integer > " );
    int age = scan.nextInt( );
    System.out.println( "Your age is " + age );

    System.out.print( "\nEnter your GPA > " );
    float gpa = scan.nextFloat( );
    System.out.println( "Your GPA is " + gpa );
  }
}
```

Description

Note that in this example and throughout the text, we place the opening curly brace of a block on a line of its own. We have found this placement easier for a student new to Java to understand where a block begins and ends.

Figures and tables are used to illustrate or summarize the concept at hand, such as these from Chapters 6 and 7:

Figure 6.1 Flow of Control of a *while* Loop

Description

Access Modifiers

Access Modifier	**Class or Member Can Be Referenced By ...**
public	methods of the same class, as well as methods of other classes
private	methods of the same class only
protected	methods in the same class, as well

	as methods of subclasses and methods in classes in the same package
no modifier (package access)	methods in the same package or same folder only

Description

In each chapter, we emphasize good design concepts using “Software Engineering Tips,” such as the one to the right from Chapter 7.

SOFTWARE ENGINEERING TIP

Define instance variables of a class as *private* so that only methods of the class will be able to set or change their values.

COMMON ERROR TRAP

Be sure that both operands of the logical AND and logical OR operators are *boolean* expressions. Expressions such as `x < y && z`, with *x, y,* and *z* being numeric types, are illegal. Instead, use the expression

x < y && x < z

We also provide “Common Error Traps,” such as the one to the right from Chapter 5, to alert students against common syntax and logic errors.

In each chapter, “active learning” Programming Activities reinforce concepts with enjoyable, hands-on projects that provide visual feedback to the students. These activities can be done in lab-type classrooms or can be assigned as projects. A header for a Programming Activity looks like this:

6.9 Programming Activity 1: Using *while* Loops

In this activity, you will work with a sentinel-controlled *while* loop, performing this activity:

> Write a *while* loop to process the contents of a grocery cart and calculate the total price of the items. It is important to understand that, in this example, we do not know how many items are in the cart.

Because technology is ever-changing, students need to be able to learn new concepts and find relevant classes on their own. To promote the development of this important skill of “learning-to-learn,” we include one or more “Look It Up” questions in the end-of-chapter exercises. These questions require the student to perform some research to acquire the knowledge necessary to answer the question and write the required code.

Description

Within the online resources, for each chapter, we provide a movie that illustrates the execution of code implementing the concepts taught in the chapter. Each movie animates a brief code sample, one line at a time, and is controlled by the user via a “Next Step” button. These modules can be beneficial for students who learn best with visual aids, graphs, illustrations, and at their own pace outside the classroom. The modules are announced in each chapter using a special icon as in the sample above.

CODE IN ACTION

To see two step-by-step illustrations of *do/while* loops, look for this chapter’s movie within the online resources. Click on the link to start the movie.

© Hemera Technologies/Photos.com/Thinkstock

Graphics Coverage

Graphics are distributed throughout the book and are used to engage the student and reinforce the chapter concepts. The graphics coordinate system, methods for drawing shapes and text, and color concepts are presented with simple JavaFX applications in Chapter 4. At least one graphical example is presented in subsequent chapters using JavaFX. In Chapter 5, a *switch* statement is used to draw a smiley face; in Chapter 6, a loop is used to draw a bull’s eye target. Classes for displayable objects are presented in Chapter 7; drawing a bar chart of array data is illustrated in Chapters 8 and 9; polymorphism is demonstrated using a Tortoise and Hare Race in Chapter 10; GUIs, dynamic charts, and JavaFX animations are covered in online chapters. The two figures that follow illustrate graphical examples from Chapters 7 and 8.

Figure 7.12 The *SpriteClient* Window

Description

Figure 8.15 The *cellBills* Array as a Bar Chart

End-of-Chapter Exercises and Problems

A large collection of exercises and problems is proposed at the end of each chapter. Short exercises cover programming from a variety of angles: multiple choice concept questions, reading and understanding code segments, filling in some code, correcting errors, and interpreting compiler error messages to diagnose application bugs. Many programming projects are proposed with an emphasis on writing *classes*, not just a *program*. A more challenging group project is proposed in each chapter, allowing students to work as a group and develop communication skills, in accordance with recommendations from accreditation organizations and potential employers in the computer industry. Small, essay-type questions are also proposed to enable students to acquire proficiency in technical writing and communication.

Web Materials Accompanying This Book

Available on the Jones & Bartlett Learning website (www.jblearning.com):

- Programming Activity framework code
- Full example code from each chapter
- Swing versions of Chapters 4 and GUI chapters using JavaFX and Swing.

Appendices

The appendices include the following:

- Java reserved words and keywords
- Operator precedence
- Unicode character set
- Representing negative numbers
- Representing floating-point numbers
- Answers to selected exercises

Instructor Resources

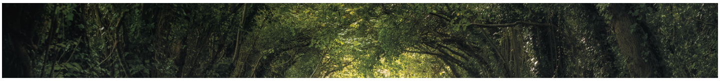
These materials are available to instructors on the Jones & Bartlett Learning website (go.jblearning.com/javailluminated6e), and include

- Programming activity solution code (for instructors only)
- Answers to many end-of-chapter exercises
- Lecture slides in PowerPoint format for each chapter
- Test banks for each chapter

Contacting the Authors

We have checked and rechecked the many technical details in this text. Despite our best efforts, however, we realize that some errors may have been missed. If you discover a technical error in the text, please contact us at hervefranceschi@gmail.com. We will post any corrections on the text's website: go.jblearning.com/javailluminated6e.

Python vs. Java: A Few Simple Concepts



© Lois GoBe/Shutterstock.

Acknowledgments

We would like to acknowledge the contributions of many partners, colleagues, and family members to this book.

First and foremost, we would like to thank our publisher, Jones & Bartlett Learning, especially Edward Hinman, Product Manager; Melissa Duffy, Content Strategist; and Jennifer Risden, Project Manager. We also want to thank the compositor, Straive; the proofreader, Charlotte Zuccarini; and Briana Yates, who designed the cover.

Second, we extend our thanks to the reviewers: Zareh Gorjian, Pasadena City College; Lee Nicholson, Alpharetta High School; Jody Paul, Metropolitan State University of Denver; Steven Kreutzer, Bloomfield College; Larry Henderson, Wenatchee Valley College; Fred D'Angelo, Pima Community College; Waleed Farag, Indiana University of Pennsylvania; Jason Smith, University of Texas, Dallas; Valerie Chau, Palomar College; Jeanann Boyce, Montgomery College; Kevin Brunner, Graceland University; Patrick Plunkett, Wheeling Jesuit University; Russel Bruhn, University of Arkansas, Little Rock; Burdett E. Wilson, Macon Area Career and Technical Education Center; Jonathan Sprague, College of Lake County; Giuseppe Turini, Kettering University; Nary Subramanian, University of Texas, Tyler; Jeffrey Kimball, Southwest Baptist University; Zhiling Lan, Illinois Institute of Technology; Peter L. Stanchev, Kettering University; Jacquelyne Lewis, North Carolina Wesleyan College; Vicky Hardin, Jefferson Community & Technical College; Jesse Kidd, Motlow State Community College; Mark Meysenburg, Doane College; Derrf Seitz, Georgia Military College; Ellen Spertus, Mills College; Scott Reed, College of Lake County; Peter Johnson, South Central College; and Sungbum Hong, Jackson State University. We have taken your thoughtful comments to heart and we think the book is better for them.

Julie Anderson would also like to acknowledge the pedagogical insight of Richard Rasala and Viera Proulx of Northeastern University. Thanks also to Jon Dornback, Garth Gerstein, and our former colleagues Pat Smit and the late Earl Gottsman.

I am extremely grateful for the help extended by many family members: my father, Glenn Austin, sons Brian and Jon Anderson, daughter-in-law Silvia Eckert, grandson, Ben Anderson (for his sound effects), sister Kathleen Austin, and mother-in-law Virginia Anderson. And of course, much gratitude goes to my loving husband, Tom, for his support and encouragement.

—Julie Anderson

I also recognize the support of my family. In particular, my brother, Paul, provided feedback on our sample chapter and the movies, and my wife, Kristin, gave her support and provided advice.

—Hervé Franceschi

CHAPTER 1

Introduction to Programming and the Java Language

CHAPTER CONTENTS

Introduction
1.1 Basic Computer Concepts
    1.1.1 Hardware
    1.1.2 Operating Systems
    1.1.3 Application Software
    1.1.4 Computer Networks and the Internet
1.2 **Practice Activity: Displaying System Configuration**
    1.2.1 Displaying Windows Configuration Information
    1.2.2 Displaying Mac OS Configuration Information
1.3 Data Representation
    1.3.1 Binary Numbers
    1.3.2 Using Hexadecimal Numbers to Represent Binary

    Numbers
    1.3.3 Representing Characters with the Unicode Character Set

1.4 Programming Languages

    1.4.1 High- and Low-Level Languages
    1.4.2 An Introduction to Object- Oriented Programming
    1.4.3 The Java Language

1.5 An Introduction to Programming

    1.5.1 Programming Basics
    1.5.2 Program Design with Pseudocode
    1.5.3 Developing a Java Application
    1.5.4 **Programming Activity 1: Writing a First Java Application**
    1.5.5 Making a JAR File

1.6 Chapter Summary
1.7 Exercises, Problems, and Projects

    1.7.1 Multiple Choice Exercises
    1.7.2 Converting Numbers
    1.7.3 General Questions
    1.7.4 Technical Writing
    1.7.5 Group Project

Introduction

Computer applications touch almost every aspect of our lives. They run automated teller machines, the grocery store's checkout register, the appointment calendar at your doctor's office, airport kiosks for flight check-in, a restaurant's meal-ordering system, and online auctions, just to name a few applications. On your personal computer, you may run a word processor, virus detection software, a spreadsheet, computer games, and an image processing system.

Someone, usually a team of programmers, wrote those applications. If you're reading this text, you're probably curious about what's involved in writing applications, and you would like to write a few yourself. Perhaps you have an idea for the world's next great application or computer game.

In this text, we'll cover the basics of writing applications. Specifically, we'll use the Java programming language. Keep in mind, however, that becoming a good programmer requires more than mastering the rules, or **syntax**, of a programming language. You also must master basic programming techniques. These are established methods for performing common programming operations, such as calculating a total, finding an average, or arranging a group of items in order.

You also must master good software engineering principles so that you design code that is readable, easily maintained, and reusable. By readable, we mean that someone else should be able to read your program and figure out what it does and how it does it. Writing readable code is especially important for programmers who want to advance in their careers, because it allows someone else to take over the maintenance of your program while you move on to bigger and better responsibilities. Ease of maintenance is also an important aspect of programming, because the specifications for any program are continually changing. How many programs can you name that have had only one version? Not many. Well-designed code allows you and others to incorporate prewritten and pretested modules into your program, thus reducing the time to develop a program and yielding code that is more robust and has fewer bugs. One useful feature of the Java programming language is the large supply of prewritten code that you are free to use in your programs.

Programming is an exciting activity. It’s very satisfying to decompose a complex task into computer instructions and watch your program come alive. It can be frustrating, however, when your program either doesn’t run at all or produces the wrong output.

Writing correct programs is critical. Someone’s life or life savings may depend on the correctness of your program. Reusing code helps in developing correct programs, but you must also master effective testing techniques to verify that the output of your program is correct.

In this text, we’ll concentrate not only on the syntax of the Java language, but also on basic programming techniques, good software engineering principles, and effective testing techniques.

Before you can write programs, however, it’s important to understand the platform on which your program will run. A platform refers to the computer hardware and the operating system. Your program will use the hardware for inputting data, for performing calculations, and for outputting results. The operating system will start your program running and will provide your program with essential resources, such as memory, and services, such as reading and writing files.

1.1 Basic Computer Concepts

1.1.1 Hardware

As shown in **Figure 1.1**, a computer typically includes the following components:

Figure 1.1 A Typical Design of a Personal Computer

Description

- a CPU, or central processing unit, which executes the instructions of a program
- a memory unit, which holds the instructions and data of a program while it is executing
- a hard disk, used to store programs and data so that they can be loaded into memory and accessed by the CPU
- a keyboard used for input of data
- a monitor, used to display output from a program
- an Ethernet port and wireless networking transceiver for connecting to the Internet or a Local Area Network (LAN)

- other components (not shown) such as a graphics card and a DVD drive

For example, if you were to go to a computer store in search of the latest personal computer, you might be shown a computer with this set of specifications:

- a i7-10700KF 4.9GHz with 8 cores Intel processor
- a touch screen
- 8 MB of cache memory
- 32 GB of RAM (Random Access Memory)
- a 1 TB (Terabyte) hard disk

In these specifications, the Intel i7-10700KF is the CPU. Other processors used as CPUs in personal computers and servers include the AMD Ryzen™, the Oracle SPARC, and the IBM POWER processor. When a CPU has multiple cores, for example 8 cores, that means that the CPU can execute several instructions at the same time, running them in parallel.

CPUs consist of an Arithmetic Logic Unit (ALU) [also called an Integer Unit (IU)], which performs basic integer arithmetic and logical operations; a Floating

Point Unit (FPU), which performs floating-point arithmetic; a set of hardware registers for holding data and memory addresses; and other supporting hardware, including a control unit to sequence the instructions. Each CPU comes with its own set of instructions, which are the operations that it can perform. The instructions typically perform arithmetic and logic operations, move data from one location to another, and change the flow of the program (that is, determine which instruction is to be executed next).

A program consists of many instructions. The first step in executing a program is loading it into memory. Each instruction in the program is executed using a **Fetch-Decode-Execute Cycle**. The **Program Counter** keeps track of the next instruction to be fetched. The CPU fetches the next instruction from memory and places it into the **Instruction Register**. The instruction is decoded (is the instruction a move, load, store, etc.?). Then, the instruction is executed. This Fetch-Decode-Execute Cycle repeats until the program ends.

The speed of a CPU is related to its clock cycle, typically rated in GHz (gigahertz); at the time of this edition, a high-end CPU speed would be rated at 5 GHz. The clock speed, measured in clock cycles per second, determines how fast a processor can perform operations such as fetching, decoding, and executing instructions. A CPU rated at 4 GHz executes 4 billion clock cycles a second. Current processors feature pipelining, which allows the CPU to process several instructions at once, so that while one instruction is executing, the processor can decode the next instruction and fetch the next instruction after that. This greatly improves performance of applications.

Memory or storage devices, such as L2 cache, memory, or hard disks, are typically rated in terms of their capacity, expressed in bytes. A **byte** is eight binary digits, or **bits**. A single bit's value is 0 or 1. Depending on the type of memory or storage device, the capacity will be stated in kilobytes, megabytes, gigabytes, or even terabytes. The sizes of these units are shown in **Table 1.1**.

Memory Units and Their Sizes

Memory Unit	**Size**
KB, or Kbytes, or kilobytes	About 1,000 bytes (exactly 2^{10} or 1,024 bytes)
MB, or Mbytes, or megabytes	About 1 million bytes (exactly 2^{20} or 1,048,576 bytes)
GB, or Gbytes, or gigabytes	About 1 billion bytes (exactly 2^{30} or 1,073,741,824 bytes)
TB, or Tbytes, or terabytes	About 1 trillion bytes (exactly 2^{40} or $1.09951\ 3\ 10^{12}$ bytes)

Description

For the CPU to execute at its rated speed, however, instructions and data must be available to the CPU at that speed as well. Instructions and data come directly from the L1 cache, which is memory directly located on the CPU chip. Since the L1 cache is located on the CPU chip, it runs at the same speed as the CPU. However, the L1 cache, which can be several Mbytes, is typically much smaller than main memory, and eventually the CPU will need to process more instructions and data than can be held in the L1 cache at one time.

At that point, the CPU typically brings data from what is called the L2 cache, which is located on separate memory chips connected to the CPU. A typical speed for the L2 cache would be a few nanoseconds (billionths of a second) access time, and this will considerably slow down the rate at which the CPU can execute instructions. L2 cache size today is typically 3 to 8 Mbytes, and again, the CPU will eventually need more space for instructions and data than the L2 cache can hold at one time.

At that point, the CPU will bring data and instructions from main memory, also located outside, but connected to, the CPU chip. This will slow down the CPU even more, because main memory typically has an access time of about 10 to 50 nanoseconds. Main memory, though, is significantly larger in size than the L1 and L2 caches, typically anywhere between 4 and 16 Gbytes. When the CPU runs out of space again, it will have to get its data from the hard disk, which is typically 1 Tbyte or more, but with an access time in the milliseconds (thousandths of a second) range.

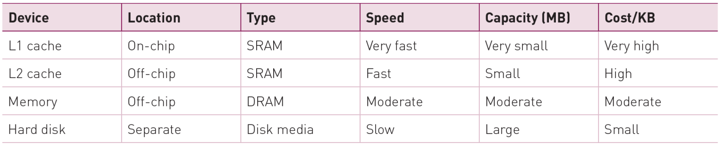
As you can see from these numbers, a considerable amount of speed is lost when the CPU goes from main memory to disk, which is why having sufficient memory is very important for the overall performance of applications.

Another factor that should be taken into consideration is cost per kilobyte. Typically the cost per kilobyte decreases significantly stepping down from L1 cache to hard disk, so high performance is often traded for low price.

Main memory (also called RAM) uses DRAM, or Dynamic Random Access Memory technology, which maintains data only when power is applied to the memory and needs to be refreshed regularly in order to retain data. The L1 and L2 caches use SRAM, or Static Random Access Memory technology, which also needs power but does not need to be refreshed in order to retain data. Memory capacities are typically stated in powers of 2. For instance, 256 Kbytes of memory is 2^{18} bytes, or 262,144 bytes.

Memory chips contain cells, each cell containing a bit, which can store either a 0 or a 1. Cells can be accessed individually or as a group of typically 4, 8, or 16 cells. For instance, a 32-Kbit RAM chip organized as 8K 3 4 is composed of exactly 2^{13}, or 8,192 units, each unit containing four cells. This RAM chip will have four data output pins (or lines) and 13 access pins (or lines), enabling access to all 8,192 units because each access pin can have a value of 0 or 1. **Table 1.2** compares the features of various memory types.

A Comparison of Memory Types



Device	Location	Type	Speed	Capacity (MB)	Cost/KB
L1 cache	On-chip	SRAM	Very fast	Very small	Very high
L2 cache	Off-chip	SRAM	Fast	Small	High
Memory	Off-chip	DRAM	Moderate	Moderate	Moderate
Hard disk	Separate	Disk media	Slow	Large	Small

Description

1.1.2 Operating Systems

An operating system (OS) is a software program that

- controls the peripheral devices (for instance, it manages the file system)
- supports multitasking, by scheduling multiple programs or tasks to execute during the same interval
- allocates memory to each program, so that there is no conflict among the memory of any programs running at the same time
- prevents the user from damaging the system. For instance, it prevents user programs from overwriting the operating system or another program’s memory

The operating system loads, or **boots**, when the computer system is turned on and is intended to run as long as the computer is running.

Examples of operating systems are macOS, Microsoft Windows, Linux, and iOS and Android for mobile devices.

1.1.3 Application Software

Application software consists of the programs written to perform specific tasks. These programs are run by the operating system, or as is typically said, they are run “on top of” the operating system. Examples of applications are word processors, such as Microsoft Word or Apache OpenOffice; spreadsheets, such as Microsoft Excel; database management systems, such as Oracle or Microsoft SQL Server; Internet browsers, such as Mozilla Firefox, Google Chrome, or Microsoft Edge; and most of the programs you will write during your study of computer science.

1.1.4 Computer Networks and the Internet

Computer Networks

Computer networks connect two or more computers. A common network used by many corporations and universities is a LAN, or Local Area Network. A typical LAN connects several computers that are geographically close to one another, often in the same building, and allows them to share resources, such as a printer, a database, or a file system. In a LAN, most user computers are called **clients**, and one or more computers act as **servers**. The server controls access to resources on the network and can supply services to the clients, such as answering database requests, storing and serving files, or managing email. The computers on the network can exchange data through physical cables or through a wireless network.

The Internet

The Internet is a network of networks, connecting millions of computers around the world. The Internet evolved from ARPANET, a 1969 U.S. military research project whose goal was to design a method for computers to communicate. Most computers on the Internet are clients, typically requesting resources, such as webpages, through an Internet browser. These resources are provided by web servers, which store webpages and respond to these requests.

Every machine on the Internet has a unique ID called its IP address (IP stands for Internet Protocol). Special computers called **routers** find a path through the Internet from one computer to another using these IP addresses. A computer can have a static IP address, which is dedicated to that machine, or a dynamic IP address, which is assigned to the computer when it connects to the Internet. An IP address is made up of four octets, whose values in decimal notation are between 0 and 255. For instance, 58.203.151.103 could represent such an IP address. In binary notation, this IP address is 111010.11001011.10010111.1100111. Later in this chapter, we will learn how to convert a decimal number, such as 103, to its binary equivalent, 1100111.

Most people are familiar with URL (Uniform Resource Locator) addresses that look like *http://www.oracle.com/technetwork/java/index.html.* A URL is actually an Internet domain name as well as the path on that domain to a specific web page. In this URL, the domain name is *www.oracle.com.* The page requested is *index.html,* which is located in the *java* folder under the *technetwork* folder.

Domain name resolution servers, which implement the Domain Name System (DNS), convert domain names to IP addresses, so that Internet users don't need to know the IP addresses of websites they want to visit. The World Wide Web Consortium (W3C), an international group developing standards for Internet access, prefers the term Uniform Resource Identifier (URI) rather than URL, because URI covers future Internet addressing schemes.

1.2 Practice Activity: Displaying System Configuration

We have explored hardware and operating systems in general. Now, let's discover some information about the hardware and operating system on your computer. Depending on whether you're using a Windows operating system or a Mac OS operating system, choose the appropriate directions that follow to display the operating system's name, the CPU type, and how much memory the computer has.

1.2.1 Displaying Windows Configuration Information

To display system configuration information on a computer running Windows 11, run *msinfo32.exe* from the command line. From the *Start* menu, type *cmd* to start the Command Prompt program and then type *msinfo32* into the Command Prompt window. You will get a display similar to the one in **Figure 1.2**, although the information displayed varies, depending on your hardware and the version of Windows you are running.

Figure 1.2 Windows System Information

Screen shots reprinted with permission from Microsoft.

Description

As you can see in Figure 1.2, this computer is running AMD Ryzen 7 5700U CPU processor with 8 cores running at 1801MHz, and the computer has 16 Gbytes of memory, 7.58 Gbytes of which are not being used at the time of the display.

1.2.2 Displaying Mac OS Configuration Information

To display system information on a Mac OS computer, click on the apple icon on the top left of the screen and select “About This Mac.” You will see something similar to the display in **Figure 1.3**, which displays the version of the MAC OS operating system that is running on the computer.

Figure 1.3 Mac Operating System Information

Screen shots reprinted with permission from Apple Inc.

Description

As you can see, this iMac is running macOS Monterey Version 12.1. The processor is an Intel Core i5 running at 3.2 GHz and the iMac has 16 Gbytes of memory. Your information may be different from that shown in the figure, depending on your hardware and operating system version.

DISCUSSION QUESTIONS

1. Compare the system information on several computers. Is it the same or different from computer to computer? Explain why the information is the same or different.
2. In the sample display for Windows 11, the computer has 16 Gbytes of memory, but only 7.58 Gbytes of memory is available. Why do you think some memory is not available?
3. Compare your computer to the ones on the previous pages. Which do you think would have better performance? Explain your answer.

1.3 Data Representation

1.3.1 Binary Numbers

As mentioned earlier, a CPU understands only binary numbers, whose digits consist of either 0 or 1. All data is stored in a computer's memory as binary digits. A bit holds one binary digit. A byte holds eight binary digits.

Binary numbers are expressed in the base 2 system, because there are only 2 values in that system, 0 and 1. By contrast, most people are used to the decimal, or base 10, system, which uses the values 0 through 9.

There are other number systems, such as the octal, or base 8, system, which uses the digits from 0 to 7, and the hexadecimal, or base 16, system, which uses the digits 0 to 9 and the letters A to F.

As we know it in the decimal system, the number 359 is composed of the following three digits:

3, representing the hundreds, or 10^2
5, representing the tens, or 10^1
9, representing the ones, or 10^0

Therefore, we can write 359 as

$$359 = 3*10^2 + 5*10^1 + 9*10^0$$

Description

Thus, the decimal number 359 is written as a linear combination of powers of 10 with coefficients from the base 10 alphabet, that is, the digits from 0 to 9. Similarly, the binary number 11011 is written as a linear combination of powers of 2 with coefficients from the base 2 alphabet, that is, the digits 0 and 1.

For example, the binary number 11011 can be written as

$$11011 = 1*2^4 + 1*2^3 + 0*2^2 + 1*2^1 + 1*2^0$$

Description

Table 1.3 lists the binary equivalents for the decimal numbers 0 through 8, while **Table 1.4** lists the decimal equivalents of the first 15 powers of 2.

Binary Equivalents of Decimal Numbers 0 Through 8

Decimal	Binary
0	0000
1	0001
2	0010
3	0011
4	0100
5	0101
6	0110
7	0111
8	1000

Description

Powers of 2 and Their Decimal Equivalents

2^{14}	2^{13}	2^{12}	2^{11}	2^{10}	2^{9}	2^{8}	2^{7}	2^{6}	2^{5}	2^{4}	2^{3}	2^{2}	2^{1}	2^{0}
16,384	8,192	4,096	2,048	1,024	512	256	128	64	32	16	8	4	2	1

Description

Note that in Table 1.3, as we count in increments of 1, the last digit alternates between 0 and 1. In fact, we can see that for even numbers, the last digit is always 0 and for odd numbers, the last digit is always 1.

Because computers store numbers as binary, and people recognize numbers as decimal values, conversion between the decimal and binary number systems often takes place inside a computer.

Let's try a few conversions. To convert a binary number to a decimal number, multiply each digit in the binary number by $2^{position21}$, counting the rightmost position as position 1 and moving left through the binary number. Then add the products together.

Using this method, let's calculate the equivalent of the binary number 11010 in our decimal system.

$$\begin{aligned} 11010 &= 1*2^4 + 1*2^3 + 0*2^2 + 1*2^1 + 0*2^0 \\ &= 16 + 8 + 0 + 2 + 0 \\ &= 26 \end{aligned}$$

Description

Now let's examine how to convert a decimal number to a binary number. Let's convert the decimal number 359 into its binary number equivalent. As we can see from the way we rewrote 11011, a binary number can be written as a sum of powers of 2 with coefficients 0 and 1.

The strategy to decompose a decimal number into a sum of powers of 2 is simple: first find the largest power of 2 that is smaller than or equal to the decimal number, subtract that number from the decimal number, then do the same with the remainder, and so on, until you reach 0.

The largest power of 2 that is smaller than 359 is 256, or 2^8 (the next larger power of 2 would be 512, which is larger than

359). Subtracting 256 from 359 gives us 103 (359 2 256 5 103), so we now have

$$359 = 2^8*1 + 103$$

Description

Now we apply the same procedure to 103. The largest power of 2 that is smaller than 103 is 64, or 2^6. That means that there is no factor for 2^7, so that digit’s value is 0. Subtracting 64 from 103 gives us 39.

Now we have

$$359 = 2^8*1 + 2^7*0 + 2^6*1 + 39$$

Description

Repeating the procedure for 39, we find that the largest power of 2 smaller than 39 is 32 or 2^5. Subtracting 32 from 39 gives us 7.

So we now have

$$359 = 2^8*1 + 2^7*0 + 2^6*1 + 2^5*1 + 7$$

Description

Repeating the procedure for 7, the largest power of 2 smaller than 7 is 2^2, or 4. That means that there are no factors for 2^4 or 2^3, so the value for each of those digits is 0. Subtracting 4 from 7 gives us 3, so we have

$$359 = 2^8*1 + 2^7*0 + 2^6*1 + 2^5*1 + 2^4*0 + 2^3*0 + 2^2*1 + 3$$

Description

Repeating the procedure for 3, the largest power of 2 smaller than 3 is 2, or 2^1, and we have:

$$359 = 2^8*1 + 2^7*0 + 2^6*1 + 2^5*1 + 2^4*0 + 2^3*0 + 2^2*1 + 2^1*1 + 1$$

Description

1 is a power of 2; it is 2^0, so we finally have

$$359 = 2^8*1 + 2^7*0 + 2^6*1 + 2^5*1 + 2^4*0 + 2^3*0 + 2^2*1 + 2^1*1 + 2^0*1$$

Description

Removing the power of 2 multipliers, 359 can be represented in the binary system as

$$\begin{array}{lllllllllllllllllll} 359 & = & 2^8*1 & + & 2^7*0 & + & 2^6*1 & + & 2^5*1 & + & 2^4*0 & + & 2^3*0 & + & 2^2*1 & + & 2^1*1 & + & 2^0*1 \\ & = & 1 & & 0 & & 1 & & 1 & & 0 & & 0 & & 1 & & 1 & & 1 \end{array}$$

Description

or

$$1\ 0110\ 0111$$

CODE IN ACTION

To see a step-by-step demonstration of converting between decimal and binary numbers, look for the movie within the online resources. Click on the link to start the movie.

© Hemera Technologies/Photos.com/Thinkstock

In a computer program, we will use both positive and negative numbers. Appendix D explains how negative numbers, such as 234, are represented in the binary system. In a computer program, we also use floating-point numbers, such as 3.75. Appendix E explains how floating-point numbers are represented using the binary system.

1.3.2 Using Hexadecimal Numbers to Represent Binary Numbers

As you can see, binary numbers can become rather long. With only two possible values, 0 and 1, it takes 16 binary digits to represent the decimal value 132,768. For that reason, the hexadecimal, or base 16, system is often used as a shorthand representation of binary numbers. The hexadecimal system uses 16 digits: 0 to 9 and A to F. The letters A to F represent the values 10, 11, 12, 13, 14, and 15.

The maximum value that can be represented in four binary digits is 2^4 2 1, or 15. The maximum value of a hexadecimal digit is also 15, which is represented by the letter F. So you can reduce the size of a binary number by using hexadecimal digits to represent each group of four binary digits.

Table 1.5 displays the hexadecimal digits along with their binary equivalents.

Hexadecimal Digits and Equivalent Binary Values

Hex Digit	Binary Value	Hex Digit	Binary Value
0	0000	8	1000
1	0001	9	1001
2	0010	A	1010
3	0011	B	1011
4	0100	C	1100
5	0101	D	1101
6	0110	E	1110
7	0111	F	1111

Description

To represent the following binary number in hexadecimal, you simply substitute the appropriate hex digit for each set of four binary digits.

```
0001 1010 1111 1001 1011 0011 1011 1110
  1    A    F    9    B    3    B    E
```

Description

Here’s an interesting sequence of hexadecimal numbers. The first 32 bits of every Java applet are:

```
1100 1010 1111 1110 1011 1010 1011 1110
```

Description

Translated into hexadecimal, that binary number becomes:

CAFE BABE

Description

1.3.3 Representing Characters with the Unicode Character Set

Java represents characters using the Unicode Worldwide Character Standard, or simply Unicode. Each Unicode character is represented as 16 bits, or two bytes. This means that the Unicode character set can encode 65,536 characters.

The Unicode character set was developed by the Unicode Consortium, which consists of computer manufacturers, software vendors, the governments of several nations, and others. The consortium’s goal was to support an international character set, including the printable characters on the standard QWERTY keyboard, as well as international characters such as e or λ.

Many programming languages store characters using the ASCII (American Standard Code for Information Interchange) character set, which uses 7 bits to encode each character, and thus, can represent only 128 characters. For compatibility with the ASCII character set, the first 128 characters in the Unicode character set are the same as the ASCII character set.

Table 1.6 shows a few examples of Unicode characters and their decimal equivalents.

Selected Unicode Characters and Their Decimal Equivalents

Unicode Character	Decimal Value	Hex Value
NUL, the null character (a nonprintable character)	0	0000
*	42	002A
1	49	0031
2	50	0032

A	65	0041
B	66	0042
a	97	0061
b	98	0062
}	125	007D
delete (a nonprintable character)	127	007F

Description

For more information on the Unicode character set, see Appendix C or visit the Unicode Consortium's website at *http://www.Unicode.org*.

1.4 Programming Languages

1.4.1 High- and Low-Level Languages

Programming languages can be categorized into three types:

- machine language
- assembly language
- high-level language

In the early days of computing, programmers often used machine language or assembly language. Machine language uses binary codes, or strings of 0s and 1s, to execute the instruction set of the CPU and to refer to memory addresses. This method of programming is extremely challenging and time consuming. Also, the code written in machine language is not portable to other computer architectures because each CPU has its own set of instructions. Machine language's early popularity can be attributed largely to the fact that programmers had no other choices. However, programmers rarely use machine language today.

Assembly languages are one step above machine language, using symbolic names for memory addresses and mnemonics for processor instructions—for example: *BEQ* (branch if equal), *SW* (store), or *LW* (load). An Assembler program converts the code to machine language before it is executed. Like machine language, assembly languages are also CPU-dependent and are not portable among computers with different processors (for instance, between Intel and SPARC). Assembly language is easier to write than machine language but still requires a significant effort and, thus, is usually used only when the program requires features, such as direct hardware access, that are not supported by a high-level language.

High-level languages, such as Java, C+ + , Swift, PHP, and Python, are closer to the English language than they are to machine language, making them a lot easier to use for software development and more portable among CPU architectures. For this reason, programmers have embraced high-level languages for more and more applications.

Characteristics of high-level languages, such as Java, are

- The languages are highly symbolic. Programmers write instructions using keywords and special characters and use symbolic names for data.
- The languages are somewhat portable (some more portable than others) among different CPUs.
- Some high-level programming languages, such as C++ , Java, and Python, can be used for general-purpose applications, and some high-level programming languages can be used for specialized applications, such as Swift for iPhone development and PHP for Internet applications.

High-level languages are compiled, interpreted, or a combination of both. A program written in a compiled language, such as C++ , is converted by a compiler into machine code, then the machine code is executed.

By contrast, a program written using an interpreted language, such as Perl, is read and converted to machine code, line by line, at execution time. Typically, a program written in an interpreted language will run more slowly than its equivalent written in a compiled language.

Java uses a combination of a compiler and an interpreter. A Java program is first compiled into processor-independent **byte codes**, then the byte code file is interpreted at run time by software called the **Java Virtual Machine (JVM)**.

1.4.2 An Introduction to Object-Oriented Programming

Initial high-level languages, such as Fortran or C, were procedural. Typically, programmers wrote task-specific code in separate procedures, or functions, and invoked these procedures from other sections of the program in order to perform various tasks. The program’s data was generally shared among the procedures.

In the mid-1970s, the first object-oriented programming language, Smalltalk, was introduced, enabling programmers to write code with a different approach. Whereas procedures or functions dealt mainly with basic data types such as integers, real numbers, or single characters, Smalltalk provided the programmer with a new tool: classes and objects of those classes.

A class enables the programmer to encapsulate data and the functions to manipulate that data into one package. A class essentially defines a template, or model, from which objects are created. Creating an object is called **instantiation**. Thus, objects are created—instantiated—according to the design of the class.

A class could represent something in real life, such as a person. The class could have various attributes such as, in the example of a "person" class, a first name, a last name, and an age. The class would also provide code, called **methods**, that allow the creator of the object to set and retrieve the values of the attributes.

One big advantage to object-oriented programming is that well-written classes can be reused in new programs, thereby reducing future development time.

Smalltalk was somewhat successful, but had a major deficiency: its syntax was unlike any syntax already known by most programmers. Most programmers who knew the procedural C programming language were attracted by the object-oriented features of Smalltalk but were reluctant to use it because its syntax was so different from C's syntax. C+ + added object-oriented features to C, but also added complexity.

Meanwhile, the Internet was growing by leaps and bounds and gaining popularity daily. Web developers used HTML to develop webpages and soon felt the need to incorporate programming features not only on the server side, but also directly on the client side. Fortunately, Java appeared on the scene.

1.4.3 The Java Language

On May 23, 1995, Sun Microsystems introduced Java, originally named Oak, as a free, object-oriented language targeted at embedded applications for consumer devices. A Java Virtual Machine was incorporated immediately into the Netscape

Navigator Internet browser, and as the Internet grew, small Java programs, known as applets, began to appear on webpages in increasing numbers. Java syntax is basically identical (with some minor exceptions) to that of C+ +, and soon programmers all over the world started to realize the benefits of using Java. Those benefits include

- syntax identical to that of C + +, except that Java eliminates some of C ++ “s more complex features
- object orientation
- Internet-related features, such as servlets, which are run by the web server
- an extensive library of classes that can be reused readily, including classes for providing a Graphical User Interface and Java Database Connectivity (JDBC) for communicating with a database
- portability among every platform that supports a Java Virtual Machine
- built-in networking
- open source availability of the Java Development Kit

As we mentioned earlier, a Java program is first compiled into processorindependent byte codes, then the byte codes are interpreted at run time by the Java Virtual Machine (JVM). As its name implies, the JVM simulates a virtual processor with its own instruction set, registers, and instruction pointer. Thus, to run a Java program, we only need a JVM. Fortunately, JVMs are available on every major computing platform.

Because Java programs are interpreted at run time, they typically run more slowly than their C++ counterparts. However, many platforms provide Java compilers that convert source code directly to machine code. This results in greater execution speed, but with an accompanying loss of portability. Just-inTime (JIT) compilers are also available. These JITs compile code at run time so that subsequent execution of the same code runs much faster.

Java programs can be written as servlets, Android apps, or applications.

Java servlets are invoked by the web server and run on the server, without being downloaded to the client. Typically, servlets dynamically generate web content by reading and writing to a database using JDBC (Java Database Connectivity).

The Android Open Source project has chosen Java to be the language for developing apps for Android devices, such as cell phones, tablets, and smart TVs.

Java applications run standalone on a client computer. In this text, we will write Java applications.

Oracle Corporation, which acquired Sun Microsystems in January 2010, provides a valuable Java website (*www.oracle.com/technetwork/java*), which has information on using the prewritten classes, a tutorial on Java, and many more resources for the Java programmer. We will refer you to that site often in this text.

1.5 An Introduction to Programming

1.5.1 Programming Basics

In many ways, programming is like solving a puzzle. We have a task to perform and we know the operations that a computer can perform (input, calculations, comparisons, rearranging of items, and output). As programmers, our job is to decompose a task into individual, ordered steps of inputting, calculating, comparing, rearranging, and outputting.

For example, suppose our task is to find the sum of two numbers. First, our program needs to read (input) the numbers into the computer. Next, our program needs to add the two numbers together (calculate). Finally, our program needs to write (output) the sum.

Notice that this program consists of steps, called **instructions**, which are performed in order (“First,” “Next,” “Finally”). Performing operations in order, one after another, is called **sequential processing**.

The order in which instructions are executed by the computer is critical in programming. You can’t calculate the sum of two numbers before you have read the two numbers, and you can’t output a sum before you have calculated it. Programming, therefore, requires the programmer to specify the ordering of instructions, which is called the **flow of control** of the program. There are four different ways that the flow of control can progress through a program: sequential execution, method call, selection, and looping. We’ve just seen sequential execution, and we’ll discuss the other types of flow of control in the next section.

Because getting the flow of control correct is essential to getting a program to produce correct output, programmers use a tool called **pseudocode** (pronounced *sue dough code*) to help them design the flow of control before writing the code.

1.5.2 Program Design with Pseudocode

Pseudocode, from *pseudo*, which means “appearing like,” is a method for expressing a program’s order of instructions in the English language, rather than a programming language. In this way, the programmer can concentrate on designing a program without also being bogged down in the syntax of the particular programming language.

The pseudocode for calculating the sum of two numbers would look like **Example 1.1**.

Example 1.1 Pseudocode for Summing Two Numbers

```
read first number
read second number
set total to (first number + second number)
output total
```

Description

Fortunately, the rules for writing pseudocode are not rigid. Essentially, you can use any wording that works for you.

Let’s look at another example. Suppose our program needs to calculate the square root of a number. The instructions for calculating a square root are rather complex; fortunately, Java provides prewritten code that computes the square root of a number. The prewritten code is called a **method**, and our program can execute that code by **calling the method**. As part of the method call, we tell the method which number’s square root we want to calculate. This is called **passing an argument to the method**. When the method finishes executing its instructions, control is passed back to our program just after the method call and our program can use the square root of the number calculated by the method. This is called **returning a value**. Another way of looking at method calls is to consider what happens when we’re reading a book and find a word we don’t understand. We mark our place in the book and look up the word in a dictionary. When we’re finished looking up the word, we go back to our place in the book and continue reading.

Example 1.2 shows the pseudocode for calculating the square root of an integer.

Example 1.2 Using a Method Call to Calculate a Square Root

```
read a number
call the square root method, passing the number and
   receiving the square root
output the square root of the number
```

Description

The order of operations is still input, calculate, and output, but we're calling a method to perform the calculation for us.

Now suppose our task is to determine whether a number is positive or negative. First, our program should input the number into the computer. Next, we need to determine whether the number is positive or negative. We know that numbers greater than or equal to 0 are positive and numbers less than 0 are negative, so our program should compare the number to 0. Finally, our program should write a message indicating whether the number is positive or negative.

Like Examples 1.1 and 1.2, the operations are input, calculate, and output, in that order. However, depending on whether the number is positive or negative, our program should write a different message. If the number is greater than or equal to 0, the program should write a message that the number is positive, but if the number is less than 0, the program should write a message that the number is negative. Code used to handle this situation is called **selection**; the program selects which code to execute based on the value of the data.

The pseudocode for this program could be written as that shown in **Example 1.3**.

Example 1.3 Using Selection

```
read a number
if the number is greater than or equal to 0
  write "Number is positive."
else
  write "Number is negative."
```

Description

Notice the indentation for the code that will be selected based on the comparison of the number with 0. Programmers use indentation to make it easier to see the flow of control of the program.

Now let's get a little more complicated. Suppose our program needs to find the sum of a group of numbers. This is called **accumulating**. To accomplish this, we can take the same approach as if we were adding a group of numbers using a calculator. We start with a total of 0 and add each number, one at a time, to the running total. When we have no more numbers to add, the running total is the total of all the numbers.

Translating this into pseudocode, we get the code shown in **Example 1.4**.

Example 1.4 Accumulating a Total

```
set total to 0
read a number
while there was a number to read, repeat next two instructions
  add number to total
  read the next number
write total
```

Description

The indented code will be repeated for each number read until there are no more numbers. This repeated execution of the same code is called **looping**, or **iteration**, and is used extensively in programming whenever the same processing needs to be performed on each item in a set.

Accumulating a total and determining whether a number is positive or negative are just two of many commonly performed operations. In programming, we will often perform tasks for which there are standard methods of processing, called **algorithms**. For example, the algorithm for accumulation is to set a total to 0, use looping to add each item to the total, then output the total. More generally, we can think of an algorithm as a strategy to solve a problem. Earlier in the chapter, we used an algorithm to convert a decimal number to its binary representation.

Other common programming tasks are counting items, calculating an average, sorting items into order, and finding the minimum and maximum values. In this text, we will learn the standard algorithms for performing these common operations. Once we learn these algorithms, our programming job will become easier. When we recognize that a program requires any of these tasks, we can simply plug in the appropriate algorithm with some minor modifications.

Programming, in large part, is simply reducing a complex task to a set of subtasks that can be implemented by combining standard algorithms that use sequential processing, method calls, selection, and looping.

The most difficult part of programming, however, is recognizing which algorithms to apply to the problem at hand. This requires analytical skills and the ability to see patterns. Throughout this text, we will point out common patterns wherever possible.

SOFTWARE ENGINEERING TIP

Looking for patterns will help you determine the appropriate algorithms for your programs.

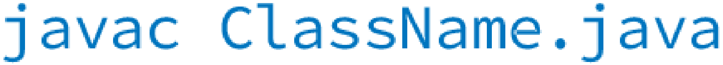
1.5.3 Developing a Java Application

Writing a Java application consists of several steps: writing the code, compiling the code, and executing the application. Java source code is stored in a text file with the extension *. java*. Compiling the code creates one or more *. class* files, which contain processor-independent byte codes. The Java Virtual Machine (JVM) translates the byte codes into machine-level instructions for the processor on which the Java application is running. Thus, if a Java application is running on an Intel i7 processor, the JVM translates the byte codes into the i7’s instruction set.

Oracle provides a Java SE Development Toolkit (JDK) on its website (*www .oracle.com/technetwork/java),* which is downloadable free of charge. The JDK contains a compiler, JVM, and jshell, which is a tool for immediate execution of Java code. In addition, the JDK contains a broad range of prewritten Java classes that programmers can use in their Java applications.

If you are downloading and installing Java yourself, be sure to follow the directions on the Oracle website, including the directions for setting the path for *javac,* the Java compiler. You need to set the path correctly so that you can run the Java compiler from any folder on your computer.

To develop an application using the JDK, write the source code using any text editor, such as Notepad on Windows, TextEdit on Macs, or the vi editor on Linux. To compile the code, invoke the compiler from the command line:



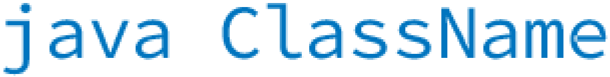
```
javac ClassName.java
```

Description

where *ClassName.java* is the name of the source file.

If our program, written in the file *ClassName.java,* compiles correctly, a new file, *ClassName.class,* will be created in our current directory.

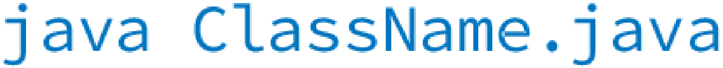
To run the application, we invoke the JVM from the command line:



```
java ClassName
```

Description

Since Java version 11, we can now compile and run a program using the *java* command only, without using *javac*, as in:

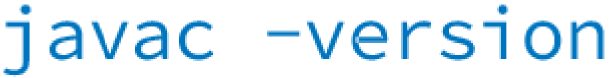


```
java ClassName.java
```

Description

Note that if we do that, the *ClassName.class* file will not be generated.

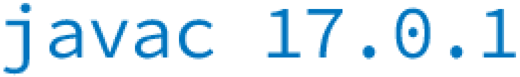
We can check what version of *javac* we have installed by typing:



```
javac -version
```

Description

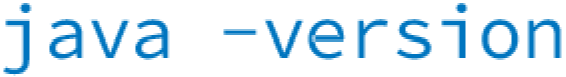
An example of output is:



```
javac 17.0.1
```

Description

In order to check what version of *java* we have installed, we type:



```
java -version
```

Description

An example of output is:

```
java version "17.0.1" 2021-10-19 LTS
Java(TM) SE Runtime Environment (build 17.0.1+12-LTS-39)
Java HotSpot(TM) 64-Bit Server VM (build 17.0.1+12-LTS-39, mixed mode, sharing)
```

Description

Typically, programmers use an Integrated Development Environment (IDE) to develop applications rather than invoking the compiler and JVM from the command line. An IDE consists of a program editor, a compiler, and a run-time environment, integrated via a Graphical User Interface. The advantage to using an IDE is that errors in the Java code that are found by the compiler or the JVM can be linked directly to the program editor at the line in the source file that caused the error. Additionally, the Graphical User Interface enables the programmer to switch among the editor, compiler, and execution of the program without launching separate applications.

Some of the many available IDEs include Eclipse from the Eclipse Foundation, Inc.; IntelliJ from JetBrains s.r.o.; JGRASP, developed at Auburn University; NetBeans, downloadable from Oracle; and TextPad from Helios Software Solutions. Some IDEs are freely available, while others require a software license fee.

with these end-of-chapter questions

1.7.1	Multiple Choice Exercises Questions 9, 10, 11, 12, 13, 14
1.7.3	General Questions Questions 27, 28, 29, 30
1.7.4	Technical Writing Question 34

1.5.4 Programming Activity 1: Writing a First Java Application

Let’s create our first Java program. This program prints the message, “Programming is not a spectator sport!”

Start by launching your IDE and open a new editor window. This is where you will write the code for the program.

Before you type any code, however, let’s name the document. You do this by saving the document as *FirstProgram.java*. Be sure to capitalize the F and the P and keep the other letters lowercase. Java is case-sensitive, so Java considers *firstprogram.java* or even *Firstprogram.java* to be a different name. Also, note that there is no space between *First* and *Program*.

Keeping case sensitivity in mind, type in the program shown in **Example 1.5**.

Example 1.5 A First Program in Java

```java
// First program in Java
// Anderson, Franceschi

public class FirstProgram
{
  public static void main( String [ ] args )
  {
    System.out.println( "Programming is not a spectator sport!" );

    System.exit( 0 );
  }
}
```

Description

At this point, we ask that you just type the program as you see it here, except for the line numbers, which are not part of the program. Line numbers are displayed in this example to allow easy reference to a particular line in the code. We'll explain a little about the program now; additional details will become clear as the semester progresses.

COMMON ERROR TRAP

Java is case-sensitive. The class name and the file name must match exactly, including capitalization.

The first two lines, which start with two forward slashes, are comments. They will not be compiled or executed; they are simply information for the programmer and are used to increase the readability of the program.

Line 4 defines the class name as *FirstProgram*. Notice that the class name must be spelled exactly the same way—including capitalization—as the file name, *FirstProgram.java*.

The curly braces in lines 5 and 12 mark the beginning and ending of the *FirstProgram* class, and the curly braces in lines 7 and 11 mark the beginning and ending of the *main* method. Every Java application must define a class and a *main* method. Execution of a Java application always begins with the code inside *main*. So when this application begins, it will execute line 8, which writes the message "*Programming is not a spectator sport!*" to the system console. Next, it executes line 10, *System.exit(0),* which exits the program. Including this line is optional; if you omit this line, the application will still exit normally.

As you type the program, notice that your IDE automatically colors your text to help you distinguish comments, *String* literals ("*Programming is not a spectator sport!*"), Java class names (*String, System*), and keywords (*public, class, static*), which are reserved for specific uses in Java. Curly braces, brackets, and parentheses, which have syntactical meaning in Java, are usually displayed in color as well. Your IDE may use different colors than those shown in Example 1.5.

When you have completed typing the code in Example 1.5, compile it. If everything is typed correctly, the compiler will create a *FirstProgram.class* file, which contains the byte codes for the program.

If you received any compiler errors, check that you have entered the code exactly as it is written in Example 1.5. We give you tips on finding and fixing the errors in the next section.

If you got a clean compile with no errors, congratulations! You're ready to execute the application. This will invoke the JVM and pass it the *First Program .class* file created by the compiler. If all is well, you will see the message, *Programming is not a spectator sport!*, displayed on the Java console, which is the text window that opens automatically. **Figure 1.4** shows the correct output of the program.

Figure 1.4 Output from Example 1.5

Debugging Techniques

If the compiler found syntax errors in the code, these are called **compiler errors**, not because the compiler caused them, but because the compiler found them. When the compiler detects errors in the code, it writes diagnostic information about the errors.

For example, try typing *println* with a capital P (as *Println*), and recompiling. The compiler displays the following message:

```
FirstProgram.java:8: error: cannot find symbol
    System.out.Println( "Programming is not a spectator sport!" );
              ^
  symbol: method Println(String)
  location: variable out of type PrintStream
1 error
```

Description

The first line identifies the file name that contains the Java source code, as well as the line number in the source code where the error occurred. In this case, the error occurred on line 8. The second line displays line 8 from the source code with a caret (^) pointing to *Println* as being the cause of the error. The symbol and location information in the third and fourth lines indicate that the *Println* method is unknown. Remember that Java is case-sensitive, so *println* and *Println* are considered to be different. As you gain experience with Java, these error messages will become more meaningful to you. With most IDEs, double-clicking on the first line in the error message transfers you to the source code window with your cursor positioned on line 8 so you can correct the error.

Many times, the compiler will find more than one error in the source code. When that happens, don’t panic. Often, a single problem, such as a missing semicolon or curly brace, can cause multiple compiler errors.

For example, after correcting the preceding error, try deleting the left curly brace in line 7, then recompiling. The compiler reports four errors:

```
FirstProgram.java:6: error: ';' expected
        public static void main( String [ ] args )
                                                  ^

FirstProgram.java:10: error: <identifier> expected
        System.exit( 0 );
                   ^

FirstProgram.java:10: error: illegal start of type
        System.exit( 0 );
                     ^

FirstProgram.java:12: error: class, interface or enum expected
}
^
4 errors
```

Description

As you can see, the compiler messages do not always report the problem exactly. When you receive a compiler message, looking at the surrounding lines will often help you find the error. Depending on your IDE, you might see messages other than those shown here because some IDEs attempt to interpret the error messages from the compiler to provide more relevant information on the errors.

SOFTWARE ENGINEERING TIP

Because one syntax error can cause multiple compiler errors, correct only the obvious errors and recompile after each correction.

It is sometimes easier to fix one error at a time and recompile after each fix, because the first fix might eliminate many of the reported errors.

When all the compiler errors are corrected, you’re ready to execute the program.

It is possible to get a clean bill of health from the compiler, yet the program still won't run. To demonstrate this, try eliminating the brackets in line 6 after the word *String*. If you then compile the program, no errors are reported. But when you try to run the program, you get a **run-time error**.

Instead of *Programming is not a spectator sport!*, the following message is displayed on the Java console:

```
Error: Main method not found in class FirstProgram, please define the main method as:
   public static void main(String[] args)
or a JavaFX application class must extend javafx.application.Application
```

Description

This means that the *main* method header (line 6) was not typed correctly.

Thus, we've seen that two types of errors can occur while you are developing a Java program: compiler errors, which are usually caused by language syntax errors or misspellings, and run-time errors, which are often caused by problems using the prewritten classes. Run-time errors can also be caused by exceptions that the JVM detects as it is running, such as an attempt to divide by zero.

Testing Techniques

Once your program compiles cleanly and executes without run-time errors, you may be tempted to conclude that your job is finished. Far from it—you must also verify the results, or output, of the program.

In the sample program, it's difficult to get incorrect results—other than misspelling the message or omitting the spaces between the words. But any nontrivial program should be tested thoroughly before declaring it production ready.

To test a program, consider all the possible inputs and the corresponding correct outputs. It often isn't feasible to test every possible input, so programmers usually test **boundary conditions**, which are the values that sit on the boundaries of producing different output for a program.

For example, to test the code that determines whether an integer is negative or nonnegative, you would feed the program -1 and 0. These are the boundaries of negative and nonnegative integers. In other words, the boundary between negative and nonnegative integers is between -1 and 0.

When a program does not produce the correct output, we say the program contains **logic errors**. By testing your program thoroughly, you can discover and correct most logic errors. **Table 1.7** shows types of program errors and their usual causes.

Types of Program Errors and Their Causes

Type of Error	Usual Causes
Compiler errors	Incorrect language syntax or misspellings
Run-time errors	Incorrect use of classes
Logic errors	Incorrect program design or incorrect implementation of the design

Description

We'll talk more about testing techniques throughout the text.

DISCUSSION QUESTIONS

1. In the Debugging Techniques section, we saw that making one typo could generate several compiler errors. Why do you think that happens?
2. Explain why testing boundary conditions is an efficient way to verify a program's correctness.
3. Did any errors occur while you were developing the first application? If so, explain whether they were compiler or run-time errors and what you did to fix them.

1.5.5 Making a JAR File

After we finish writing, compiling, and testing our application, we may want to distribute it. Java programs are typically distributed as **JARs**, which stands for Java ARchive. The JAR format allows the compression and aggregation of multiple files into one. The *.jar* extension is, by default, associated with the Java Virtual Machine. Thus, a user can double-click on a JAR file and launch its corresponding application directly. Most IDEs include a tool to easily create a JAR file. But you can also create a JAR file from the command line. The general syntax to create a JAR file is:

```
jar cf jarfile inputfile(s)
```

- The *c* and *f* characters are options. The *c* option means that we want to create a JAR file. The *f* option means that we want to send the output to a file.
- *jarfile* is the name of the JAR file that we want to create; it can be a different name from the name of our Java file(s).
- inputfile(s) is a space-separated list of files that we want to include in the JAR file. It typically includes the .class files and may include folders or files containing resources used in our application, such as images or sounds.

We can create a JAR file named *Greetingjar* from our *FirstProgram* application by typing the following at the command line:

```
jar cf Greeting.jar FirstProgram.class
```

Note that the input file is the *. class* file, not the *.java* file. **Figure 1.5** shows the contents of the folder after executing the command above.

Figure 1.5 The Folder After the JAR File Is Created

Description

The file *Greetingjar* is created in the current folder, as shown in Figure 1.5.

If our application includes several Java files, we can use the wildcard character * to include all the corresponding *. class* files. The following creates a JAR file for all the *. class* files located in the current folder:

```
jar cf Greetings.jar *.class
```

If the *jar* command is not recognized, you can always go to the folder where it is (on the author’s laptop, it is *C:\Program Files\Java\jdk-17.0.1\bin)* and run the following command:

```
.\jar cf 'C:\Users\herve\Documents\MyJar.jar' FirstProgram.class
```

Description

As we can see above, we can also specify an absolute path for our destination *jar* file (here, we intend to place the JAR file in the *C:\Users\herve\Documents* folder).

Instead of *cf*, we can also use *create* and *file* as explicit options of the *jar* command as in:

```
.\jar --create --file 'C:\Users\herve\Documents\MyJar.jar' .\FirstProgram.class
```

CHAPTER REVIEW

1.6 Chapter Summary

- Basic components of a computer include the CPU, memory, a hard disk, keyboard, and monitor.
- Each type of CPU has its own set of instructions for performing arithmetic and logical operations, moving data, and changing the order of execution of instructions.
- An operating system controls peripheral devices, supports multitasking, allocates memory to programs, and prevents the user from damaging the system.
- Computer networks link two or more computers so that they can share resources, such as files or printers.
- The Internet connects millions of computers around the world. Web servers deliver webpages to clients running Internet browsers.
- Binary numbers are composed of bits. Each bit has the value 0 or 1. A byte holds eight binary digits.
- To convert a binary number to a decimal number, multiply each digit in the binary number by $2^{\text{position}21}$, counting the rightmost position as position 1 and moving left through the number. Then add the products together.
- To convert a decimal number into a binary number, first find the largest power of 2 that is smaller than or equal to the decimal number, subtract that number from the decimal

number, then do the same with the remainder, and so on, until the decimal number reaches 0.

- Hexadecimal digits can be used to represent groups of four bits.
- The Unicode character set, which Java uses, can encode up to 65,536 characters using 16 bits per character.
- Machine language and assembly language are early forms of programming languages that require the programmer to write to the CPU's instruction set. Because this low-level programming is time consuming and difficult, and the programs are not portable to other CPU architectures, machine language and assembly language are rarely used.
- High-level languages are highly symbolic and somewhat portable. They can be compiled, interpreted, or as in the case of Java, converted to byte codes, which are interpreted at run time by the Java Virtual Machine.
- A good program is readable, easily maintainable, and reusable.
- Object-oriented programming uses classes to encapsulate data and the functions needed to manipulate that data. Objects are instantiated according to the class design. An advantage to object-oriented programming is the ability to reuse classes.
- Programs use a combination of sequential processing, method calls, selection, and iteration to control the order of execution of instructions. Performing operations in order, one after another, is called sequential processing. Temporarily executing other code, then returning, is called a method call. Selecting which code to execute based on the value of data is called selection. Repeating the same code on each item in a group of values is called iteration, or looping.
- Pseudocode allows a programmer to design a program without worrying about the syntax of the language.
- In programming, we often perform tasks for which there are standard methods of processing, called algorithms. For example, accumulating is a common programming operation that finds the sum of a group of numbers.

- Programming, in large part, is reducing a complex task to a set of subtasks that can be implemented by combining standard algorithms that use sequential processing, selection, and looping.
- Java source code is stored in a text file with an extension of *.java*. Compiling the code produces one or more *.class* files.
- An Integrated Development Environment (IDE) consists of a program editor, a compiler, and a run-time environment, integrated via a Graphical User Interface.
- Compiler errors are detected by the compiler and are usually caused by incorrect Java syntax or misspellings. Run-time errors are detected by the Java Virtual Machine and are usually caused by exceptions or incorrect use of classes. Logic errors occur during program execution and are caused by incorrect program design.

1.7 Exercises, Problems, and Projects

1.7.1 Multiple Choice Exercises

1. Which one of these is not an operating system?

    - Linux
    - Java
    - Windows
    - Android

6. Which one of these is not an application?

    - Word
    - Firefox
    - Linux
    - Excel

11. How many bits are in three bytes?

    - 3
    - 8
    - 24
    - 0

16. In a network, the computers providing services to the other computers are called

    - clients.
    - servers.
    - laptops.

20. A binary number ending with a 0

- is even.
- is odd.
- cannot tell.

24. A binary number ending with a 1

    - is even.
    - is odd.
    - cannot tell.

28. A binary number ending with two 0s

    - is a multiple of 4.
    - is not a multiple of 4.
    - cannot tell.

32. Using four bits, the largest positive binary number we can represent is 1111.

    - true
    - false

35. Which one of these is not a programming language?

    - C+ +
    - Java
    - Windows
    - Fortran

40. Which one of these is not an object-oriented programming language?

    - C
    - Java
    - C+ +
    - Smalltalk

45. What is the file extension for a Java source code file?

    - .java
    - .exe
    - .class

49. What is the file extension of a compiled Java program?

    - .java
    - .exe
    - .class

53. In order to compile a program named *Hello.java*, what do you type at the command line?

    - java Hello
    - java Hello.java
    - javac Hello
    - javac Hello.java

58. You have successfully compiled *Hello.java* into *Hello.class.* What do you type at the command line in order to run the application?

    - java Hello.class
    - java Hello
    - javac Hello
    - javac Hello.class

1.7.2 Converting Numbers

1. Convert the decimal number 67 into binary.
2. Convert the decimal number 1,564 into binary.
3. Convert the binary number 0001 0101 into decimal.
4. Convert the binary number 1101 0101 0101 into decimal.

5. Convert the binary number 0001 0101 into hexadecimal.
6. Convert the hexadecimal number D8F into binary.

1.7.3 General Questions

1. A RAM chip is organized as × 8 memory, i.e., each unit contains 8 bits, or a byte. There are 7 address pins on the chip. How many bytes does that memory chip contain?
2. If a CPU is rated at 3 GHz, how many clock cycles per second are performed?
3. If a CPU's clock cycles 2.6 billion times per second, what is the rating of the CPU in MHz?
4. Suppose we are using binary encoding to represent colors. For example, a black-and-white color system has only two colors and therefore needs only 1 bit to encode the color system as follows:

Bit	Color
0	black
I	white

   With 2 bits, we can encode four colors as follows:

Bit pattern	Color
00	black
01	red
10	blue
11	white

   With 5 bits, how many colors can we encode?
   With *n* bits (*n* being a positive integer), how many colors can we encode? (Express your answer as a function of *n*.)
5. In HTML, a color can be coded in the following hexadecimal notation: *#rrggbb,* where
   rr represents the amount of red in the color
   gg represents the amount of green in the color
   bb represents the amount of blue in the color

rr, gg, and *bb* vary between 00 and FF in hexadecimal notation, i.e., 0 and 255 in decimal equivalent notation. Give the decimal values of the red, green, and blue values in the color #33AB12.

6. RGB is a color system representing colors: R stands for red, G for green, and B for blue. A color can be coded as *rgb* where *r* is a number between 0 and 255 representing how much red there is in the color, *g* is a number between 0 and 255 representing how much green there is in the color, and *b* is a number between 0 and 255 representing how much blue there is in the color. The color gray is created by using the same value for *r*, *g*, and *b*. How many shades of gray are there?
7. List three benefits of the Java programming language.
8. What is the name of the Java compiler?
9. Write the pseudocode for a program that finds the product of two numbers.
10. Write the pseudocode for a program that finds the sums of the numbers input that are greater than or equal to 10 and the numbers input that are less than 10.

1.7.4 Technical Writing

1. List the benefits of having a Local Area Network versus standalone computer systems.
2. For one day, keep a diary of the computer applications that you use. Also note any features of the applications that you think should be improved or any features you'd like to see added.
3. You are looking at two computers with the following specifications, everything else being equal:

PC # 1	PC # 2
3.4-GHz CPU	3.3-GHz CPU

16 MB L2 cache	16 MB L2 cache
4 GB RAM	12 GB RAM
1 TB hard drive	1 TB hard drive
$399	$399

Which PC would you buy? Explain the reasoning behind your selection.

4. Go to Oracles Java site *(www.oracle.com/technetwork/java).* Explain what resources are available there for someone who wants to learn Java.

1.7.5 Group Project (for a group of 1, 2, or 3 students)

1. In the octal system (base 8), numbers are represented using digits from 0 to 7; a 0 is placed in front of the octal number to indicate that the octal system is being used. For instance, here are some examples of the equivalent of some octal numbers in the decimal system:

Octal	Decimal
000	0
001	1

007	7
010	8
011	9

In the hexadecimal system, numbers are represented using digits from 0 to 9 and letters A to F; 0x is placed in front of the hexadecimal number to indicate that the hexadecimal system is being used. For instance, here are some examples of the decimal equivalents of some hexadecimal numbers:

Hexadecimal	Decimal
0×0	0
0×1	1
0×9	9
0×A	10
0×B	11
0×F	15
0×10	16
0×11	17
0×1C	28

1. Convert 0xC3E (in hexadecimal notation) into an octal number.
2. Convert 0377 (in octal notation) into a hexadecimal number.
3. Discuss how, in general, you would convert a hexadecimal number into an octal number and an octal number into a hexadecimal number.

CHAPTER 2

Programming Building Blocks—Java Basics

CHAPTER CONTENTS

Introduction
2.1 Java Application Structure
2.2 Data Types, Variables, and Constants

  2.2.1 Declaring Variables
  2.2.2 Integer Data Types
  2.2.3 Floating-Point Data Types
  2.2.4 Character Data Type
  2.2.5 Boolean Data Type
  2.2.6 The Assignment Operator, Initial Values, and Literals
  2.2.7 *String* Literals and Escape Sequences
  2.2.8 Text Blocks
  2.2.9 Constants

2.3 Expressions and Arithmetic Operators

    - 2.3.1 The Assignment Operator and Expressions
    - 2.3.2 Arithmetic Operators
    - 2.3.3 Operator Precedence
    - 2.3.4 **Programming Activity 1: Converting Inches to Centimeters**
    - 2.3.5 Integer Division and Modulus
    - 2.3.6 Division by Zero
    - 2.3.7 Mixed-Type Arithmetic and Type Casting
    - 2.3.8 Shortcut Operators

- 2.4 **Programming Activity 2: Temperature Conversion**
- 2.5 Chapter Summary
- 2.6 Exercises, Problems, and Projects

    - 2.6.1 Multiple Choice Exercises
    - 2.6.2 Reading and Understanding Code
    - 2.6.3 Fill In the Code
    - 2.6.4 Identifying Errors in Code
    - 2.6.5 Debugging Area—Using Messages from the Java Compiler and Java JVM
    - 2.6.6 Write a Short Program
    - 2.6.7 Programming Projects
    - 2.6.8 Technical Writing

Introduction

If we boil it down to the basics, a program has two elements: instructions and data. The instructions tell the CPU what to do with the data. Typically, a program's structure will consist of the following operations:

1. Input the data.
2. Perform some processing on the data.
3. Output the results.

The data used by a program can come from a variety of sources. The user can enter data from the keyboard, for example, when we type a new document into a word processor. The program can read the data from a file, for example, when we load an existing document into the word processor. Or the program can generate the data randomly, for example, when a computer card game deals hands. Finally, some data is already known; for example, the number of hours in a day is 24, the number of days in December is 31, and the value of pi is 3.14159. This type of data is constant. The Java language provides a syntax for describing a program's data using keywords, symbolic names, and data types.

Although the data may be different in each execution of the program, the instructions stay the same. In a word processor, the words (data) are different from document to document, but the operation (instructions) of the word processor remains the same. When a line becomes full, for example, the word processor automatically wraps to the next line. It doesn't matter which words are on the line, only that the line is full. When we select a word and change the font to bold, it doesn't matter which word we select; it will become bold. Thus, a program's instructions (its algorithm) must be written to correctly handle any data it may receive.

We will write our programs by translating our algorithms into the basic operations that the computer can perform: input and output of data and various operations related to processing data, such as arithmetic calculations, comparisons of data and subsequent changes to the flow of control, and movement of data from one location in memory to another.

In this chapter, we’ll look at basic Java syntax for defining the data to be used in the program, performing calculations on that data, and outputting program results to the screen.

```
The area of the circle is 38.4844775
```

```
The area of the circle is 1256.636
```

2.1 Java Application Structure

Every Java program consists of at least one class. It is impossible to write a Java program that doesn’t use classes. Classes describe a logical entity that has data as well as methods (the instructions) to manipulate that data. An object is a physical instantiation of the class that contains specific data. In **Example 2.1** we provide a shell that contains the basic format of a Java application with a class name of *ShellApplication*. Our source code will use this format, changing the class name as appropriate.

Example 2.1 A Shell for a Java Application

```java
/* An application shell
   Anderson, Franceschi
*/
public class ShellApplication
{
   public static void main( String [ ] args ) // required
   {
      // write your code here
   }
}
```

Description

In Example 2.1, the numbers to the left of each line are not part of the program code; they are included here for our convenience. IDEs typically allow us to display line numbers.

From application to application, the name of the class, *ShellApplication*, will change, because we will want to name our class something meaningful that reflects its function. Each Java source code file must have the same name as the class name with a *.java* extension. In this case, the source file must be *ShellApplication.java*. Whatever name we select for a class must comply with the Java syntax for identifiers.

Java **identifiers** are symbolic names that we assign to classes, methods, and data. Identifiers must start with a **Java letter** and may contain any combination of letters and digits, but no spaces. A Java letter is any character in the range *a–z* or *A–Z*, the underscore (_), or the dollar sign ($), as well as many Unicode characters that are used as letters in other languages. Digits are any character between 0 and 9. The length of an identifier is essentially unlimited. Identifier names are case sensitive, so *Number1* and *number1* are considered to be different identifiers.

In addition, none of Java's **reserved words** can be used as identifiers. These reserved words, which are listed in Appendix A, consist of keywords used in Java instructions, as well as three special data values: *true*, *false*, and *null*. As of Java 9, the single underscore (_) is a reserved word and cannot be used as an identifier. Given that Java identifiers are case sensitive, note that it is legal to use *True* or *TRUE* as identifiers, but *true* is not a legal variable name. **Table 2.1** lists the rules for creating Java identifiers.

Rules for Creating Identifiers

Java Identifiers

- Must start with a Java letter (*A–Z*, *a–z*, _, $, or many Unicode characters)
- Can contain an almost unlimited number of letters and/or digits (0–9)
- Cannot contain spaces
- Are case sensitive
- Cannot be a Java reserved word

Description

The shell code in Example 2.1 uses four identifiers: *ShellApplication*, *main*, *String*, and *args*. The remainder of Example 2.1 consists of comments, Java keywords, and required punctuation.

The basic building block of a Java program is the **statement**.

A statement is terminated with a semicolon and can span several lines.

Any amount of **white space** is permitted between identifiers, Java keywords, operands, operators, and literals. White space characters are the space, tab, newline, carriage return, and a few other rarely used characters. Liberal use of white space makes our program more readable. It is good programming style to surround identifiers, operands, and operators with spaces and to skip lines between logical sections of the program.

A **block**, which consists of 0, 1, or more statements, starts with a left curly brace ({) and ends with a right curly brace (}). Blocks are required for class and method definitions and can be used anywhere else in the program that a statement is legal. Example 2.1 has two blocks: the class definition (lines 5 through 10) and the *main* method definition (lines 7 through 9). As we can see, nesting blocks within blocks is perfectly legal. The *main* block is nested completely within the class definition block.

SOFTWARE ENGINEERING TIP

Liberal use of white space makes your program more readable. It is good programming style to surround identifiers, operands, and operators with spaces and to skip lines between logical sections of the program.

SOFTWARE ENGINEERING TIP

Include a block comment at the beginning of each source file that identifies the author of the program and briefly describes the function of the program.

Comments document the operation of the program and are notes to ourselves and to other programmers who read our code. Comments are not compiled and can be coded in two ways. **Block comments** can span several lines; they begin with a forward slash-asterisk (/*) and end with an asterisk-forward slash (*/). Everything between the /* and the */ is ignored by the compiler. Note that there are no spaces between the asterisk and forward slash. Lines 1–3 in Example 2.1 are block comments and illustrate the good software engineering practice of providing at the beginning of our source code a few comments that identify ourselves as the author and briefly describe what the program does.

The second way to include comments in our code is to precede the comment with two forward slashes (//). There are no spaces between the forward slashes. The compiler ignores everything from the two forward slashes to the end of the line. In Example 2.1, the compiler ignores all of line 8, but only the part of line 6 after the two forward slashes.

Let's look at an example to get a sense of what a simple program looks like and to get a feel for how a program operates. **Example 2.2** calculates the area of a circle.

Example 2.2 Calculating the Area of a Circle

```
 1 /* Calculate the area of a circle
 2    Anderson, Franceschi
 3 */
 4
 5 public class AreaOfCircle
 6 {
 7   public static void main( String [ ] args )
 8   {
 9      // define the data we know
10      final double PI = 3.14159;
11
12      // define other data we will use
13      double radius = 3.5;
14
15      // perform the calculation and store the result
16      double area = PI * radius * radius;
17
18      // output the result
19      System.out.println( "The area of the circle is " + area );
20   }
21 }
```

Description

Figure 2.1a shows the output when the program is run with a radius of 3.5. To calculate the area of a circle with a different radius, replace the value 3.5 in line 13 with the new radius value. For example, to calculate the area of a circle with a radius of 20, change line 13 to

```
double radius = 20;
```

Then recompile the program and run it again. **Figure 2.1b** shows the output for a radius of 20.

Figure 2.1a Output from Example 2.2 with a Radius of 3.5

Description

Figure 2.1b Output from Example 2.2 with a Radius of 20

Description

We can see that Example 2.2 has the basic elements that we saw in the *ShellApplication* (Example 2.1). We have added some statements in lines 9 through 19 that do the work of the program. First, we identify the data we will need. To calculate the area of a circle, we use the formula (πr^2). We know the value of π (3.14159), so we store that value in a memory location we name PI (line 10). We also need places in memory to hold the radius and the area. In line 13 we name the radius and, we give the radius a value; here we have chosen 3.5, but our program will need to work with any value for the radius.

Now we're ready to calculate the area. We want this program to output correct results with any radius, so we need to write the algorithm of the program using the formula for calculating a circle's area given above. Java provides arithmetic operators for performing calculations. We use Java's multiplication operator (*) in line 16 to multiply PI times the radius times the radius and store the result into the memory location we named *area*. Now we're ready to output the result. On line 19, we write a message that includes the *area* value we calculated.

With Java 9, we have another option to running Java code. If we just want to try out some Java code without writing a complete application, we can use the **jshell** utility. The jshell utility is an REPL (Read, Evaluate, Print, Loop) tool that allows us to type small amounts of code, called snippets, and see the immediate result without compiling. Some IDEs (Integrated Development Environments) already provide an interactive utility like jshell. For example, jGRASP (*jgrasp.org*) provides an Interactions tool. We will use jshell to illustrate many concepts in this chapter. You will find jshell in the *bin* folder where the Java JDK is stored. If you have already updated your classpath environment variable for javac and java, then it is automatically set for jshell because these three programs are in the same folder. Consult your operating system instructions for details about setting the classpath.

To use jshell, open a command line application and launch jshell. To try out some code, simply type it at the prompt. To see a complete list of jshell commands, type */help*. As you will see, jshell commands start with a forward slash (/). To exit jshell, type */exit*.

```
Please choose a language:
    1 - Java
    2 - Python
    3 - C++
```

```
The value of constant ZORRO is Z
The value of constant PI is 3.14159
The number of days in a leap year is 366
The number of days in a non-leap year is 365
```

2.2 Data Types, Variables, and Constants

In Example 2.2, we used as data the value of PI and the radius, and we calculated the area of the circle. For each of these values, we assigned a name. We also used the Java keyword *double,* which defines the **data type** of the data. The keyword *double* means that the value will be a floating-point number.

Java allows us to refer to the data in a program by defining **variables**, which are named locations in memory where we can store values. A variable can store one data value at a time, but that value might change as the program executes, and it might change from one execution of the program to the next. The real advantage of using variables is that we can name a variable, assign it a value, and subsequently refer to the name of the variable in an expression rather than hard coding the specific value.

When we use a named variable, we need to tell the compiler which kind of data we will store in the variable. We do this by giving a data type for each variable.

Java supports eight primitive data types: *byte, short, int, long, float, double, char,* and *boolean*. They are called primitive data types because they are part of the core Java language.

The data type we specify for a variable tells the compiler how much memory to allocate and the format in which to store the data. For example, if we specify that a data item is an *int*, then the compiler will allocate four bytes of memory and store its value as a 32-bit signed binary number. If, however, we specify that a data item is a *double* (a double-precision floating-point number), then the compiler will allocate 8 bytes of memory and store its value as a double-precision IEEE 754 floating-point number.

SOFTWARE ENGINEERING TIP

When selecting identifiers, choose meaningful names that reflect the use of the identifier in the program; this will make your code self-documented. Use as many characters as necessary to make the identifier clear, but avoid extremely long identifiers. Also, for clarity in your program logic, avoid identifiers that resemble Java keywords.

Once we declare a data type for a data item, the compiler will monitor our use of that data item. If we attempt to perform operations that are not allowed for that type or are not compatible with that type, the compiler will generate an error. Because the Java compiler monitors the operations on each data item, Java is called a **strongly typed language**.

Take care in selecting identifiers for your programs. The identifiers should be meaningful and should reflect the data that will be stored in a variable, the concept encapsulated by a class, or the function of a method. For example, the identifier *age* clearly indicates that the variable will hold the age of a person. When we select meaningful variable names, the logic of our program is more easily understood, and we are less likely to introduce errors. Sometimes, it may be necessary to create a long identifier in order to clearly indicate its use, for example, *numberOfStudentsWhoPassedCS1*. Although the length of identifiers is essentially unlimited, avoid creating extremely long identifiers because they are more cumbersome to use. Also, the longer the identifier, the more likely we are to make typos when entering the identifier into our program. Finally, although it is legal to use identifiers, such as *TRUE*, which differ from Java keywords only in case, it isn't a good idea because they easily can be confused with Java keywords, making the program logic less clear.

2.2.1 Declaring Variables

Every variable must be given a name and a data type before it can be used. This is called **declaring a variable**.

The syntax for declaring a variable is:

```
dataType identifier; // this declares one variable
```

Description

or

```
dataType identifier1, identifier2, ...; // this declares multiple
                                        // variables of the same
                                        // data type
```

Description

Note that a comma follows each identifier in the list except the last identifier, which is followed by a semicolon.

By convention, the identifiers for variable names should start with a lowercase letter. If the variable name consists of more than one word, then each word after the first should begin with a capital letter. For example, these identifiers are conventional Java variable names: *number1*, *highScore*, *booksToRead*, *ageInYears*, and *xAxis*. Underscores conventionally are not used in variable names; they are reserved for the identifiers of constants, as we shall discuss later in the chapter. Similarly, do not use dollar signs to begin variable names. The dollar sign is reserved for the first letter of programmatically generated variable names—that is, variable names generated by software, not people. Although this may sound arbitrary now, the value of following these conventions will become clearer as we gain more experience in Java and our programs become more complex.

SOFTWARE ENGINEERING TIP

Begin variable names with a lowercase letter. If the variable name consists of more than one word, begin each word after the first with a capital letter. Avoid underscores in variable names, and do not begin a variable name with a dollar sign.

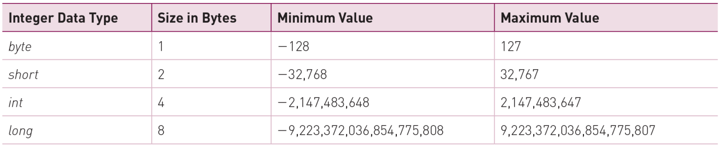
2.2.2 Integer Data Types

An integer data type is one that evaluates to a positive or negative whole number. Java provides four integer data types: *int*, *short*, *long*, and *byte*.

The *int*, *short*, *long*, and *byte* types differ in the number of bytes of memory allocated to store each type and, therefore, the maximum and minimum values that can be stored in a variable of that type. All of Java's integer types are signed, meaning that they can be positive or negative; the high-order, or leftmost, bit is reserved for the sign.

Table 2.2 summarizes the integer data types, their sizes in memory, and their maximum and minimum values.

Integer Data Types



Integer Data Type	Size in Bytes	Minimum Value	Maximum Value
byte	1	−128	127
short	2	−32,768	32,767
int	4	−2,147,483,648	2,147,483,647
long	8	−9,223,372,036,854,775,808	9,223,372,036,854,775,807

Description

In most applications, the *int* type will be sufficient for our needs, since it can store positive and negative numbers into the 2 billion range. The *short* and *byte* data types typically are used only when memory space is critical, and the *long* data type is needed only for data values larger than 2 billion.

Let's look at some examples of integer variable declarations.

Note that the variables' names clearly indicate the data that the variables will hold.

```
int testGrade;
int numPlayers, highScore, diceRoll;
short xCoordinate, yCoordinate;
long cityPopulation;
byte ageInYears;
```

Description

2.2.3 Floating-Point Data Types

Floating-point data types store numbers with fractional parts. Java supports two floating-point data types: the single-precision *float* and the double-precision *double*.

REFERENCE POINT

Floating-point numbers are stored using the IEEE 754 standard, which is discussed in Appendix E.

The two types differ in the amount of memory allocated and the size and precision of the number that can be represented. The single-precision type (*float*) is stored in 32 bits, while the double-precision type (*double*) is stored in 64 bits. *Floats* and *doubles* can be positive or negative.

Table 2.3 summarizes Java's floating-point data types, their sizes in memory, and their maximum and minimum positive nonzero values.

Floating-Point Data Types

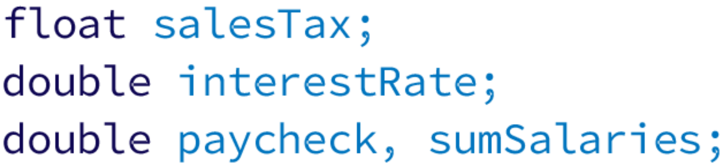
Floating-Point Data Type	Size in Bytes	Minimum Positive Nonzero Value	Maximum Value
float	4	1.4E-45	3.4028235E38
double	8	4.9E-324	1.7976931348623157E308

Description

Because of its greater precision, the *double* data type is usually preferred over the *float* data type. However, for calculations not requiring such precision, *floats* are often used because they require less memory.

Although integers can be stored as *doubles* or *floats*, it isn't advisable to do so because floating-point numbers require more processing time for calculations.

Let's look at a few examples of floating-point variable declarations:



```
float salesTax;
double interestRate;
double paycheck, sumSalaries;
```

Description

2.2.4 Character Data Type

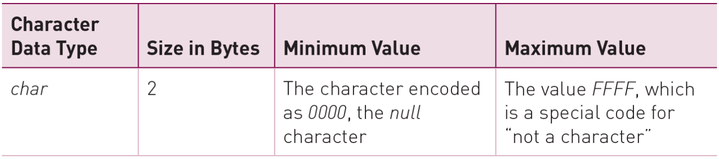
The *char* data type stores one Unicode character. Because Unicode characters are encoded as unsigned numbers using 16 bits, a *char* variable is stored in two bytes of memory.

REFERENCE POINT

The encoding of ASCII and Unicode characters is discussed in Appendix C.

Table 2.4 shows the size of the *char* data type, as well as the minimum and maximum values. The maximum value is the unsigned hexadecimal number *FFFF*, which is reserved as a special code for "not a character."

The Character Data Type

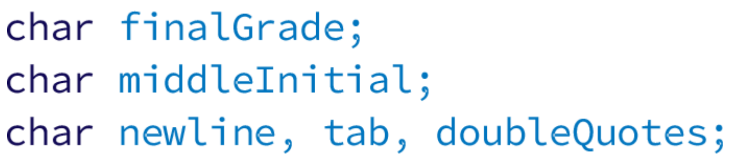


Character Data Type	Size in Bytes	Minimum Value	Maximum Value
char	2	The character encoded as *0000*, the *null* character	The value *FFFF*, which is a special code for "not a character"

Description

Obviously, since the *char* data type can store only a single character, such as a *K***,** a *char* variable is not useful for storing names, titles, or other text data. For text data, Java provides a *String* class, which we'll discuss later in this chapter.

Here are a few declarations of *char* variables:



```
char finalGrade;
char middleInitial;
char newline, tab, doubleQuotes;
```

Description

2.2.5 Boolean Data Type

The *boolean* data type can store only two values, which are expressed using the Java reserved words *true* and *false*, as shown in **Table 2.5**.

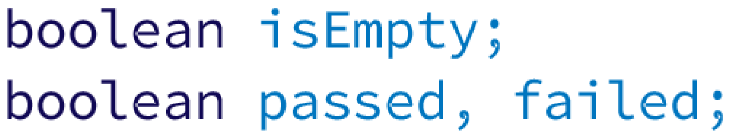
The *boolean* Data Type

***boolean* Data Type**	**Possible Values**
boolean	*true* *false*

Description

Booleans are typically used for decision making and for controlling the order of execution of a program.

Here are examples of declarations of *boolean* variables:



```
boolean isEmpty;
boolean passed, failed;
```

Description

2.2.6 The Assignment Operator, Initial Values, and

Literals

When we declare a variable, we can also assign an initial value for the data. To do that, we use the **assignment operator** (5) with the following syntax:

```
dataType variableName = initialValue;
```

Description

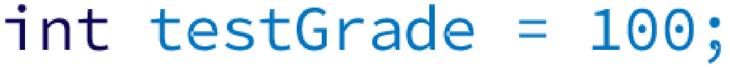
This statement is read as "*variableName* **gets** *initialValue*".
or

```
dataType variable1 = initialValue1, variable2 = initialValue2;
```

Description

Notice that assignment is right to left. The initial value is assigned to the variable.

One way to specify the initial value is by using a **literal value.** In the following statement, the value *100* is an *int* literal value, which is assigned to the variable *testGrade*.



```
int testGrade = 100;
```

Description

COMMON ERROR TRAP

Although Unicode characters occupy two bytes in memory, they still represent a single character. Therefore, a literal value must also represent only one character.

Table 2.6 summarizes the legal characters in literals for all primitive data types.

Literal Formats for Java Data Types

Data Type	**Literal Format**
int, short, byte	Optional initial sign (+ or –)

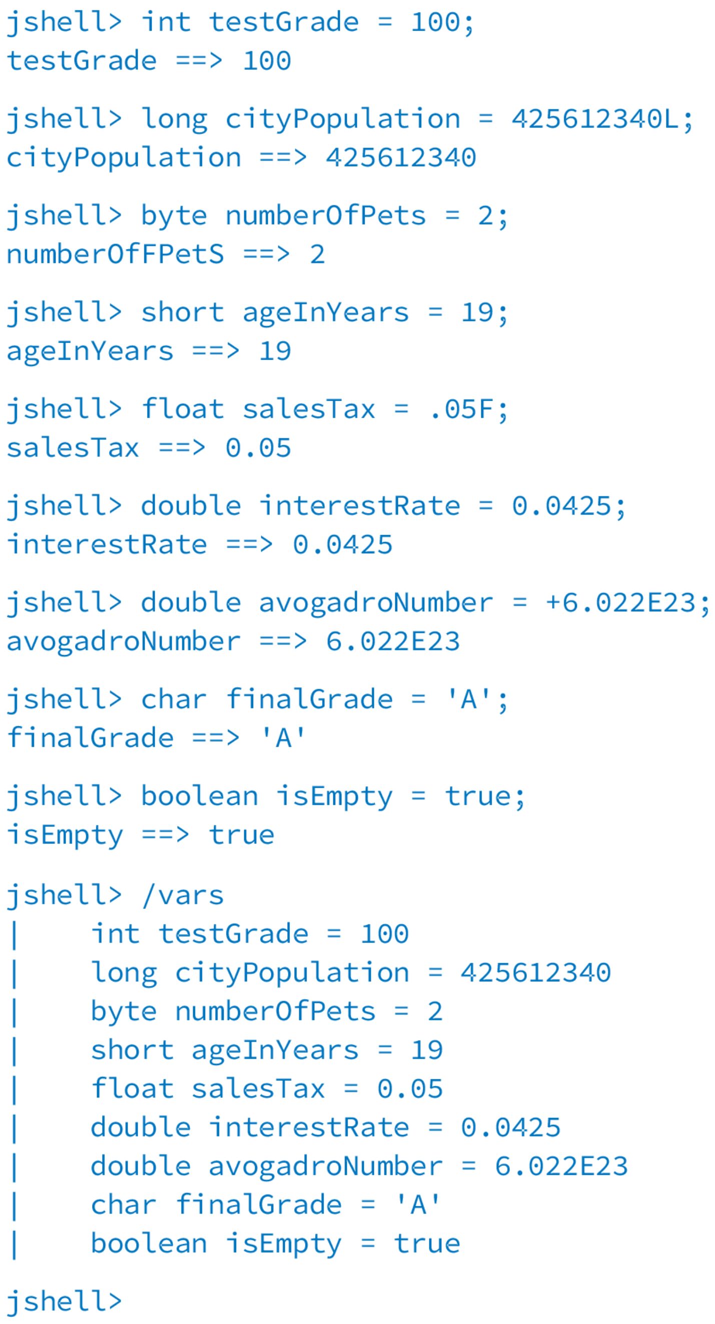
	followed by digits 0–9 in any combination. A literal in this format is an *int* literal; however, an *int* literal may be assigned to a *byte* or *short* variable if the literal is a legal value for the assigned data type. An integer literal that begins with a 0 digit is considered to be an octal number (base 8) and the remaining digits must be 0–7. An integer literal that begins with 0x is considered to be a hexadecimal number (base 16) and the remaining digits must be 0–9 or A–F.
long	Optional initial sign (+ or –) followed by digits 0–9 in any combination, terminated with an *L* or *l*. It's preferable to use the capital *L*, because the lowercase *l* can be confused with the number *1*. An integer literal that begins with a 0 digit is considered to be an octal number (base 8) and the remaining digits must be 0–7. An integer literal that begins with 0x is considered to be a hexadecimal number (base 16) and the remaining digits must be 0–9 or A–F.
float	Optional initial sign (+ or –) followed by a floating-point number in fixed or scientific format, terminated by an *F* or *f*.
double	Optional initial sign (+ or –) followed by a floating-point number in fixed or scientific format.
char	■ Any printable character enclosed in single quotes. ■ A decimal value from 0 to 65,535. ■ '\unnnn' where nnnn are hexadecimal digits. ■ '\m', where \m is an escape sequence. For example, '\n' represents a newline, and '\t' represents a tab character.
boolean	*true* or *false*

Description

Notice in Table 2.6 under the literal format for *char*, that *\n* and *\t* can be used to format output. We'll discuss these and other escape sequences in the next section of this chapter.

Example 2.3 shows a jshell session where we declare variables and assign a value using a literal. We then execute the jshell */vars* command to see our variables and their values.

Example 2.3 Declaring and Initializing Variables



```
jshell> int testGrade = 100;
testGrade ==> 100

jshell> long cityPopulation = 425612340L;
cityPopulation ==> 425612340

jshell> byte numberOfPets = 2;
numberOfFPetS ==> 2

jshell> short ageInYears = 19;
ageInYears ==> 19

jshell> float salesTax = .05F;
salesTax ==> 0.05

jshell> double interestRate = 0.0425;
interestRate ==> 0.0425

jshell> double avogadroNumber = +6.022E23;
avogadroNumber ==> 6.022E23

jshell> char finalGrade = 'A';
finalGrade ==> 'A'

jshell> boolean isEmpty = true;
isEmpty ==> true

jshell> /vars
|    int testGrade = 100
|    long cityPopulation = 425612340
|    byte numberOfPets = 2
|    short ageInYears = 19
|    float salesTax = 0.05
|    double interestRate = 0.0425
|    double avogadroNumber = 6.022E23
|    char finalGrade = 'A'
|    boolean isEmpty = true

jshell>
```

Description

Another way to specify an initial value for a variable is to assign the variable the value of another variable, using this syntax:

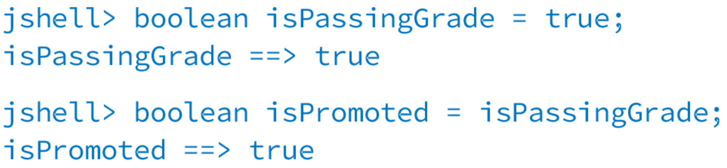
```
dataType variable2 = variable1;
```

Description

Two things need to be true for this assignment to work:

- *variable1* needs to be declared and assigned a value before this statement appears in the source code.
- *variable1* and *variable2* need to be compatible data types; in other words, the precision of *variable1* must be lower than or equal to that of *variable2*.

For example, in these statements:



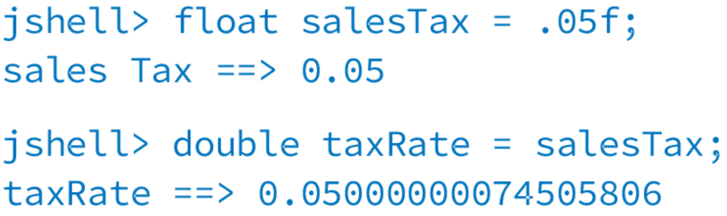
```
jshell> boolean isPassingGrade = true;
isPassingGrade ==> true

jshell> boolean isPromoted = isPassingGrade;
isPromoted ==> true
```

Description

isPassingGrade is given an initial value of *true*. Then *isPromoted* is assigned the value already given to *isPassingGrade*. Thus, *isPromoted* is also assigned the initial value *true*. If *isPassingGrade* were assigned the initial value *false*, then *isPromoted* would also be assigned the initial value *false*.

And in these statements,



```
jshell> float salesTax = .05f;
sales Tax ==> 0.05

jshell> double taxRate = salesTax;
taxRate ==> 0.05000000074505806
```

Description

the initial value of .05 is assigned to *salesTax* and then to *taxRate*. It’s legal to assign a *float* value to a *double*, because all values that can be stored as *floats* are also valid *double* values. Note that after assigning the *float* value to the *double,* that *taxRate* has some extraneous digits. This is due to rounding errors when converting the *float* value to a *double*. Essentially, the two values are equivalent.

However, assigning a *double* value to a *float* variable is *not* valid:

```
jshell> double taxRate = .05;
taxRate ==> 0.05

jshell> float salesTax = taxRate;
|  Error:
|  incompatible types: possible lossy conversion from double to float
|  float salesTax = taxRate;
|                   ^-----^
```

Description

Even though .05 is a valid *float* value, the compiler will generate a “`possible lossy conversion`” error similar to the error shown in jshell above.

Similarly, we can assign a lower-precision integer value to a higher-precision integer variable.

Table 2.7 summarizes compatible data types; a variable or literal of any type in the right column can be assigned to a variable of the data type in the left column.

Valid Data Types for Assignment

Data Type	**Compatible Data Types**
byte	*byte*
short	*byte, short*
int	*byte, short, int, char*
long	*byte, short, int, char, long*
float	*byte, short, int, char, long, float*
double	*byte, short, int, char, long, float, double*
boolean	*boolean*
char	*char*

Description

Variables need to be declared before they can be used in our program, but be careful to declare each variable only once; that is, specify the data type of the variable only the first time that variable is used in the program. If we attempt to declare a variable that has already been declared, as in the following statements:

```
double twoCents;
double twoCents = 2; // incorrect, second declaration of twoCents
```

Description

we will receive a compiler error similar to the following:

```
variable twoCents is already defined in method
```

COMMON ERROR TRAP

Declare each variable only once, the first time the variable is used. After the variable has been declared, its data type cannot be changed.

Similarly, once we have declared a variable, we cannot change its data type. Thus, these statements:

```
double cashInHand;
int cashInHand; // incorrect, data type cannot be changed
```

Description

will generate a compiler error similar to the following:

```
variable cashInHand is already defined in method
```

CODE IN ACTION

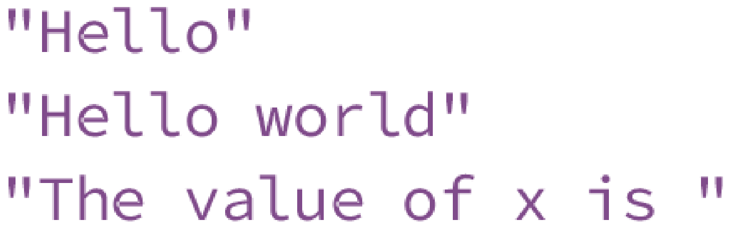
Within the online resources, you will find a movie showing a step-by-step illustration of declaring variables and assigning initial values. Click on this chapter's link to start the movie.

© Hemera Technologies/Photos.com/Thinkstock

2.2.7 *String* Literals and Escape Sequences

In addition to literals for all the primitive data types, Java also supports *String* literals. *String* literals are objects of Java's *String* class.

A ***String* literal** is a sequence of characters enclosed by double quotes. One set of quotes "opens" the *String* literal and the second set of quotes "closes" the literal. For example, these are all *String* literals:



```
"Hello"
"Hello world"
"The value of x is "
```

Description

We used *String* literals in output statements in Example 2.2 to label the data that we printed:

```
System.out.println( "The area of the circle is " + area );
```

The `+` operator is the ***String* concatenation operator**. Among other uses, the concatenation operator allows us to print the values of variables along with *String* literals. As we can see from the output of Example 2.2, the characters in the *String* literal are output exactly as typed, whereas the variable *area* is replaced by its current value.

SOFTWARE ENGINEERING TIP

Add a space to the end of a *String* literal before concatenating a value for more readable output.

String literals using double quotes cannot extend over more than one line. If the compiler finds a newline character in the middle of a *String* literal, it will generate a compiler error. For example, the following statement is not valid:

```
System.out.println( "Never pass a water fountain
                     without taking a drink." );
```

Description

COMMON ERROR TRAP

All open quotes for a *String* literal should be matched with a set of closing quotes, and the closing quotes must appear before the line ends.

In fact, that statement will generate errors:

```
jshell> System.out.println( "Never pass a water fountain
|  Error:
|  unclosed string literal
|  System.out.println( "Never pass a water fountain
|                      ^
```

Description

If we have a long *String* to print, break it into several strings and use the concatenation operator. This statement is a correction of the previous invalid statement:

```
jshell> System.out.println( "Never pass a water fountain"
 ... >                       + "without taking a drink." );
Never pass a water fountain without taking a drink.
```

Description

Another common programming error is omitting the closing quotes. Be sure that all open quotes have matching closing quotes on the same line.

Now that we know that quotes open and close *String* literals, how can we define a literal that includes quotes? This statement, which has quotes inside a *String* literal

```
System.out.println( "She said, "Java is fun".");  // illegal quotes
                                                  // within literal
```

Description

generates this error:

```
jshell> System.out.println( "She said, "Java is fun"." );
|  Error:
|  ')' expected
|  System.out.println( "She said, "Java is fun"." );
|                                  ^
```

Description

Java provides a set of escape sequences that can be used to include a special character within *String* and *char* literals. The escape sequences *\n, \t, \b, \r,* and *\f* are nonprintable characters. **Table 2.8** lists the Java escape sequences.

Java Escape Sequences

Character	**Escape Sequence**
newline	\n
tab	\t
double quotes	\"
single quote	\'
backslash	\\
backspace	\b
carriage return	\r
form feed	\f

Description

Using the \" escape character, we can now output embedded quotes as:

```
jshell> System.out.println( "She said, \"Java is fun\"." );
She said, "Java is fun".
```

Description

We can force part of the output to the next line by inserting a *\n* escape character, as in:

```
jshell> System.out.println( "One potato\nTwo potatoes" );
One potato
Two potatoes
```

Description

We will find that the *\n* escape character is useful for skipping lines in output.

Finally, we can format output by inserting *\t* where we want a tab, as in:

```
jshell> System.out.println( "\tTabs can make the output easier to read." );
        Tabs can make the output easier to read.
```

Description

2.2.8 Text Blocks

Text blocks, *String* literals delimited by **triple quotes**, allow us to define literal *Strings* over several lines without using the concatenation operator. In addition to being convenient, using text blocks can improve the readability of our code. At lines 9 to 14 of **Example 2.4**, we define the *String menu* using a text block. Furthermore, we can use escape sequences, such as \t, \n, \\, \”, and so on, within a text block. **Figure 2.2** shows the output of Example 2.4.

Example 2.4 Using Text Blocks

```
/* Using Text Blocks
   Anderson, Franceschi
*/

public class TextBlock
{
  public static void main( String [ ] args )
  {
    String menu = """
      Please choose a language:
      \t1 - Java
      \t2 - Python
      \t3 - C++
      """;

    System.out.println( menu );
  }
}
```

Description

Figure 2.2 Output of Example 2.4

Description

2.2.9 Constants

Sometimes we know the value of a data item, and we know that its value will not (and should not) change during program execution, nor is it likely to change from one execution of the program to another. In this case, it is a good software engineering practice to define that data item as a **constant**.

Defining constants uses the same syntax as declaring variables, except that the data type is preceded by the keyword *final*.

```
final dataType CONSTANT_IDENTIFIER = assignedValue;
```

Assigning a value is optional when the constant is defined, but we must assign a value before the constant is used in the program. Also, once the constant has been assigned a value, its value cannot be changed (reassigned) later in the program. Any attempt by our program to change the value of a constant will generate the following compiler error:

```
cannot assign a value to final variable
```

Think of this as a service of the compiler in preventing our program from unintentionally corrupting its data.

By convention, *CONSTANT_IDENTIFIER* consists of all capital letters, and embedded words are separated by an underscore. This makes constants stand out in the code and easily identified as constants. Also, constants are usually defined at the top of a program where their values can be seen easily.

Example 2.5 shows how to use constants in a program.

Example 2.5 Using Constants

```
 1 /* Constants Class
 2    Anderson, Franceschi
 3 */
 4
 5 public class Constants
 6 {
 7     public static void main( String [ ] args )
 8     {
 9          final char ZORRO = 'Z';
10          final double PI = 3.14159;
11          final int DAYS_IN_LEAP_YEAR = 366, DAYS_IN_NON_LEAP_YEAR = 365;
12
13          System.out.println( "The value of constant ZORRO is " + ZORRO );
14          System.out.println( "The value of constant PI is " + PI );
15          System.out.println( "The number of days in a leap year is "
16                                     + DAYS_IN_LEAP_YEAR );
17          System.out.println( "The number of days in a non-leap year is "
18                                     + DAYS_IN_NON_LEAP_YEAR );
19
20          // PI = 3.14;
21          // The statement above would generate a compiler error
22          // You cannot change the value of a constant
23     }
24 }
```

Description

Lines 9, 10, and 11 define four constants. On line 11, note that both *DAYS_IN_LEAP_YEAR* and *DAYS_IN_NON_LEAP_YEAR* are constants. We don’t need to repeat the keyword final to define two (or more) constants of the same data types. Lines 13 to 18 output the values of the four constants. If line 20 were not commented out, it would generate a compiler error because once a constant is assigned a value, its value cannot be changed. **Figure 2.3** shows the output of Example 2.5.

Figure 2.3 Output of Example 2.5

Description

SOFTWARE ENGINEERING TIP

Use all capital letters for a constant’s identifier; separate words with an underscore (_). Declare constants at the top of the program so their value can be seen easily.

SOFTWARE ENGINEERING TIP

Declare as a constant any data that should not change during program execution. The compiler will then flag any attempts by your program to change the value of the constant, thus preventing any unintentional corruption of the data.

Constants can make our code more readable: PI is more meaningful than 3.14159 when used inside an arithmetic expression. Another advantage of using constants is to keep programmers from making logic errors: Let’s say we set a constant to a particular value and it is used at various places throughout the code (for instance, a constant representing a tax rate); we then discover that the value of that constant needs to be changed. All we have to do is make the change in one place, most likely at the beginning of the code. If we had to change the value at many places throughout the code, that could very well result in logic errors or typos.

After a %= 3; a is 1
```

2.3 Expressions and Arithmetic Operators

2.3.1 The Assignment Operator and Expressions

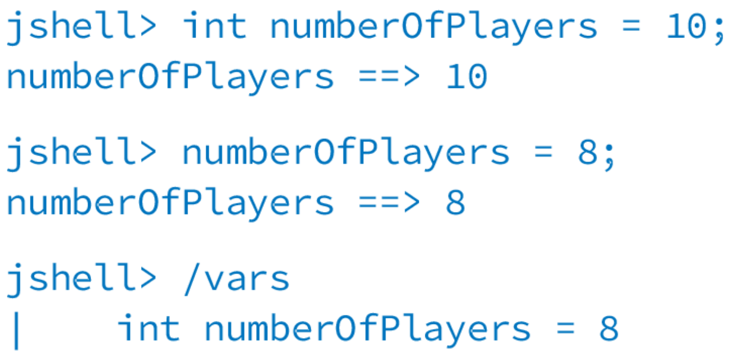
In a previous section, we mentioned using the assignment operator to assign initial values to variables and constants. Now let’s look at the assignment operator in more detail.
The syntax for the assignment operator is:

```
target = expression;
```

Description

An expression consists of operators and operands that evaluate to a single value. The value of the expression is then assigned to *target* (*target* gets *expression*), which must be a variable or a constant having a data type compatible with the value of the expression.

If *target* is a variable, the value of the expression replaces any previous value the variable was holding. For example, let's look at these instructions:



```
jshell> int numberOfPlayers = 10;
numberOfPlayers ==> 10

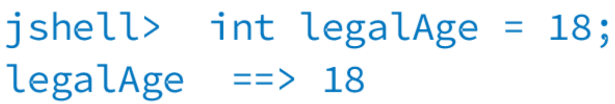
jshell> numberOfPlayers = 8;
numberOfPlayers ==> 8

jshell> /vars
|    int numberOfPlayers = 8
```

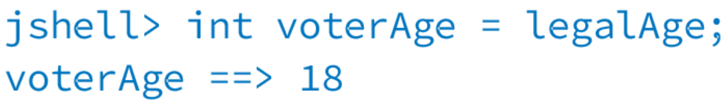
Description

The first instruction declares an *int* named *numberOfPlayers*. This allocates four bytes in memory to a variable named *numberOfPlayers* and stores the value 10 in that variable. Then, the second statement changes the value stored in the variable *numberOfPlayers* to 8. The previous value, 10, is discarded. Note that we do not repeat "*int*." As mentioned earlier, we declare the data type only the first time we use a variable.

An expression can be a single variable name or a literal of any type, in which case, the value of the expression is simply the value of the variable or the literal. For example, in these statements,



```
jshell>  int legalAge = 18;
legalAge  ==> 18
```



```
jshell> int voterAge = legalAge;
voterAge ==> 18
```

Description

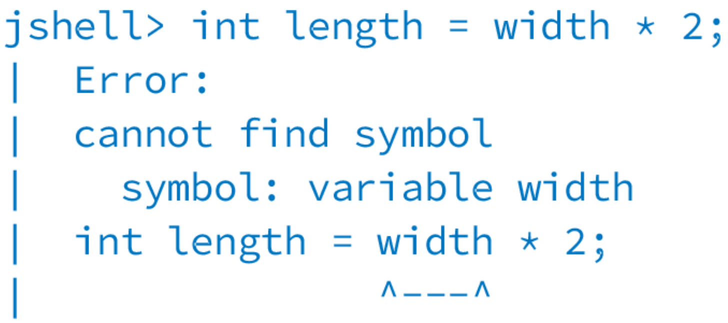
the literal 18 is an expression. Its value is 18, which is assigned to the variable *legalAge*. Then, in the second statement, *legalAge* is an expression, whose value is 18. Thus, the value 18 is assigned to *voterAge*. So after these statements have been executed, both *legalAge* and *voterAge* will have the value 18.

One restriction, however, is that an assignment expression cannot include another variable unless that variable has been defined previously. The statement defining the *length* variable that follows is **invalid**, because it refers to *width*, which is not defined until the next line.

```
int length = width * 2; // invalid, width is not yet defined
int width = 30;
```

Description

The compiler will flag the statement defining *length* as an error with a message similar to the one in the jshell session below



```
jshell> int length = width * 2;
|   Error:
|   cannot find symbol
|     symbol: variable width
|   int length = width * 2;
|                ^---^
```

Description

because *width* has not yet been defined.

An expression can be quite complex, consisting of multiple variables, constants, literals, and operators. Before we can look at examples of more complex expressions, however, we need to discuss the **arithmetic operators**.

2.3.2 Arithmetic Operators

Java’s arithmetic operators are used for performing calculations on numeric data. Some of these operators are shown in **Table 2.9**.

Arithmetic Operators

Operator	Operation
1	addition
2	subtraction
*	multiplication
/	division
%	modulus (remainder after division)

Description

All these operators take two operands; thus, they are called **binary operators**. Each operand is an expression.

In **Example 2.6**, we make a variety of calculations to demonstrate the addition, subtraction, multiplication, and division arithmetic operators. We will discuss integer division and the modulus operator later in the chapter. The output from this program is shown in **Figure 2.4**.

Example 2.6 Using Arithmetic Operators

```
 1 /* Arithmetic Operators
 2    Anderson, Franceschi
 3 */
 4
 5 public class ArithmeticOperators
 6 {
 7   public static void main( String [ ] args )
 8   {
 9      // calculate the cost of lunch
10      double salad = 5.95;
11      double water = .89;
12      System.out.println( "The cost of lunch is $"
13                          + ( salad + water ) );
14
15      // calculate your age as of a certain year
16      int targetYear = 2025;
17      int birthYear = 2005;
18      System.out.println( "Your age in " + targetYear + " is "
19                          + ( targetYear - birthYear ) );
20
21      // calculate the total calories of apples
22      int caloriesPerApple = 127;
23      int numberOfApples = 3;
24      System.out.println( "The calories in " + numberOfApples
25                          + " apples is " +
26                          + ( caloriesPerApple * numberOfApples ) );
27
28      // calculate miles per gallon
29      double miles = 426.8;
30      double gallons = 15.2;
31      double mileage = miles / gallons;
32      System.out.println( "The mileage is "
33                          + mileage + " miles per gallon." );
34   }
35 }
```

Description

Figure 2.4 Output from Example 2.6

Description

SOFTWARE ENGINEERING TIP

For readable code, insert a space between operators and operands.

Example 2.6 demonstrates a number of small operations. To calculate a total price (lines 12 and 13), we add the individual prices. To calculate an age (lines 18 and 19), we subtract the birth year from the target year. To calculate the number of calories in multiple apples (lines 24–26), we multiply the number of calories in one apple by the number of apples. We calculate miles per gallon by dividing the number of miles driven by the number of gallons of gas used (line 31). Note that we can either store the result in another variable, as we did in line 31, and subsequently output the result (lines 32–33), or we can output the result of the calculation directly by writing the expression in the *System.out.println* statement, as we did in the other calculations in this example.

SOFTWARE ENGINEERING TIP

Developing and testing your code in steps makes it easier to find and fix errors.

2.3.3 Operator Precedence

The statements in Example 2.6 perform simple calculations, but what if we want to make more complex calculations using several operations, such as calculating how much money we have in coins? Let’s say we have two quarters, three dimes, and two nickels. To calculate the value of these coins in pennies, we might use this expression:

```
int pennies = 2 * 25 + 3 * 10 + 2 * 5;
```

In which order should the computer do the calculation? If the value of the expression were calculated left to right, then the result would be

```
= 2 * 25 + 3 * 10 + 2 * 5
=   50   + 3 * 10 + 2 * 5
=        53   * 10 + 2 * 5
=            530    + 2 * 5
=                  532 * 5
=                     2660
```

Description

Clearly, 2,660 pennies is not the right answer. To calculate the correct number of pennies, the multiplications should be performed first, then the additions. This, in fact, is the order in which Java will calculate the preceding expression.

The Java compiler follows a set of rules called **operator precedence** to determine the order in which the operations should be performed.

Table 2.10 provides the order of precedence of the operators we’ve discussed so far. The operators in the first row—parentheses—are evaluated first, then the operators in the second row (*, /, %) are evaluated, and so on with the operators in each row. When two or more operators on the same level appear in the same expression, the order of evaluation is left to right, except for the assignment operator, which is evaluated right to left.

Operator Precedence

Operator Hierarchy	Order of Same-Statement Evaluation	Operation
()	left to right	parentheses for explicit grouping
*, /, %	left to right	multiplication, division, modulus
+, −	left to right	addition, subtraction
5	right to left	assignment

Description

As we introduce more operators, we’ll add them to the Order of Precedence chart. The complete chart is provided in Appendix B.

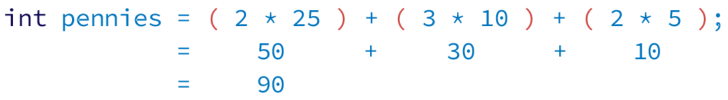
Using Table 2.10 as a guide, let’s recalculate the number of pennies:

```
int pennies = 2 * 25 +  3 * 10 + 2 * 5;
            =   50    +   30    +   10
            = 90
```

Description

As we can see, *90* is the correct number of pennies in two quarters, three dimes, and two nickels.

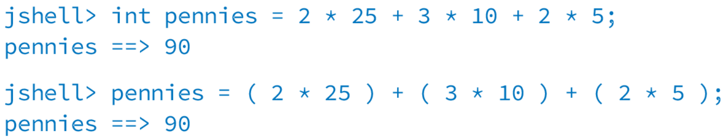
We also could have used parentheses to clearly display the order of calculation. For example,



```
int pennies = ( 2 * 25 ) + ( 3 * 10 ) + ( 2 * 5 );
            =     50     +     30     +     10
            =     90
```

Description

The result is the same, 90 pennies as shown below:



```
jshell> int pennies = 2 * 25 + 3 * 10 + 2 * 5;
pennies ==> 90

jshell> pennies = ( 2 * 25 ) + ( 3 * 10 ) + ( 2 * 5 );
pennies ==> 90
```

Description

It sometimes helps to use parentheses to clarify the order of calculations, but parentheses are essential when our desired order of evaluation is different from the rules of operator precedence. For example, to calculate the value of this formula:

$$\frac{x}{2+y}$$

we could write this code:

```
double result = x / 2 + y;
```

This would generate incorrect results because, according to the rules of precedence, *x/2* would be calculated first, then *y* would be added to the result of that division. In algebraic terms, the preceding statement is equivalent to:

$$\frac{x}{2} + y$$

To code the original formula correctly, we need to use parentheses to force the addition to occur before the division:

```
double result = x / ( 2 + y );
```

2.3.4 Programming Activity 1: Converting Inches to Centimeters

Now that we know how to define variables and constants and make calculations, let's put this all together by writing a program that converts inches into the equivalent centimeters.

Locate the *MetricLength.java* source file found in this chapter's Programming Activity 1 folder in the supplied code files. Copy the file to your computer.

Open the *MetricLength.java* source file. You'll notice that the class already contains some source code. Your job is to fill in the blanks.

When we write a program, we begin by considering these questions:

1. What data values does the program require?
    a. What data values do we know?
    b. What data values will change from one execution of the program to the next?
2. What processing (algorithm) do we need to implement?
3. What is the output?

The comments in the source file will guide you through the answers to these questions, and by doing so, you will complete the program. Search for five asterisks in a row (*****). This will position you to the places in the source code where you will add your code. The *MetricLength.java* source code is shown in **Example 2.7**. Sample output for a value of 5.2 inches is shown in **Figure 2.5**.

Example 2.7 Converting Inches to Centimeters

```java
/* MetricLength - converts inches to centimeters
   Anderson, Franceschi
*/

public class MetricLength
{
   public static void main( String [ ] args )
   {

      /***** 1. What data values do we know?
         We know that there are 2.54 centimeters in an inch.
         Declare a double constant named CM_PER_INCH.
         Assign CM_PER_INCH the value 2.54.
      */

      /***** 2. What other data does the program require?
         For this program, we require the number of inches.
         Declare a double variable named inches.
         Assign any desired value to this variable.
      */

      /***** 3. Calculation: convert inches to centimeters
         Declare a double variable named centimeters.
         Multiply inches by CM_PER_INCH
         and store the result in centimeters.
      */

      /***** 4. Output
         Write one or two statements that output
         the original inches and the equivalent centimeters.
         Try to match the sample output in Figure 2.5
      */

   }
}
```

Description

Figure 2.5 Sample Output for Programming Activity 1

DISCUSSION QUESTIONS

1. How do you know that your program results are correct?
2. If you change the inches data value, does your program still produce correct results?

2.3.5 Integer Division and Modulus

Division of a floating-point number by another floating-point number will result in a floating-point number; that is, a number with a fractional part. This is like the result you would receive using a calculator. For example, 12.6 / 2.4 will yield 5.25. Division with two integer operands, however, is performed in the Arithmetic Logic Unit (ALU), which can calculate only an integer result. Any fractional part is truncated; no rounding is performed. The remainder after division is available, however, as an integer, by taking the modulus (%) of the two integer operands. Thus, in Java, the integer division (/) operator will calculate the quotient of the division, whereas the modulus (%) operator will calculate the remainder of the division.

In **Example 2.8**, we have 113 pennies and we want to convert those pennies into quarters. We can find the number of quarters by dividing 113 by 25. The *int* variable *pennies* is assigned the value 113 at line 10. At line 12, the variable *quarters* is assigned the result of the integer division of *pennies* by the constant *PENNIES_PER_QUARTER*. Since the quotient of the division of 113 by 25 is 4, *quarters* will be assigned 4. At line 16, we use the modulus operator to assign to the variable *penniesLeftOver* the remainder of the division of *pennies* by *PENNIES_PER_QUARTER*. Since the remainder of the division of 113 by 25 is 13, 13 will be assigned to *penniesLeftOver*. Notice that integer division and modulus are independent calculations. We can perform a division without also calculating the modulus, and we can calculate the modulus without performing the division.

Example 2.8 How Integer Division and Modulus Work

```
 1 /* DivisionAndModulus Class
 2    Anderson, Franceschi
 3 */
 4
 5 public class DivisionAndModulus
 6 {
 7    public static void main( String [ ] args )
 8    {
 9      final int PENNIES_PER_QUARTER = 25;
10      int pennies = 113;
11
12      int quarters = pennies / PENNIES_PER_QUARTER;
13      System.out.println( "There are " + quarters + " quarters in "
14              + pennies + " pennies" );
15
16      int penniesLeftOver = pennies % PENNIES_PER_QUARTER;
17      System.out.println( "There are " + penniesLeftOver
18              + " pennies left over" );
19
20      final double MONTHS_PER_YEAR = 12;
21      double annualSalary = 50000.0;
22
23      double monthlySalary = annualSalary / MONTHS_PER_YEAR;
24      System.out.println( "The monthly salary is " + monthlySalary );
25    }
26 }
```

Description

At line 23, we divide a *double* by a *double;* therefore, a floating-point division will be performed by the floating-point unit (FPU), and the floating-point result will be assigned to the variable *monthlySalary*. **Figure 2.6** shows the output of the program.

Figure 2.6 Output of Example 2.8

Description

The modulus is a useful operator. It can be used to determine whether a number is even or odd, to control the number of data items that are written per line, to determine if one number is a factor of another, and for many other uses, as we will see later in this text.

CODE IN ACTION

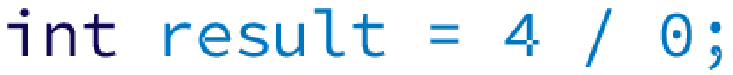
2.6.3	Fill In the Code Questions 27, 29, 32
2.6.4	Identifying Errors in Code Question 35
2.6.6	Write a Short Program Question 44

2.3.6 Division by Zero

As we might expect, Java does not allow integer division by 0. If we include this statement in our program,



```
int result = 4 / 0;
```

the code will compile without errors, but at run time, when this statement is executed, the JVM will generate an exception and print an error message on the Java console:

```
Exception in thread "main" java.lang.ArithmeticException: / by zero
```

In most cases, this stops the program. After we discuss selection techniques, we will be able to avoid dividing by zero by first testing whether the divisor is zero before performing the division.

In contrast, floating-point division by zero does not generate an exception. If the dividend is not zero, the answer is *Infinity*. If both the dividend and divisor are zero, the answer is *NaN*, which stands for “Not a Number.”

Example 2.9 illustrates the three cases of dividing by zero. As we can see on the output shown in **Figure 2.7**, line 16 never executes. We can see from the last line in the figure:

Example 2.9 Results of Division by Zero

```
 1 /* DivisionByZero Class
 2    Anderson, Franceschi
 3 */
 4
 5 public class DivisionByZero
 6 {
 7    public static void main( String [ ] args )
 8    {
 9      double result1 = 4.3 / 0.0;
10      System.out.println( "The value of result1 is " + result1 );
11
12      double result2 = 0.0 / 0.0;
13      System.out.println( "The value of result2 is " + result2 );
14
15      int result3 = 4 / 0;
16      System.out.println( "The value of result3 is " + result3 );
17    }
18 }
```

Description

Figure 2.7 Output of Example 2.9

Description

```
at DivisionByZero.main(DivisionByZero.java.15)
```

that an exception is generated at line 15 and the program halts execution. Line 16 was not executed.

Although floating-point division by zero doesn't bring our program to a halt, it doesn't provide useful results either. It's a good practice to avoid dividing by zero in the first place.

2.3.7 Mixed-Type Arithmetic and Type Casting

So far, we've used a single data type in the expressions we've evaluated. But life isn't always like that. Calculations often involve data of different primitive types.

When calculations of mixed types are performed, lower-precision operands are converted, or **promoted**, to the type of the operand that has the higher precision.

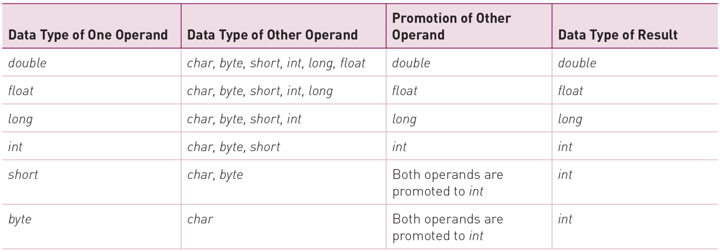
The promotions are performed using the *first* of these rules that fits the situation:

1. If either operand is a *double*, the other operand is converted to a *double*.

2. If either operand is a *float*, the other operand is converted to a *float*.
3. If either operand is a *long*, the other operand is converted to a *long*.
4. If either operand is an *int*, the other operand is promoted to an *int*.
5. If neither operand is a *double*, *float*, *long*, or an *int*, both operands are promoted to *int*.

Table 2.11 summarizes these rules of promotion.

Rules of Operand Promotion



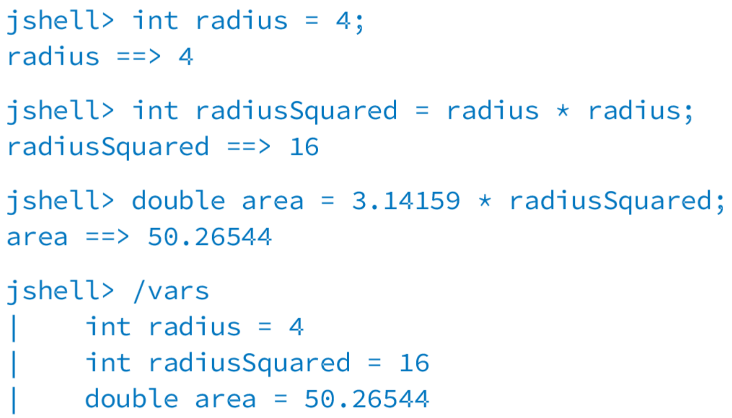
Data Type of One Operand	Data Type of Other Operand	Promotion of Other Operand	Data Type of Result
double	*char, byte, short, int, long, float*	*double*	*double*
float	*char, byte, short, int, long*	*float*	*float*
long	*char, byte, short, int*	*long*	*long*
int	*char, byte, short*	*int*	*int*
short	*char, byte*	Both operands are promoted to *int*	*int*
byte	*char*	Both operands are promoted to *int*	*int*

Description

This arithmetic promotion of operands is called **implicit type casting** because the compiler performs the promotions automatically, without our specifying that the conversions should be made. Note that the data type of any promoted variable is not permanently changed; its type remains the same after the calculation has been performed.

Table 2.11 shows many rules, but essentially, any arithmetic expression involving integers and floating-point numbers will evaluate to a floating-point number.

The code snippet below illustrates the rules of promotion. We calculate the area of a circle using a radius that is an *int* and 3.14159, which is a *double*. Our first calculation is to square the radius. Because *radius* is an *int*, the result is also an *int*. Then we multiply *radiusSquared* by 3.14159, a *double*. At this point, the *radiusSquared* value is promoted to a *double* and the resulting area is a *double*. Note that when we list our variables that *radiusSquared* is still an *int*.



```
jshell> int radius = 4;
radius ==> 4

jshell> int radiusSquared = radius * radius;
radiusSquared ==> 16

jshell> double area = 3.14159 * radiusSquared;
area ==> 50.26544

jshell> /vars
|    int radius = 4
|    int radiusSquared = 16
|    double area = 50.26544
```

Description

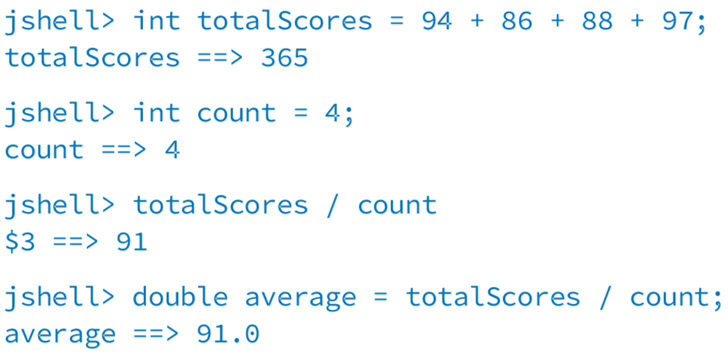
Sometimes, it’s useful to instruct the compiler specifically to convert the type of a variable. In this case, we use **explicit type casting**, which uses this syntax:

```
(dataType) ( expression )
```

The expression will be converted, or type cast, to the data type specified. The parentheses around *expression* are needed only when the expression consists of a calculation that we want to be performed before the type casting. If the expression consists of a single variable or value, the parentheses around *expression* are not needed.

Type casting is useful in calculating an average. The snippet below shows how to calculate an average test grade. The test scores are 94, 86, 88, and 97, making the combined total score 365. We expect the average to be 91.25.

Our first attempt to calculate the average results in the wrong answer. Because *totalScores* and *count* are both integers, integer division is performed. This truncates any remainder, as shown by the value of the temporary variable $3 (91). When we then assign the integer result to the *double average*, the integer value is promoted to a *double*. The result, 91.0, appears to be accurate to one decimal place, but it is, in fact, incorrect.



```
jshell> int totalScores = 94 + 86 + 88 + 97;
totalScores ==> 365

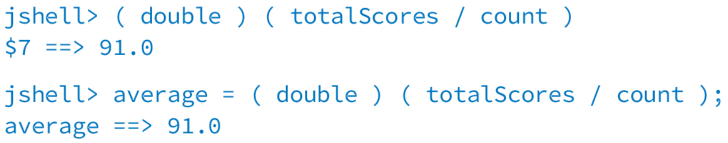
jshell> int count = 4;
count ==> 4

jshell> totalScores / count
$3 ==> 91

jshell> double average = totalScores / count;
average ==> 91.0
```

Description

In our second attempt, we explicitly type cast the division to a double. But we are too late. The integer division is performed first (which we’ve seen is 91), then the result of the integer division is type cast to a double. Again, we receive the same incorrect and misleading result, 91.0.

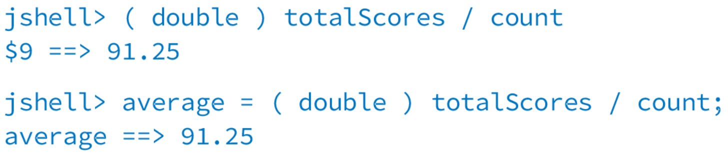


```
jshell> ( double ) ( totalScores / count )
$7 ==> 91.0

jshell> average = ( double ) ( totalScores / count );
average ==> 91.0
```

Description

In our third attempt, we calculate the correct answer by type casting the *totalScores* variable to a *double*, then dividing. The result is that floating-point division is performed and we get the correct answer, 91.25. It doesn’t matter whether we type cast *totalScores* or *count* to a *double* before performing the division. Casting either to a *double* forces floating-point division. Casting has higher precedence than division.



```
jshell> ( double ) totalScores / count
$9 ==> 91.25

jshell> average = ( double ) totalScores / count;
average ==> 91.25
```

Description

CODE IN ACTION

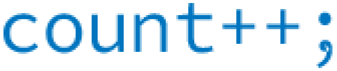
2.3.8 Shortcut Operators

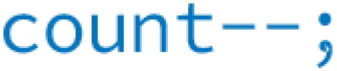
A common operation in programming is adding 1 to a number - (**incrementing**) or subtracting 1 from a number (**decrementing**). For example, if we want to count how many data items the user enters, every time we read another data item, we could add 1 to a count variable.

Because incrementing or decrementing a value is so common in programming, Java provides shortcut operators to do this: ++ and −−. (Note that there are no spaces between the two plus and minus signs.) The statement



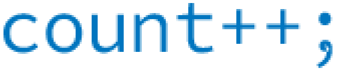
```
count++;
```

adds 1 to the value of *count*, and the statement



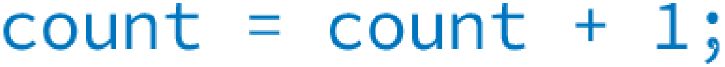
```
count--;
```

subtracts 1 from the value of *count*. Thus,



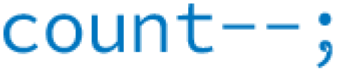
```
count++;
```

is equivalent to



```
count = count + 1;
```

and



```
count--;
```

is equivalent to

```
count = count - 1;
```

Both of these operators have **prefix** and **postfix** versions. The prefix versions precede the variable name (`++a` or `--a`) whereas the postfix versions follow the variable name (`a++` or `a--`). Both increment or decrement the variable. If they are used as a single, atomic statement (as in the preceding statements), there is no difference between the two versions. So

```
a++;
```

is functionally equivalent to

```
++a;
```

and

```
a--;
```

is functionally equivalent to

```
--a;
```

However, if they are used inside a more complex expression, then they differ as follows. The prefix versions increment or decrement the variable first, then the new value of the variable is used in evaluating the expression. The postfix versions increment or decrement the variable after the old value of the variable is used in the expression.

Example 2.10 illustrates this difference.

Example 2.10 Prefix and Postfix Increment Operators

```java
1  /* ShortcutOperators Class
2     Anderson, Franceschi
3  */
4
5  public class ShortcutOperators
6  {
7    public static void main( String [ ] args )
8    {
9      int a = 6;
10     int b = 2;
11
12     System.out.println( "At the beginning, a is " + a );
13     System.out.println( "Increment a with prefix notation: " + ++a );
14     System.out.println( "In the end, a is " + a );
15
16     System.out.println( "\nAt the beginning, b is " + b );
17     System.out.println( "Increment b with postfix notation: " + b++ );
18     System.out.println( "In the end, b is " + b );
19   }
20 }
```

Description

Lines 9 and 10 declare and initialize two *int* variables, *a* and *b*, to 6 and 2, respectively. In order to illustrate the effect of both the prefix and postfix increment operators, we output their original values at lines 12 and 16. At line 13, we use the prefix increment operator to increment *a* inside an output statement; *a* is incremented before the output statement is executed, resulting in the output statement using the value 7 for *a*. At line 17, we use the postfix increment operator to increment *b* inside an output statement; *b* is incremented after the output statement is executed, resulting in the output statement using the value 2 for *b*. Lines 14 and 18 simply output the values of *a* and *b* after the prefix and postfix operators were used at lines 13 and 17. **Figure 2.8** shows the output of this example.

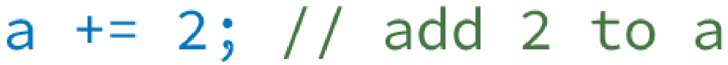
Figure 2.8 Output of Example 2.10

Description

Another set of shortcut operators simplify common calculations that change a single value. For example, the statement

```java
a = a + 2: // add 2 to a
```

can be simplified as



```
a += 2; // add 2 to a
```

The value added to the target variable can be a variable name or a larger expression.

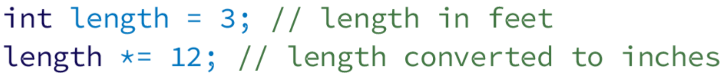
The shortcut addition operator (+=) is a single operator; there are no spaces between the 1 and the 5. Also, be careful not to reverse the order of the operators. For example, in the following statement, the operators are reversed, so the compiler interprets the statement as “assign positive 2 to a.”

COMMON ERROR TRAP

No spaces are allowed between the arithmetic operator (1) and the equal sign. Note also that the sequence is 15, not 51.

```
a =+ 2 ; // Incorrect! Assigns positive 2 to a
```

Java provides shortcut operators for each of the basic arithmetic operations: addition, subtraction, multiplication, division, and modulus. These operators are especially useful in performing repetitive calculations and in converting values from one scale to another. For example, to convert feet to inches, we multiply the number of feet by 12. So we can use the *5 shortcut operator:



```
int length = 3; // length in feet
length *= 12; // length converted to inches
```

Description

Converting from one scale to another is a common operation in programming. For example, earlier in the chapter we converted quarters, dimes, and nickels to pennies. We might also need to convert hours to seconds, feet to meters, or Fahrenheit temperatures to Celsius.

Example 2.11 demonstrates each of the shortcut arithmetic operators. The output is shown in **Figure 2.9**.

Example 2.11 Shortcut Arithmetic Operators

```java
/* Shortcut Arithmetic Operators
   Anderson, Franceschi
*/

public class ShortcutArithmeticOperators
{
  public static void main( String [ ] args )
  {
    int a = 5;
    System.out.println( "a is " + a );

    a += 10;      // a = a + 10;
    System.out.println( "\nAfter a += 10; a is " + a );

    a -= 3;       // a = a - 3;
    System.out.println( "\nAfter a -= 3; a is " + a );

    a *= 2;       // a = a * 2;
    System.out.println( "\nAfter a *= 2; a is " + a );

    a /= 6;       // a = a / 6;
    System.out.println( "\nAfter a /= 6; a is " + a );

    a %= 3;       // a = a % 3;
    System.out.println( "\nAfter a %= 3; a is " + a );
  }
}
```

Description

Figure 2.9 Output of Example 2.11

Description

Table 2.12 summarizes the shortcut operators, and **Table 2.13** shows where the shortcut operators fit into the order of operator precedence.

Shortcut Operators

Shortcut Operator	**Example**	**Equivalent Statement**
+ +	a + +; or + + a;	a = a + 1;
– –	a– –; or – –a;	a = a – 1;
+ =	a + = 3;	a = a + 3;

– =	a – = 10;	a = a – 10;
* =	a *= 4;	a = a * 4;
/ =	a / = 7;	a = a / 7;
% =	a % = 10;	a = a % 10;

Description

Order of Operator Precedence

Operator Hierarchy	**Order of Same-Statement Evaluation**	**Operation**
( )	left to right	parentheses for explicit grouping
+ +, – –	**right to left**	**shortcut postincrement**
+ +, – –	**right to left**	**shortcut preincrement**

2.4 Programming Activity 2: Temperature Conversion

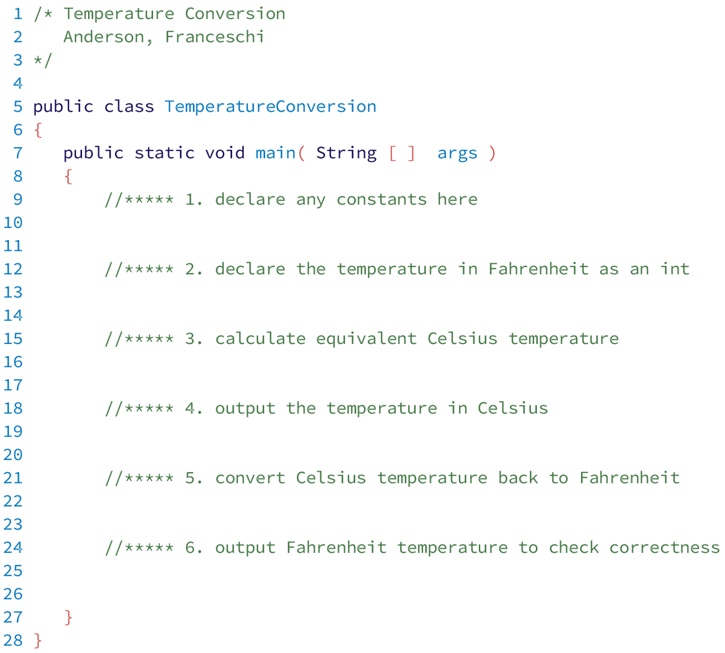
For this Programming Activity, you will write a program to convert a temperature in Fahrenheit to Celsius. The conversion formula is the following:

$$T_c = 5/9\ (T_f - 32)$$

where T_c is the temperature in Celsius and T_f is the temperature in Fahrenheit, and 32 is the freezing point of water.

Locate the *TemperatureConversion.java* source file found in this chapter's Programming Activity 2 folder in the supplied code files. Copy the file to your computer. The source code is shown in **Example 2.12**.

Example 2.12 TemperatureConversion.java



```java
/* Temperature Conversion
   Anderson, Franceschi
*/

public class TemperatureConversion
{
   public static void main( String [ ]  args )
   {
       //***** 1. declare any constants here

       //***** 2. declare the temperature in Fahrenheit as an int

       //***** 3. calculate equivalent Celsius temperature

       //***** 4. output the temperature in Celsius

       //***** 5. convert Celsius temperature back to Fahrenheit

       //***** 6. output Fahrenheit temperature to check correctness

   }
}
```

Description

Open the *TemperatureConversion.java* source file. You'll notice that the class already contains a class name and the *main* method. Your job is to fill in the blanks.

To verify that your code produces the correct output, add code to convert your calculated Celsius temperature back to Fahrenheit and compare that value to the original Fahrenheit temperature. The formula for converting Celsius to Fahrenheit is:

$$T_f = 9/5 * T_c + 32$$

Before writing this program, you need to design a plan of attack. Ask yourself:

- What data do I need to define?
- What calculations should I make?
- What is the output of the program?

- How do I select data values so they will provide good test data for my code?

Choose any input value for the Fahrenheit temperature. After you write the program, try changing the original temperature value, recompiling and rerunning the program to verify that the temperature conversion works for multiple input values.

DISCUSSION QUESTIONS

1. How did you change the expression 5 / 9 so that the value was not 0?
2. What constant(s) did you define?
3. What data type did you use for the Celsius temperature? Why?

CHAPTER REVIEW

2.5 Chapter Summary

- Java programs consist of at least one class.
- Identifiers are symbolic names for classes, methods, and data. Identifiers should start with a letter and may contain any combination of letters and digits, but no spaces. The length of an identifier is essentially unlimited. Identifier names are case sensitive.
- Java's reserved words cannot be used as identifiers.
- The basic building block of a Java program is the statement. A statement is terminated with a semicolon and can span several lines.
- Any amount of white space is permitted between identifiers, Java keywords, operands, operators, and literals. White space characters are the space, tab, newline, and carriage return.
- A block, which consists of 0, 1, or more statements, starts with a left curly brace and ends with a right curly brace. Blocks can be used anywhere in the program that a statement is legal.
- Comments are ignored by the compiler. Block comments are delineated by /* and */. Line comments start with // and continue to the end of the line.
- Java supports eight primitive data types: *double*, *float*, *long*,

int, *short*, *byte*, *char*, and *boolean*.

- The jshell utility, part of the JDK, is a tool that allows us to type code and see the immediate result without compiling.
- Variables must be declared before they are used. Declaring a variable is specifying the data item's identifier and data type. The syntax for declaring a variable is: `datatype identifier1, identifier2, . . .;`
- Begin variable names with a lowercase letter. If the variable name consists of more than one word, begin each word after the first with a capital letter. Do not put spaces between words.
- An integer data type is one that evaluates to a positive or negative whole number. Java recognizes four integer data types: *int*, *short*, *long*, and *byte*.
- Floating-point data types store numbers with fractional parts. Java supports two floating-point data types: the single-precision type *float*, and the double-precision type *double*.
- The *char* data type stores one Unicode character. Because Unicode characters are encoded as unsigned numbers using 16 bits, a *char* variable is stored in two bytes of memory.
- The *boolean* data type can store only two values, which are expressed using the Java reserved words *true* and *false*.
- The assignment operator (5) is used to give a value to a variable.
- To assign an initial value to a variable, use this syntax when declaring the variable:

```
dataType variable1 = initialValue1;
```

- Literals can be used to assign initial values or to reassign the value of a variable.
- Constants are data items whose value, once assigned, cannot be changed. Data items that we know should not change throughout the execution of a program should be declared as a constant, using this syntax:

```
final dataType CONSTANT_IDENTIFIER = initialValue;
```

Description

- Constant identifiers, by convention, are composed of all capital letters with underscores separating words.
- An expression consists of operators and operands that evaluate to a single value.
- The value of an expression can be assigned to a variable or constant, which must be a data type compatible with the value of the expression and cannot be a constant that has been assigned a value already.
- Java provides binary operators for addition, subtraction, multiplication, division, and modulus.
- Calculation of the value of expressions follows the rules of operator precedence.
- Integer division truncates any fractional part of the quotient.
- When an arithmetic operator is invoked with operands that are of different primitive types, the compiler temporarily converts, or promotes, one or both of the operands.
- An expression or a variable can be temporarily cast to a different data type using this syntax:

```
(dataType) ( expression )
```

Description

- Shortcut operators + + and – – simplify incrementing or decrementing a value by 1. The prefix versions precede the variable name and increment or decrement the variable, then use its new value in evaluation of the expression. The postfix versions follow the variable name and increment or decrement the variable after using the old value in the expression.
- Java provides shortcut operators for each of the basic arithmetic operations: addition, subtraction, multiplication, division, and modulus.

2.6 Exercises, Problems, and Projects

2.6.1 Multiple Choice Exercises

1. What is the valid way to declare an integer variable named *a*? (Check all that apply.)
    - `int a;`
    - `a int ;`
    - `integer a;`
5. Which of the following identifiers are valid?
    - `a`

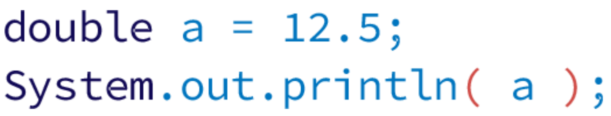
- `sales`
- `sales&profit`
- `int`
- `inter`
- `doubleSales`
- `TAX_RATE`
- `1stLetterChar`
- `char`

15. Given three declared and initialized *int* variables *a*, *b*, and *c*, which of the following statements are valid?

    - `a = b;`
    - `a = 67;`
    - `b = 8.7;`
    - `a + b = 8;`
    - `a * b = 12;`
    - `c = a – b;`
    - `c = a / 2.3;`
    - `boolean t = a;`
    - `a /= 4;`
    - `a += c;`

2.6.2 Reading and Understanding Code

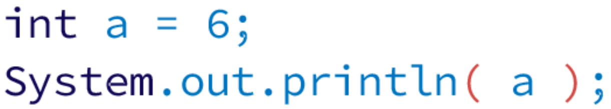
1. What is the output of this code sequence?



```
double a = 12.5;
System.out.println( a );
```

Description

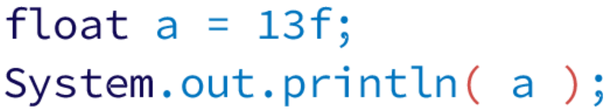
2. What is the output of this code sequence?



```
int a = 6;
System.out.println( a );
```

Description

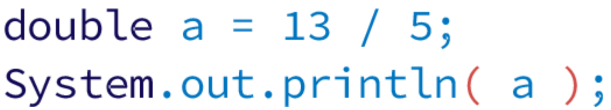
3. What is the output of this code sequence?



```
float a = 13f;
System.out.println( a );
```

Description

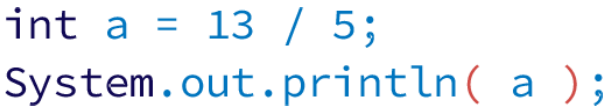
4. What is the output of this code sequence?



```
double a = 13 / 5;
System.out.println( a );
```

Description

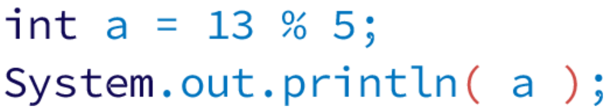
5. What is the output of this code sequence?



```
int a = 13 / 5;
System.out.println( a );
```

Description

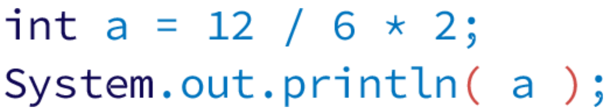
6. What is the output of this code sequence?



```
int a = 13 % 5;
System.out.println( a );
```

Description

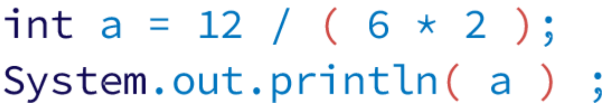
7. What is the output of this code sequence?



```
int a = 12 / 6 * 2;
System.out.println( a );
```

Description

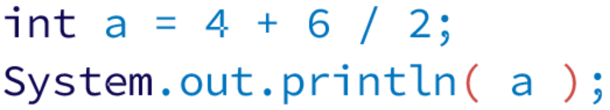
8. What is the output of this code sequence?



```
int a = 12 / ( 6 * 2 );
System.out.println( a ) ;
```

Description

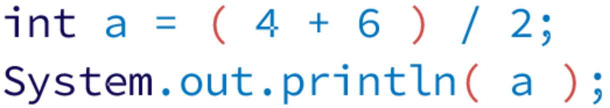
9. What is the output of this code sequence?



```
int a = 4 + 6 / 2;
System.out.println( a );
```

Description

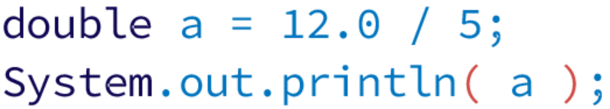
10. What is the output of this code sequence?



```
int a = ( 4 + 6 ) / 2;
System.out.println( a );
```

Description

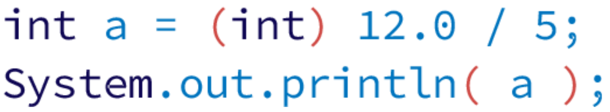
11. What is the output of this code sequence?



```
double a = 12.0 / 5;
System.out.println( a );
```

Description

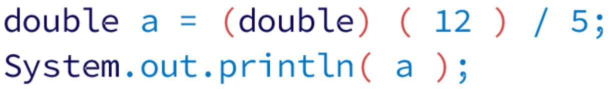
12. What is the output of this code sequence?



```
int a = (int) 12.0 / 5;
System.out.println( a );
```

Description

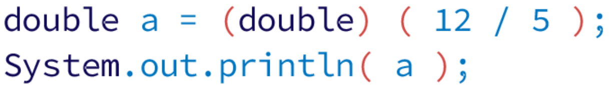
13. What is the output of this code sequence?



```
double a = (double) ( 12 ) / 5;
System.out.println( a );
```

Description

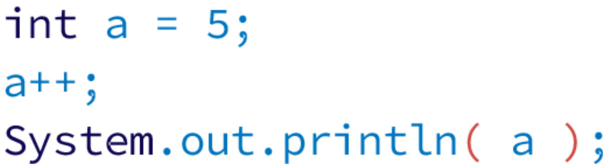
14. What is the output of this code sequence?



```
double a = (double) ( 12 / 5 );
System.out.println( a );
```

Description

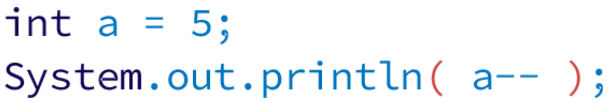
15. What is the output of this code sequence?



```
int a = 5;
a++;
System.out.println( a );
```

Description

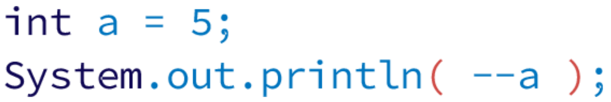
16. What is the output of this code sequence?



```
int a = 5;
System.out.println( a-- );
```

Description

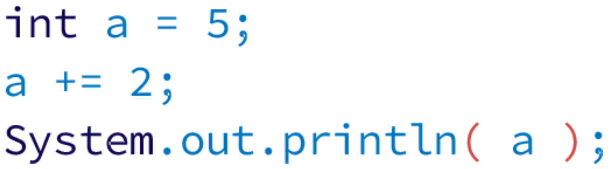
17. What is the output of this code sequence?



```
int a = 5;
System.out.println( --a );
```

Description

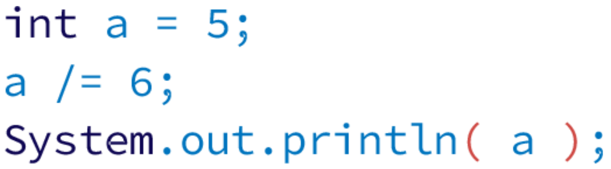
18. What is the output of this code sequence?



```
int a = 5;
a += 2;
System.out.println( a );
```

Description

19. What is the output of this code sequence?



```
int a = 5;
a /= 6;
System.out.println( a );
```

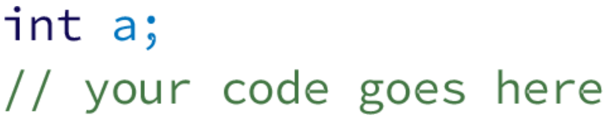
Description

2.6.3 Fill In the Code

1. Write the code to declare a *float* variable named *a* and assign *a* the value 34.2.

```
// your code goes here
```

2. Write the code to assign the value 10 to an *int* variable named *a*.



```
int a;
// your code goes here
```

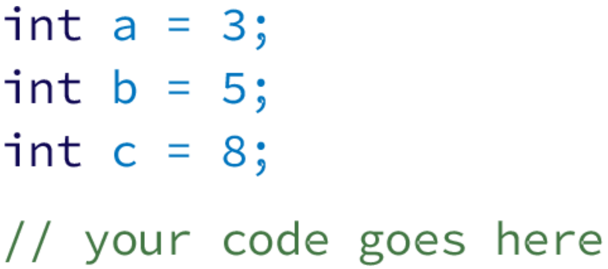
3. Write the code to declare a *boolean* variable named *a* and assign *a* the value *false*.

```
// your code goes here
```

4. Write the code to declare a *char* variable named *a* and assign *a* the character B.

```
// your code goes here
```

5. Write the code to calculate the total of three *int* variables *a*, *b*, and *c* and print the result.

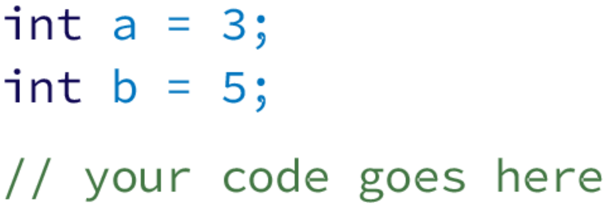


```
int a = 3;
int b = 5;
int c = 8;

// your code goes here
```

Description

6. Write the code to calculate the average of two *int* variables *a* and *b* and print the result. The average should be printed as a floating-point number.

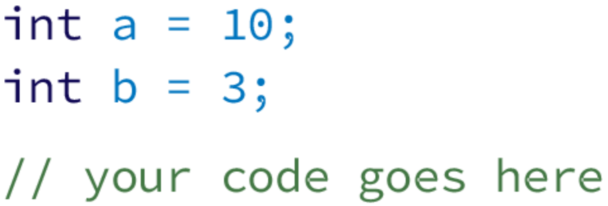


```
int a = 3;
int b = 5;

// your code goes here
```

Description

7. Write the code to calculate and print the remainder of the division of two *int* variables with the values 10 and 3 (the value printed will be 1).

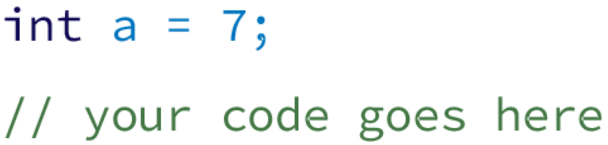


```
int a = 10;
int b = 3;

// your code goes here
```

Description

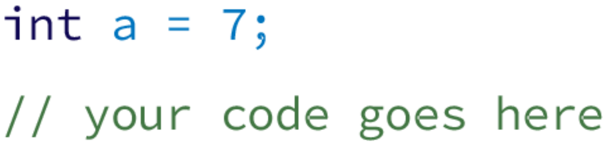
8. This code increases the value of a variable *a* by 1, using the shortcut increment operator.



```
int a = 7;

// your code goes here
```

9. This code multiplies the value of a variable *a* by 3, using a shortcut operator.



```
int a = 7;

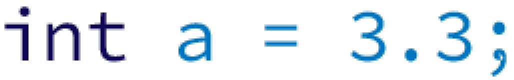
// your code goes here
```

10. Assume that we have already declared and initialized two *int* variables, *a* and *b*. Convert the following sentences to legal Java expressions and statements.

    - b gets a plus 3 minus 7
    - b gets a times 4
    - a gets b times b
    - a gets b times 3 times 5
    - b gets the quotient of the division of a by 2
    - b gets the remainder of the division of a by 3

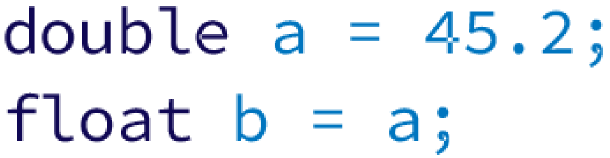
2.6.4 Identifying Errors in Code

1. Where is the error in this code sequence?



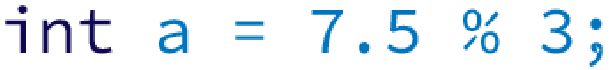
```
int a = 3.3;
```

2. Where is the error in this code sequence?



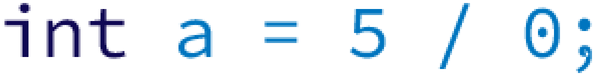
```
double a = 45.2;
float b = a;
```

3. Where is the error in this code sequence?



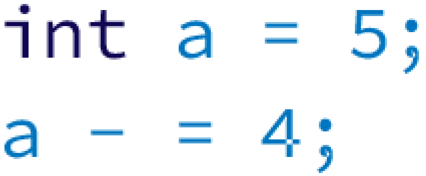
```
int a = 7.5 % 3;
```

4. What would happen when this code sequence is compiled and executed?



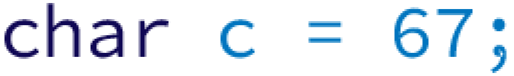
```
int a = 5 / 0;
```

5. Where is the error in this code sequence?



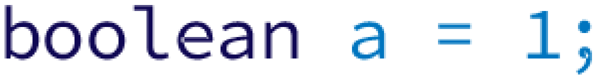
```
int a = 5;
a - = 4;
```

6. Is there an error in this code sequence? Explain.



```
char c = 67;
```

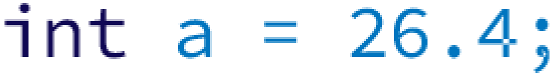
7. Is there an error in this code sequence? Explain.



```
boolean a = 1;
```

2.6.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

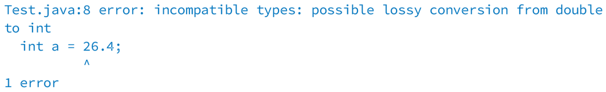
1. You coded the following on line 8 of class *Test.java*:



```
int a = 26.4;
```

Description

When you compile, you get the following message:



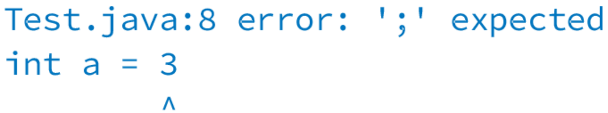
```
Test.java:8 error: incompatible types: possible lossy conversion from double
to int
  int a = 26.4;
          ^
1 error
```

Explain what the problem is and how to fix it.

2. You coded the following on line 8 of class *Test.java*:

```
int a = 3
```

When you compile, you get the following message:

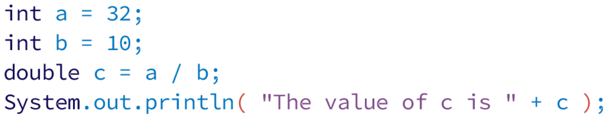


```
Test.java:8 error: ';' expected
int a = 3
         ^
```

Description

Explain what the problem is and how to fix it.

3. You coded the following in class *Test.java*:



```
int a = 32;
int b = 10;
double c = a / b;
System.out.println( "The value of c is " + c );
```

Description

The code compiles properly and runs, but the result is not what you expected. The output is

```
The value of c is 3.0
```

You expected the value of *c* to be 3.2. Explain what the problem is and how to fix it.

4. You coded the following in class *Test.java*:

```
int a = 5;
a =+ 3;
System.out.println( "The value of a is " + a );
```

Description

The code compiles properly and runs, but the result is not what you expected. The output is

```
The value of a is 3
```

You expected the value of *a* to be 8. Explain what the problem is and how to fix it.

2.6.6 Write a Short Program

1. Write a program that calculates and outputs the square of each integer from 1 to 9.
2. Write a program that calculates and outputs the average of integers 1, 7, 9, and 34.
3. Write a program that outputs the following:

```
****
```

2.6.7 Programming Projects

1. Write a program, not using a text block, that prints the letter X composed of asterisks (*). Your output should look like this:

```
*   *
 * *
  *
 * *
*   *
```

Description

2. Write a program, using a text block, that prints the letter X composed of asterisks (*). Your output should look like this:

```
*   *
 * *
  *
 * *
*   *
```

Description

3. Write a program that converts 10, 50, and 100 kilograms to pounds (1 lb = 0.454 kg).
4. Write a program that converts 2, 5, and 10 inches to millimeters (1 inch = 25.4 mm).
5. Write a program to compute and output the circumference of a circle having a radius of 3.2 inches.

6. Write a program that outputs this *String* :
   $a^3 + b^3 = c^3$

Description

2.6.8 Technical Writing

1. Some programmers like to write code that is as compact as possible, for instance, using the increment (or decrement) operator in the middle of another statement. Typically, these programmers use very few comments in their programs. Discuss whether this is a good idea, keeping in mind that a program “lives” through a certain period of time.
2. Compare the following data types for integer numbers: *int*, *short*, and *long*. Discuss their representation in binary, how much space they take in memory, and the purpose of having these data types available to programmers.

Introduction

Writing computer programs that use classes and objects is called **object-oriented programming**, or **OOP**. Every Java program consists of at least one class.

In this chapter, we'll introduce object-oriented programming as a way to use classes that have already been written. Classes provide services to the program. These services might include writing a message to the program's user, popping up a dialog box, performing some mathematical calculations, formatting numbers, drawing shapes in a window, or many other basic tasks that add a more professional look to even simple programs. The program that uses a class is called the **client** of the class. Thus, in this chapter we will be writing client programs.

One benefit of using a prewritten class is that we don't need to write the code ourselves; it has already been written and tested for us. This means that we can write our client programs more quickly. In other words, we shorten the development time of the program. Using prewritten and pretested classes provides other benefits as well, including more reliable programs with fewer errors.

In this chapter, we'll explore how using prewritten classes can add functionality to our programs.

3.1 Class Basics and Benefits

In Java, classes are composed of data and operations—or functions—that operate on the data. Objects of a class are created using the class as a template, or guide. Think of the class as a generic description, and an object as a specific item of that class. Or you can think of a class as a cookie cutter; the objects of that class are the cookies made with the cookie cutter. For example, a *Student* class might have the following data: name, year, and grade point average. All students have these three data items. We can create an object of the *Student* class by specifying an identifier for the object (for example, *student1*) along with a name, year, and grade point average for a particular student (for example, *Maria Gonzales, Sophomore, 3.5*). The identifier of the object is called the **object reference**. Creating an object of a class is called **instantiating an object**, and the object is called an **instance of the class**. Many objects can be instantiated from one class. There can be many instances of the *Student* class, that is, many *Student* objects can be instantiated from the *Student* class. For example, we could create a second object of the *Student* class, *student2*, with its data as *Mike Smith, Junior, 3.0*.

The data associated with an object of a class are called **instance variables**, or **fields**, and can be variables and constants of any primitive data type (*byte, short, int, long, float, double, char*, and *boolean*), or they can be objects of a class.

The operations for a class, called **methods**, set the values of the data, retrieve the current values of the data, and perform other class-related functions on the data. For example, the *Student* class would provide methods to set the values of the name, year, and grade point average; retrieve the current values of the name, year, and grade point average; and perhaps promote a student to the next year. Invoking a method on an object is called **calling the method**. With a few exceptions, only the methods of a class can directly access or change the instance variables of an object. Programs using the class, such as clients, must call the methods to set or retrieve the values of the instance variables. Together, the fields and methods of a class are called its **members**.

In essence, a class is a new data type, which is created by combining items of Java primitive data types and objects of classes. Just as the primitive data types can be manipulated using arithmetic operators (+, –, *, /, and %), an object can be manipulated by calling the methods of its class.

The data of a class are typically declared to be *private*. In this case, only the methods of the class can change the data of an object, and thus the methods provide a protective layer around the data. In other words, the class **encapsulates** the data, and the methods of the class provide the only interface to set or change the data values from outside the class. The benefit from this encapsulation is that the class methods ensure that only valid values are assigned to an object. For example, a method to set a student's grade point average would accept values only between 0.0 and 4.0.

Let's look at another example of a class. The *String* class, an existing class of the Java library, stores a sequence of characters. An object of the *String* class, *firstName*, could be instantiated with the data value *Jane*. Another object of this class, *lastName*, might be instantiated with the data value *Jones*. Methods of the *String* class provide functionality related to a sequence of characters, such as retrieving the number of characters, converting the characters to uppercase, retrieving a character given its position, retrieving the position of a given character, and so on. Depending on the class, other methods could ensure that only valid values are set for the instance variables of the class. For example, if a class includes an instance variable named *price* that stores the price of an object, methods will ensure that the price is never negative.

Notice that the class names *Student* and *String* begin with a capital letter, and the object names, *student1*, *firstName* and *lastName*, start with a lowercase letter. By convention, class names start with a capital letter. Object names, instance variables, and method names conventionally start with a lowercase letter. Internal words start with a capital letter in class names, object names, variables, and methods.

SOFTWARE ENGINEERING TIP

By convention, class names in Java start with a capital letter. Method names, instance variables, and object names start with a lowercase letter. In all of these names, embedded words begin with a capital letter.

There are many benefits to using classes in a program. Some of the most important benefits include reusability (not only in the current program but also in other programs), encapsulation, and reliability.

A well-written class can be reused in many programs. For example, the *String* class could be used in a program involving country and city names, login name and password, and many more applications that use words. Reusing code is much faster than writing and testing new code. As an added bonus, reusing a tested and debugged class in another program makes the program more reliable.

Further, encapsulation of a class's data and methods helps to isolate operations on the data. This makes it easier to track the source of a bug. For example, when a bug is discovered in an object of the *Student class*, then we know to look for the problem in the methods of the *Student class*, because no other code in our program can directly change the data in a *Student object*.

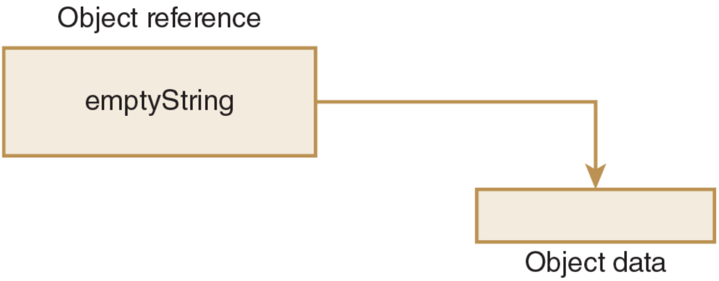
We do not need to know the implementation details of a class in order to use it in our program. The beauty of object orientation is that we don't need to know the implementation of the class; all we need to know is the class **application programming interface (API)**, that is, how to instantiate objects and how to call the methods of the class.

```java
/* A Demonstration of Using Constructors
   Anderson, Franceschi
*/

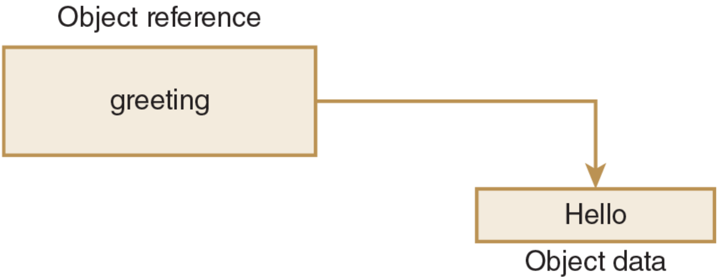
public class Constructors
{
  public static void main( String [ ] args )
  {
    String emptyString;
    emptyString = new String( );

    String greeting;
    greeting = new String( "Hello" );

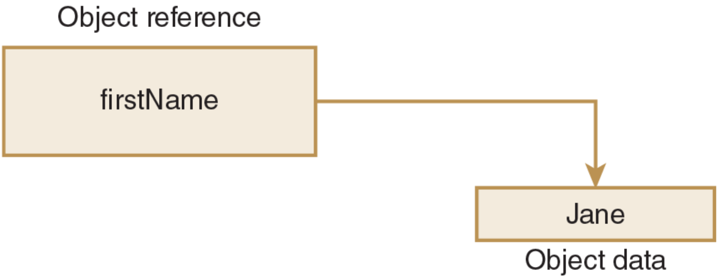
    String firstName = new String( "Jane" );
  }
}
```



Object reference
emptyString
Object data



Object reference
greeting
Hello
Object data



Object reference
firstName
Jane
Object data

3.2 Creating Objects Using Constructors

A class describes a generic template for creating, or instantiating, objects. In fact, an object must be instantiated before it can be used. To understand how to instantiate an object of a class and how to call methods of the class, we must know the API of a class, which the creators of the class make public. **Table 3.1** shows part of the API of the *String* class.

String Class Constructors

String Class Constructor Summary

`String( String str )`	allocates a *String* object with the value of *str*, which can be a *String* object or a *String* literal
`String( )`	allocates an empty *String* object

Description

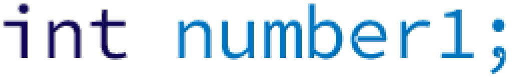
Instantiating an object consists of defining an object reference —which will hold the address of the object in memory—and calling a special method of the class called a **constructor**, which has the same name as the class. The job of the constructor is to assign initial values to the data of the class.

Example 3.1 illustrates how to instantiate objects of the *String* class.

Example 3.1 Demonstrating Constructors

Description

Declaring an object reference is very much like declaring a variable of a primitive type; we specify the data type and an identifier. For example, to declare an integer variable named *number1*, we provide the data type (*int*) and the identifier (*number1*), as follows:



```
int number1;
```

One notable difference in declaring an object reference is that its data type is the class name, not a primitive data type. Here is the syntax for declaring an object reference:

```
ClassName objectReference1, objectReference2, . . .;
```

In Example 3.1, lines 9, 12, and 15 declare object references for a *String* object. *String*, the class name, is the data type, and *emptyString, greeting*, and *firstName* are the object references.

Object references can refer to **any** object of its class. For example, *String* object references can point to any *String* object, but a *String* object reference cannot point to objects of other classes, such as a *Student* object.

Once an object reference has been declared, we instantiate the object using the following syntax:

```
objectReference = new ClassName( argument list );
```

Description

This calls a constructor of the class to initialize the data. The **argument list** consists of a comma-separated list of initial data values to assign to the object. Classes often provide multiple constructors with different argument lists. Depending on which constructor we call, we can accept default values for the data or specify initial values for the data. When we instantiate an object, our argument list—that is, the number of arguments and their data types—must match one of the constructors' argument lists.

Two constructors of the *String* class are shown in Table 3.1. Note that the API of a constructor does not have a return value; nevertheless, constructors implicitly return an object reference to the newly instantiated object. The first constructor, *String( )*, is called the **default constructor**, because its **argument list is empty**. This constructor assigns default values to all data in the object. Thus, in line 10 of Example 3.1, which uses the default constructor, the data for the *emptyString* object is set to the default value for the *String* class, which is an empty character sequence.

We see from Table 3.1 that the second constructor for the *String* class, *String*(*String original*), takes one argument, which evaluates to a *String*.

Lines 13 and 15 of Example 3.1 instantiate *String* objects using the second constructor. In line 13, the argument list tells the constructor to give the value *Hello* to *greeting*. Note that no data types are given when calling the constructors, only the initial values for the data. The data types of the arguments are specified in the API so that the client of the class knows what data types the constructor is expecting for its arguments.

Line 15 also illustrates that we can combine the declaration of the object reference and instantiation of the object in a single statement.

When an object is instantiated, the JVM allocates memory to the new object. The object reference is assigned an address that the JVM uses to find that object in memory. **Figure 3.1** shows the three objects instantiated in Example 3.1.

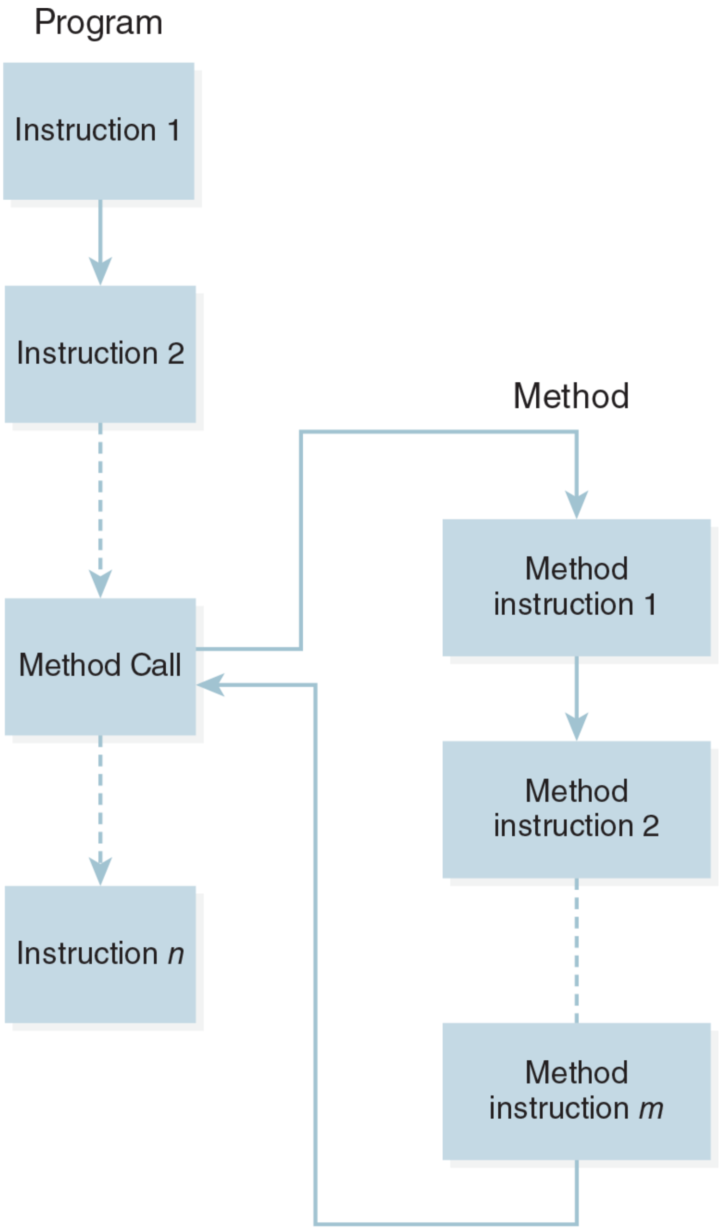
Figure 3.1 Three *String* Objects after Instantiation

Description

It’s important to understand that an object reference and the object data are different: The object reference represents a memory location. Notice in Figure 3.1 that the object references, *emptyString*, *greeting*, and *firstName*, point to the locations of the object data.

COMMON ERROR TRAP

Do not forget to instantiate all objects that your program needs. Objects must be instantiated before they can be used.



Program
Instruction 1
Instruction 2
Method Call
Instruction *n*
Method
Method instruction 1
Method instruction 2
Method instruction *m*

```
There are 12 characters
The index of M is 5
At index 3, we have a d
sub5 is Morning
In caps: GOOD MORNING
greeting is still Good Morning
```

3.3 Calling Methods

Once an object is instantiated, we can use the object by calling its methods. As we mentioned earlier, the authors of classes publish their API so that their clients know what methods are available and how to call those methods.

Figure 3.2 illustrates how calling a class method alters the flow of control in our program. When this program starts running, the JVM executes instruction 1, then instruction 2, then it encounters a method call.

Figure 3.2 Flow of Control of a Method Call

Description

At that point, the JVM **transfers control to the method** and starts executing instructions in the method. When the method finishes executing, the JVM transfers control back to the program immediately after the point the method was called and continues executing instructions in the program.

A class API consists of the method names, their return values, and their parameter lists. **Table 3.2** lists several methods of the *String* class. The parameter list for a method indicates the order and number of arguments to send to the method, along with the data type of each argument. Each item in the parameter list consists of a data type and a name. Formally, we use the term parameter when we talk about the method's API, and we use the term argument to describe a value passed to the method when we call it. Often, these two terms are used interchangeably. The arguments sent to the method can be literals, constants, variables, or any expression that evaluates to the data type specified in the API of the method. For example, the API in Table 3.2 shows that the *indexOf* method takes one argument, which must evaluate to a character value. It also shows that the *charAt* method takes one argument, which must evaluate to an integer value.

String Methods

String Class Method Summary

Return value	Method name and argument list
`int`	`length( )` returns the length of the *String*
`String`	`toUpperCase( )` returns a copy of the *String* with all letters in uppercase
`String`	`toLowerCase( )` returns a copy of the *String* with all letters in lowercase
`char`	`charAt( int index )` returns the character at the position specified by *index*
`int`	`indexOf( String searchString )` returns the index of the beginning of the first occurrence of *searchString* or –1 if *searchString* is not found
`int`	`indexOf( char searchChar )` returns the index of the first occurrence of *searchChar* in the *String* or –1 if *searchChar* is not found
`String`	`substring( int startIndex, int endIndex )` returns a substring of the *String* object beginning at the character at index *startIndex* and ending at the character at index *endIndex – 1*

`String`	`substring( int startIndex )` returns a substring of the *String* object beginning at the character at index *startIndex* and continuing to the end of the *String*
`boolean`	`isBlank( )` returns *true* if this *String* is empty or only contains white space character (including \t or \n)
`String`	`strip( )` returns a copy of this *String* with all the leading and trailing white characters removed (including \t or \n)

Description

A method may or may not return a value, as indicated by a data type, class type, or the keyword **void** in front of the method name. If the method returns a value, then the data type or class type of its **return value** will precede the method's name. For instance, in Table 3.2, the *indexOf* method returns a character value. The *charAt* method returns an integer value. The call to a **value-returning method** can be used in an expression. When the method finishes executing, its return value will replace the method call in the expression. If the keyword *void* precedes the method name, the method does not return a value. Because methods with a *void* return type have no value, they cannot be used in an expression; instead, a method call to a method with a *void* return type is a complete statement.

Another keyword we will see preceding the method call in an API is *public*. This keyword means that any client of the class can call this method. If the keyword *private* precedes the method name, only other methods of that class can call that method. Although we will not formally include the *public* keyword in the API, all the methods we discuss in this chapter are *public*.

To call a method for an object of a class, we use **dot notation**, as follows:

```
objectReference.methodName( argument list )
or
objectReference.methodName( arg1, arg2, arg3, ... )
```

Description

COMMON ERROR TRAP

When calling a method that takes no arguments, remember to include the empty parentheses after the method's name. The parentheses are required even if there are no arguments.

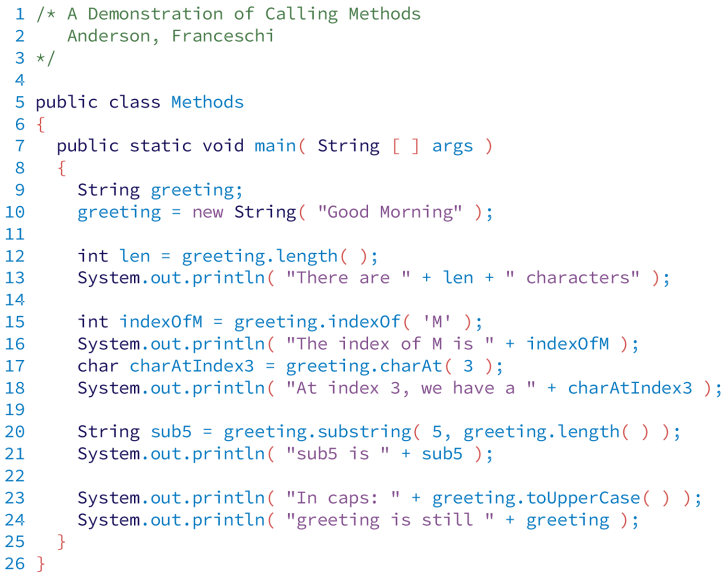
where arg1, arg2, arg3, . . . is the argument list. The object reference is followed immediately by a **dot** (a period), which is followed immediately by the method name. (Later in the chapter, when we call *static* methods, we will substitute the class name for the object reference.) The arguments for the method are enclosed in parentheses.

COMMON ERROR TRAP

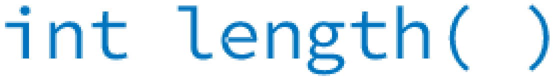
When calling a method, include only values or expressions in your argument list. Including data types in your argument list will cause a compiler error.

Example 3.2 illustrates how to use some methods of the *String* class. At line 12, we call the *length* method with the *greeting* object reference. The API of the *length* method is:

Example 3.2 Calling Methods



```
 1 /* A Demonstration of Calling Methods
 2    Anderson, Franceschi
 3 */
 4
 5 public class Methods
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     String greeting;
10     greeting = new String( "Good Morning" );
11
12     int len = greeting.length( );
13     System.out.println( "There are " + len + " characters" );
14
15     int indexOfM = greeting.indexOf( 'M' );
16     System.out.println( "The index of M is " + indexOfM );
17     char charAtIndex3 = greeting.charAt( 3 );
18     System.out.println( "At index 3, we have a " + charAtIndex3 );
19
20     String sub5 = greeting.substring( 5, greeting.length( ) );
21     System.out.println( "sub5 is " + sub5 );
22
23     System.out.println( "In caps: " + greeting.toUpperCase( ) );
24     System.out.println( "greeting is still " + greeting );
25   }
26 }
```

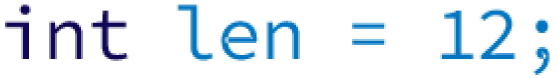


```
int length( )
```

The *length* accepts no parameter; thus, we call it with an empty argument list. It returns an *int*; thus, at line 12, we can assign the value that it returns to an *int* variable, as in:

```
int len = greeting.length( );
```

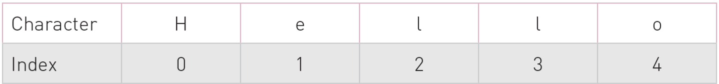
When line 12 is executed, control transfers to the *length* method. When the *length* method finishes executing, the value it returns (*12* in this example) replaces the method call in the statement. The statement effectively becomes:



```
int len = 12;
```

Before discussing the remaining methods in Table 3.2, we need to introduce the concept of **indexes**. Each character in a *String* is assigned an index representing its position within the *String*. The index of the first character is always 0. The index of the second character is always 1, and so on. Therefore, it stands to reason that the index of the last character is always the length of the *String* – 1. The following chart is the *String*

Hello and the indexes of its characters. As we can see, the index of the first letter, *H*, is 0, and the index of the last letter, *o*, is 4, which is one less than the length of the *String* (5).



Character	H	e	l	l	o
Index	0	1	2	3	4

Description

Several of the *String* methods use these indexes to identify which characters within the *String* to process.

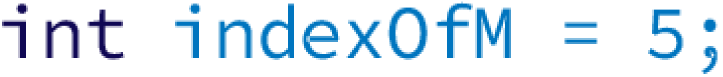
At line 15, we call the *indexOf* method (as discussed later in the chapter, there can be several methods with the same name) with the *greeting* object reference. The API of the *indexOf* method is:

```
int indexOf( char c )
```

The *indexOf* accepts one parameter, a *char*; thus, we must call it with exactly one argument, of type *char*. In this example, we pass the value 'M'. It returns an *int*; thus, at line 15, we can assign the value that it returns to an *int* variable, as in:

```
int indexOfM = greeting.indexOf( 'M' );
```

When line 15 is executed, control transfers to the *indexOf* method. When the *indexOf* method finishes executing, the value it returns (*5* in this example) replaces the method call in the statement. The statement effectively becomes:



```
int indexOfM = 5;
```

At line 20, we call the *substring* method with the *greeting* object reference. The API of the *substring* method is:

```
String substring( int start, int end )
```

The *substring* method accepts two parameters, both *ints*; thus, we must call it with exactly two arguments, of type *int*. In this example, we pass the values *5* and the *int* value returned by greeting.length( ). The *substring* method returns a *String*; thus, at line 20, we can assign the value that it returns to a *String* variable, as in:

```
String sub5 = greeting.substring( 5, greeting.length( ) );
```

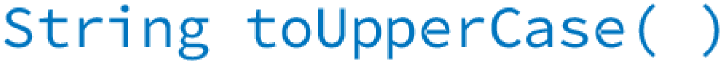
When line 20 is executed, first control transfers to the *length* method. When the *length* method finishes executing, the value it returns (*12* in this example) replaces the method call in the statement. The statement first becomes:

```
String sub5 = greeting.substring( 5, 12 );
```

Control then transfers to the *substring* method, passing the arguments *5* and *12*. When the *substring* method finishes executing, the value it returns (*Morning* in this example) replaces the method call in the statement. The statement becomes:

```
String sub5 = "Morning";
```

At line 23, we call the *toUpperCase* method with the *greeting* object reference.



```
String toUpperCase( )
```

The *toUpperCase* accepts no parameter; thus, we call it with an empty argument list. It returns a *String*; thus, at line 23, we can use the *String* value that it returns in an expression, as in:

```
System.out.println( "In caps: " + greeting.toUpperCase( ) );
```

Description

When line 23 is executed, control transfers to the *toUpperCase* method. When the *toUpperCase* method finishes executing, the value it returns (“GOOD MORNING” in this example) replaces the method call in the statement. The statement effectively becomes:

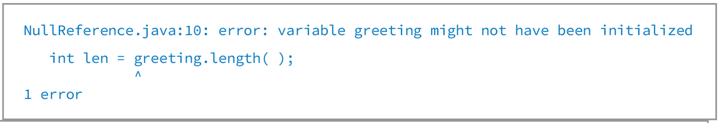
```
System.out.println( "In caps: " + "GOOD MORNING" );
```

Description

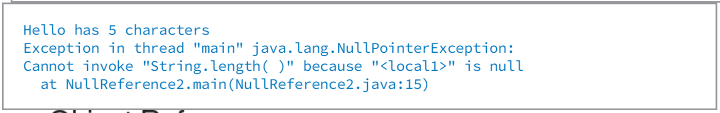
Note that the call to *toUpperCase* returns a copy of *greeting* in uppercase but does not modify the value of *greeting*. **Figure 3.3** shows the output of Example 3.2.

Figure 3.3 Output of Example 3.2

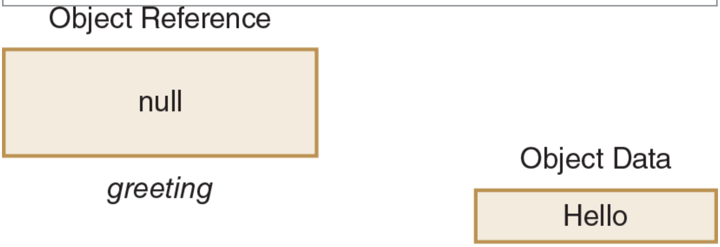
Description



```
NullReference.java:10: error: variable greeting might not have been initialized
   int len = greeting.length( );
             ^
1 error
```



```
Hello has 5 characters
Exception in thread "main" java.lang.NullPointerException:
Cannot invoke "String.length( )" because "<local1>" is null
  at NullReference2.main(NullReference2.java:15)
```



3.4 Using Object References

As we have mentioned, an object reference points to the data of an object. The object reference and the object data are distinct entities. An object can have more than one object reference pointing to it, or an object can have no object references pointing to it.

When an object no longer has an object reference pointing to it, it is marked for **garbage collection**. The **garbage collector**, which is part of the JVM, releases the memory allocated to objects that no longer have an object reference pointing to them.

When an object reference is first declared, but has not yet been assigned to an object, its value is a special literal value, **null**.

If we attempt to call a method using an object reference whose value is *null*, Java generates either a compiler error or a run-time error called an **exception**. The exception is a *NullPointerException* and results in a series of messages printed on the Java console indicating where in the program the *null* object reference was used. Line 10 of **Example 3.3** will generate a compiler error, as shown in **Figure 3.4**, because *greeting* has not been instantiated.

Example 3.3 Attempting to Use a *null* Object

Reference

```java
/* A Demonstration of Trying to Use a Null Object Reference
   Anderson, Franceschi
*/

public class NullReference
{
  public static void main( String [ ] args )
  {
    String greeting;
    int len = greeting.length( );
  }
}
```

Description

Figure 3.4 Compiler Error from Example 3.3

Description

Java does not provide support for explicitly deleting an object. One way to indicate to the garbage collector that our program is finished with an object is to set its object reference to *null*. Obviously, once an object reference has the value *null*, it can no longer be used to call methods.

COMMON ERROR TRAP

Using a *null* object reference to call a method will generate either a compiler error or a *NullPointerException* at run time. Be sure to instantiate an object before attempting to use the object reference.

Example 3.4 shows a *NullPointerException* being generated at run time. Line 9 instantiates the *greeting* object, and lines 10–11 print its number of characters. Line 13 assigns *null* to the object reference, and line 15 attempts to call the *length* method again. As **Figure 3.5** shows, a *NullPointerException* is generated. Notice that the console message indicates the name of the application class (*NullReference2*), the method *main*, and the line number *15*, where the exception occurred. The JVM often prints additional lines in the message, depending on where in our program the error occurred.

Example 3.4 Another Attempt to Use a *null* Object Reference

```
/* A Demonstration of Trying to Use a Null Object Reference
   Anderson, Franceschi
*/

public class NullReference2
{
  public static void main( String [ ] args )
  {
    String greeting = new String( "Hello" );
    int len = greeting.length( );
    System.out.println( greeting + " has " + len + " characters" );

    greeting = null;
    // attempt to use null object reference
    len = greeting.length( );
  }
}
```

Description

Figure 3.5 Output of Example 3.4

Description

Figure 3.6 shows the *greeting* object reference and object data after setting the object reference to *null*.

Figure 3.6 The *greeting* Object Reference Set to *null*

Description

3.5 More on the *String* Class

As we've discussed, Java provides the *char* primitive data type, which stores one character. Almost every program, however, needs a data type that stores more than one character. Programs need to process names, addresses, or labels of many kinds. For example, many programs involve a login procedure where the user has to enter a user ID and a password. The program reads the user ID and password, compares them to values stored in a database, and allows the user to continue only if the user ID and password match the database values.

To handle this type of data, Java provides a *String* class. Because the *String* class is part of the *java.lang* package, it is automatically available to any Java program and we do not need to use the *import* statement. As explained earlier, the *String* class provides several constructors, as well as a number of methods to manipulate, search, and compare *String* objects. In addition, the Java language provides two concatenation operators to combine *String* objects with variables, literals, or other *String* objects.

Example 3.5 shows how to use these tools in a program.

Example 3.5 Demonstrating *String* Methods

```
/* Demonstrating String methods
   Anderson, Franceschi
*/
public class StringDemo
{
  public static void main( String [ ] args )
  {
    String s1 = new String( "OOP in Java " );
    System.out.println( "s1 is: " + s1 );
    String s2 = "is not that difficult. ";
    System.out.println( "s2 is: " + s2 );

    String s3 = s1 + s2; // new String is s1, followed by s2
    System.out.println( "s1 + s2 is: " + s3 );

    System.out.println( "s1 is still: " + s1 ); // s1 is unchanged
    System.out.println( "s2 is still: " + s2 ); // s2 is unchanged

    String empty = new String( );
    System.out.println( "\nThe length of the empty String is "
                        + empty.length( ) );

    String greeting = "Hello"; // instantiate greeting
    char firstChar = greeting.charAt( 0 );
    char lastChar = greeting.charAt( greeting.length( ) - 1 );
    System.out.println( "\nThe first and last characters of "
                        + greeting + " are " + firstChar
                        + " and " + lastChar );

    int indexOfE = greeting.indexOf( 'e' );
    System.out.println( "\nThe index of e is " + indexOfE );
    System.out.println( "The index of l is "
                           + greeting.indexOf( 'l' ) );
    System.out.println( "The index of lo is "
                           + greeting.indexOf( "lo" ) );
    System.out.println( "The index of h is "
                           + greeting.indexOf( 'h' ) );

    System.out.println( "\nThe middle three characters of Hello are "
                           + greeting.substring( 1, 4 ) );
    System.out.println( "All characters of Hello except the first are "
                           + greeting.substring( 1 ) );

    String s4 = "\n\t   \t    \n \t  ";
    System.out.println( "\nIs s4 blank? " + s4.isBlank( ) );
    s4 = s4.strip( );
    System.out.println( "Is s4 now empty? " + s4.isEmpty( ) );
  }
}
```

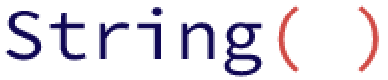
Description

When this program runs, it will produce the output shown in **Figure 3.7**.

Figure 3.7 Output from Example 3.5

Description

The default constructor



```
String( )
```

creates an empty *String*—in other words, a *String* containing no characters. We can add characters to the *String* later. This constructor will come in handy in programs where we build up our output, piece by piece. Line 19 uses the second constructor to instantiate an empty *String* named *empty*. Do not confuse a *String* that has not been instantiated, and therefore is *null*, with a *String* that has been instantiated and is empty. At line 21, we call the *length* method with *empty*. It returns the value *0*, since *empty* has no character.

Additionally, because *Strings* are used so frequently in programs, Java provides special support for instantiating *String* objects without explicitly using the *new* operator. We can simply assign a *String* literal to a *String* object reference. For example, at line 10, we assign a *String* literal to the *s2 String* reference.

Java also provides special support for appending a *String* to the end of another *String* through the **concatenation operator (+)** and the **shortcut version of the concatenation operator (+=)**. This concept is illustrated in Example 3.5. Lines 8–11 declare, instantiate, and print two *String* objects, *s1* and *s2*. Line 13 concatenates *s1* and *s2*, and the resulting *String* is assigned to the *s3 String* reference, which is printed at line 14. Finally, we output *s1* and *s2* again at lines 16 and 17 to illustrate that their values have not changed.

Note that the *String* concatenation operator is the same character as the addition arithmetic operator. In some cases, we need to make clear to the compiler which operator we want to use. For example, this statement uses both the *String* concatenation operator and the addition arithmetic operator:

```
System.out.println( "The sum of 1 and 2 is " + ( 1 + 2 ) );
```

Description

Notice that we put *1 + 2* inside parentheses to let the compiler know that we want to add two *ints* using the addition arithmetic operator (+). The addition will be performed first because of the higher operator precedence of parentheses.

Then it will become clear to the compiler that the other + operator is intended to be a *String* concatenation operator because its operands are a *String* and an *int*.

Example 3.5 also demonstrates some useful methods of the *String* class, which are summarized in Table 3.2.

The *length* Method

The *length* method returns the number of characters in a *String*, including any spaces and punctuation. Sometimes, the number of characters in a user ID is limited, for example, to eight, and this method is useful to ensure that the length of the ID does not exceed the limit.

The *length* method is called using a *String* object reference and the dot operator. As we can see in Table 3.2, the *length* method does not take any arguments and returns an *int*, which contains the number of characters in the *String*. We can output the return value or we can store the return value in an *int* variable. In Example 3.5, at line 21, we call the *length* method inside the output statement. The return value replaces the method call, so the result is that we output the number of characters—in this case 0, as seen in Figure 3.7.

The *charAt* Method

The *charAt* method returns the character at a specified index in a *String*.

One of the uses of this method is for extracting just the first character of a *String*, which might be advantageous when prompting the user for an answer to a question.

For example, we might ask users if they want to play a game again. They can answer “y,” “yes,” or “you bet!” Our only concern is whether the first character is a *y*, so we could use this method to store just the first character of their answer into a *char* variable. Assuming the user’s answer was previously read and stored into a *String* variable named *answerString*, we could use the following statement to extract the first character of *answerString*:

```
char answerChar = answerString.charAt( 0 );
```

Later in this text, when we talk about selection, we will be able to test whether *answerChar* is a *'y'.*

As shown in Table 3.2, the *charAt* method takes one argument, an *int*, which is the index of the character within the *String* to extract. The method returns that character as a *char*. In Example 3.5, at line 24, we call the *charAt* method with an argument of 0 to extract the first character in *greeting* and store the return value in the *char* variable, *firstChar*. At line 25, we extract the last character in *greeting* by calling the *charAt* method with the argument *greeting.length( ) – 1* and store the return value in the *char* variable, *lastChar*. Although in this case we could have sent an argument of *4* and gotten the same result, sending an argument of *length( ) -1* to the *charAt* method will extract the last character of any *String*. We then output both characters (lines 26–28). Note that we assume that *greeting* has at least one character; otherwise, the expression *greeting.length( ) –1* is equal to *-1*, an invalid index.

The *indexOf* Methods

The same method name can be used for several methods, provided that these methods have a different parameter list. The *indexOf* methods are useful for searching a *String* for a specific character or *String*. Table 3.2 shows two versions of this method, one that accepts a single *char* as the argument and one that accepts a *String* as an argument. In either case, the methods return as an *int* the index of the first occurrence of the *char* or the first occurrence of the first character of the *String* if the *String* is found. If the character or *String* is not found, the *indexOf* methods return –1.

In Example 3.5, we use the *indexOf* method to search the *String greeting* for various characters. First, at line 30, we search *greeting* for the character *'e'* and store the returned index in *indexOfE*. When we output that index at line 31, we see in Figure 3.7 that *'e'* was found at index 1. At lines 32–33, we search *greeting* for the letter *'l'* and output the returned index. Notice that *greeting* has two letter *l*s, but the *indexOf* method returns only the index of the first occurrence, which is 2. Then at lines 34–35, we search *greeting* for the *String "lo"*, which the *indexOf* method finds beginning at index 3. Finally, at lines 36–

37, we search *greeting* for the lowercase letter '*h*', which is not in our *String*. We see when outputting the return value that the method returned −1, indicating that the *indexOf* method did not find a lowercase *h* in *greeting*.

The *substring* Methods

The *substring* methods are useful for creating a new *String* from characters in an existing *String*. The *substring* method returns a group of characters, or **substring**, from a *String*. The original *String* is unchanged. Table 3.2 shows two versions of the *substring* method. The first version takes two *int* arguments. The first argument is the index at which to start extracting the characters, and the second argument is the index of the first character not to extract. Thus, the *endIndex* argument is one position past the last character to extract. We know this sounds a little awkward, but setting up the arguments this way actually makes the method easier to use, as we will demonstrate.

In Example 3.5, we create and output a new *String* containing the middle three characters of *greeting* (lines 39–40). The first argument specifies that the new *String* should start with the character at index 1, which is an '*e*', and the *String* should include all succeeding characters up to but not including the character at index 4. The result is a *String* containing "*ell*".

The second version of the *substring* method is convenient for extracting all characters in a *String* from one position to the end of the *String*. This version of *substring* takes only one *int* argument, which is the index at which to start collecting characters. The returned *String* will consist of all characters starting at *startIndex* and continuing to the end of the *String*. We call this version at lines 41–42, where we extract and output all characters in *greeting* except the first.

The *isBlank* and *strip* Methods

The *isBlank* method is useful to check if a *String* does not contain any character other than white space characters (including tabs and newline characters). We can use the *strip* method to delete all the leading and trailing white space characters. We demonstrate them at lines 44–47.

String Processing

With the popularity of large search engines and Big Data, the ability to find, extract, and reformat information in a *String* of characters is becoming an important part of computer science. We call this **string processing**. For example, using the *String* methods we have just discussed, we can write an application to extract and format a first and last name from a *String*. Assume we know that a *String* contains a name in this format:

```
<lastname>, <firstname>
```

that is, with the last name first, followed by a comma and a space, then the first name.

Our job is to produce a *String* in this format:

```
<Firstname> <Lastname>
```

with a space separating the first and last names and with the first character of each name capitalized and all other letters in lowercase.

Example 3.6 shows the code to accomplish this, and its output is shown in **Figure 3.8**. In this example, we have hard-coded the name in the *String invertedName* (line 8) to be: “lincoln, abraham” but the code we write needs to work for any name in this format.

Example 3.6 ***StringProcessing.java***

```java
/* Demonstrating String Processing
   Anderson, Franceschi
*/
public class StringProcessing
{
  public static void main( String [ ] args )
  {
    String invertedName = "lincoln, abraham";

    int comma = invertedName.indexOf( ',' ); // find the comma
    System.out.println( "\nThe index of ',' in \""
                        + invertedName + "\" is " + comma );

    // last name: extract all characters before the comma
    String lastName = invertedName.substring( 0, comma );
    System.out.println( "The last name is " + lastName );

    // first name: extract all characters after the space
    String firstName = invertedName.substring( comma + 2 );
    System.out.println( "The first name is " + firstName );

    // convert the first letter of each name to uppercase
    String firstNameStart = firstName.substring( 0, 1 );
    firstNameStart = firstNameStart.toUpperCase( );
    String firstNameRemainder = firstName.substring( 1 );
    firstNameRemainder = firstNameRemainder.toLowerCase( );
    firstName = firstNameStart + firstNameRemainder;

    String lastNameStart = lastName.substring( 0, 1 );
    lastNameStart = lastNameStart.toUpperCase( );
    String lastNameRemainder = lastName.substring( 1 );
    lastNameRemainder = lastNameRemainder.toLowerCase( );
    lastName = lastNameStart + lastNameRemainder;

    String fullName = firstName + " " + lastName;
    System.out.println( "\nThe formatted full name is "
                           + fullName );
  }
}
```

Description

Figure 3.8 The Output of Example 3.6

Description

REFERENCE POINT

You can read more about the *String* class on Oracle's Java website *www.oracle.com/technetwork/java*.

Let's look at the characters and indexes of this *String*. (Again, this is just one example. We are writing code to work with any name in this format.)

Description

Let's begin by extracting the last name. We know the last name starts at the beginning of the *String* and ends at the character before the comma, so we need to find the comma. As we have seen, the *indexOf* method allows us to search for the location of a character. At line 10, we call the *indexOf* method, sending it a comma as the search argument, and storing the return value in the *int* variable, *indexOfComma*. We output the *indexOfComma* at lines 11–12 to verify that we have indeed found the comma at index 7.

Description

We then use the *substring* method to extract all the characters from the first character up to, **but not including**, the location of the comma. Our two arguments, then, are 0 as the start index, and *indexOfComma* as the end index. At line 16, we output the extracted last name.

Description

Next, we want to extract the first name. Looking at our inverted name above, we see that the first name starts at the character after the space (index 9 in this case) and continues to the end of the *String*. We could either search for the space, or we could specify the starting index for the first name as an offset from the location of the comma that we have already found. Let's do the latter.

Because we want to extract all characters starting two positions after the comma until the end of the *String*, we can use the version of the *substring* method that accepts one argument. At line 19, we call the *substring* method with the argument *indexOfComma + 2*. This will extract all characters from index 9 to the end of *invertedName*. We output the returned *String*, *firstName*, at line 20.

Description

We have now isolated the first and last names in their own

Strings.

We have one more task to perform: formatting the capitalization of the names. As mentioned, we want to capitalize the first character of each name and make the rest of the characters lowercase. We can do this by dividing each name into two *Strings*: one *String* that will contain just the first character, and the second *String* that will contain the remaining characters. At line 23, we extract just the first character of the first name using the *substring* method with the start index being 0 and the end index being 1. We then capitalize the first letter by calling the *toUpperCase* method on that *String* and storing the return value back into *firstNameStart* (line 24). We again call the *substring* method to extract the remaining characters of the first name (line 25), starting at index 1 and continuing to the end of the *String* and convert that *String* to lowercase by calling the *toLowerCase* method *(line 26)*, storing the result back into the *firstNameRemainder String*. We can now combine those two *Strings* into a formatted first name using the *String* concatenation operator (line 27).

At lines 29–33, we perform the corresponding operations on the last name.

COMMON ERROR TRAP

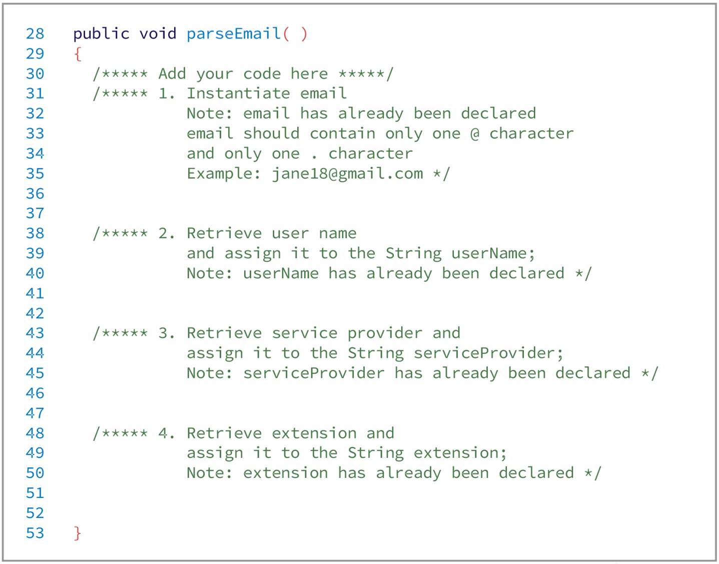
Specifying a negative start index or a start index past the last character of the *String* will generate a *StringIndexOutOfBoundsException*. Specifying a negative end index or an end index greater than the length of the *String* will also generate a *StringIndexOutOfBoundsException*.

At this point, the formatting of the name is complete and we concatenate the first name, a space, and the last name to form the full name (line 35), which we output at lines 36–37.

Description

Try running this example with your name and with a mixture of upper- and lowercase letters to verify that it does indeed work with other names.

When we are calculating indexes and the number of characters to extract, we need to be careful not to specify an index that is not in the *String*, because that will generate a run-time error, *StringIndexOutOfBoundsException*.



```
public void parseEmail( )
{
  /***** Add your code here *****/
  /***** 1. Instantiate email
            Note: email has already been declared
            email should contain only one @ character
            and only one . character
            Example: jane18@gmail.com */

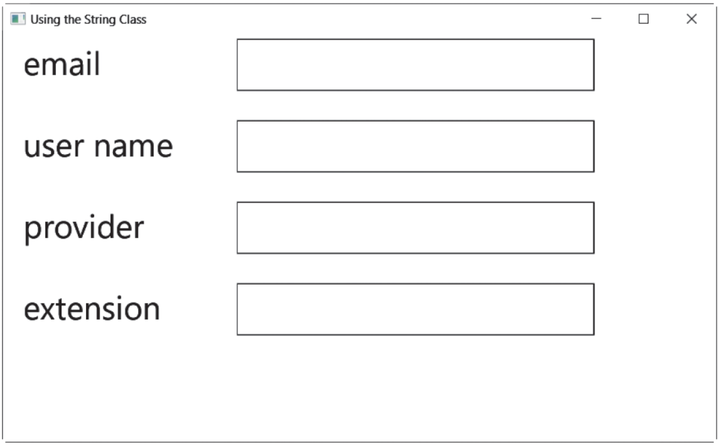
  /***** 2. Retrieve user name
            and assign it to the String userName;
            Note: userName has already been declared */

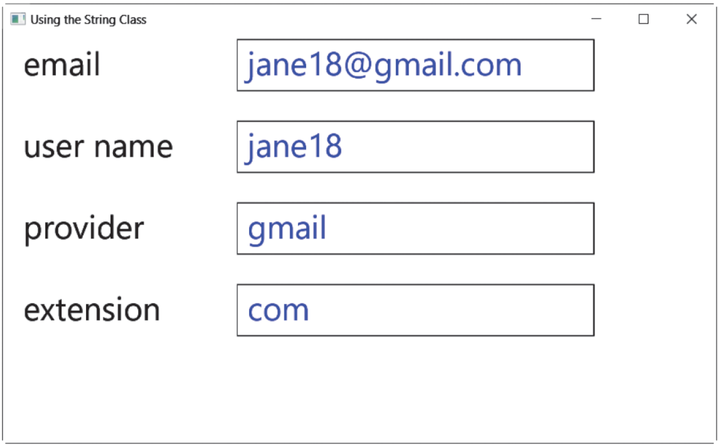
  /***** 3. Retrieve service provider and
            assign it to the String serviceProvider;
            Note: serviceProvider has already been declared */

  /***** 4. Retrieve extension and
            assign it to the String extension;
            Note: extension has already been declared */

}
```

```
private String email; // String object reference
```





email jane18@gmail.com

user name jane18

provider gmail

extension com

3.6 Programming Activity 1: Calling Methods

In this Programming Activity, you'll use a program that parses a *String* storing an email and retrieves the user name, service provider, and extension. You should assume that there is exactly one @ character and one dot (.) character in the email, and that the @character is before the dot (.) character. For example, if the email is *Jane18@gmail.com*, you need to retrieve *Jane18*, *gmail*, and *com*. If the email is *Bob21@government.uk*, you need to retrieve *Bob21*, *government*, and *uk*.

Copy all the files in this chapter's Programming Activity 1 folder in the supplied code files to a folder on your computer. Note that all files should be in the same folder.

Open the *StringDrawing.java* source file. You'll notice that the class already contains some source code. Your job is to fill in the blanks. Search for five asterisks in a row (*****). This will position you to the places in the source code where you will add your code. This section of code is shown in **Figure 3.9**.

Figure 3.9 Partial Listing of *StringDrawing.java*

Description

Notice that line 25 in the source file is a declaration of a *String* object reference, *email*.

You will use this object reference for instantiating an object and for calling the methods of the *String* class.

In the source file, you will see four commented lines that instruct you to instantiate the object or call a method.

To complete the Programming Activity, write the requested code on the lines after the numbered instructions.

Compile *StringDrawing.java* and run *StringApplication* and you will see a window that looks like the one in **Figure 3.10**.

Figure 3.10 Programming Activity 1 Output

Description

Write the code for the remaining instructions, compiling and running the program after completing each task. The program will display your results, as shown in **Figure 3.11**.

Figure 3.11 Finished Programming Activity 1 Output

Description

DISCUSSION QUESTIONS

1. After instructions 6 and 7 have executed, why are the day and month values not changed?
2. How would your code change if we allowed one or more dot (.) characters before the @character in the email (in addition to the dot character after the @character)?

3.7 The Java Class Library

Java provides more than 2,000 predefined classes that we can use to add functionality to our program. In this chapter, in addition to the *String* class, we'll discuss a few commonly used Java classes:

- *Random*, which generates random numbers
- *Scanner*, which provides methods for reading input from the keyboard
- *System* and *PrintStream*, which provide data members and methods for printing data on the Java console
- *DecimalFormat* and *NumberFormat*, which allow us to format numbers for output
- *Math*, which provides methods for performing mathematical operations
- Object wrappers, which provide an object equivalent to primitive data types so they can be used in our program as if they were objects

The Java classes are arranged in **packages**, grouped according to functionality.

Table 3.3 describes some of the Java packages that we will cover in this text. We can find more details on these classes on Oracle's Java website: www.oracle.com/technetwork/java.

Commonly Used Java Packages

Package	**Categories of Classes**
java.lang	Basic functionality common to many programs, such as the *String* class, *Math* class, and object wrappers for the primitive data types

java.text	Classes for formatting numeric output
java.util	The *Scanner* class, the *Random* class, and other miscellaneous classes
java.io	Classes for reading from and writing to files

Description

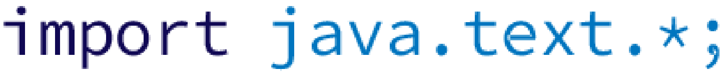
Many of the commonly used classes, such as *String* and *Math*, reside in the *java.lang* package. Any class in the *java.lang* package is automatically available to our program.

To use a class from the Java Class Library that is not in the *java.lang* package, we need to tell the compiler in which package the class resides; in other words, we need to tell the compiler where to find the class. To do this, we include an **import** statement in our program. The *import* statement is inserted at the top of the program after our introductory comments, but before the *class* statement that begins the program.

For example, if we want to use the *DecimalFormat* class to format a floating-point number for output, we would import the *DecimalFormat* class from the *java.text* package as follows:

```
import java.text.DecimalFormat;
```

If we're using more than one class from a package, we can import all those classes we use by replacing the class name with an asterisk, as in the following example:



```
import java.text.*;
```

```
The first price is: $78.67
The second price is: $34.50
The third price is: $0.33
The fourth price is: $3.00
The fifth price is: $100.23
The first average is: 98.0%
The second average is: 98.75%
The time is 05:12:00
millions is 1,234,567
```

3.8 Formatting Output with the *DecimalFormat* Class

In a computer program, numbers represent a real-life entity, for instance, a price or a winning percentage. Floating-point numbers, however, are calculated to many decimal places and, as a result of some computations, can end up with more significant digits than our programs need. For example, the price of an item after a discount could look like 3.46666666666666, when all we really want to display is $3.47; that is, a leading dollar sign and two significant digits after the decimal point. The *DecimalFormat* class allows us to specify the number of digits to display after the decimal point and to add dollar signs, commas, and percentage signs (%) to our output.

The *DecimalFormat* class is part of the *java.text* package, so to use the *DecimalFormat* class, we include the following *import* statement in our program:

```
import java.text.DecimalFormat;
```

Description

We can instantiate a *DecimalFormat* object using a simple constructor that takes a *String* object as an argument. This *String* object represents how we want our formatted number to look when it's printed. The API for that constructor is shown in **Table 3.4**.

A *DecimalFormat* Constructor and the *format* Method

DecimalFormat Class Constructor

`DecimalFormat( String pattern )`

instantiates a *DecimalFormat* object with the output pattern specified in the argument

The *format* Method

Return value	**Method name and argument list**
`String`	`format( double number )` returns a *String* representation of *number* formatted according to the *DecimalFormat* object used to call the method

Description

The pattern that we use to instantiate the *DecimalFormat* object consists of special characters and symbols and creates a "picture" of how we want the number to look when printed. Some of the more commonly used symbols and their meanings are listed in **Table 3.5**.

Special Characters for *DecimalFormat* Patterns

Common Pattern Symbols for a *DecimalFormat* object

Symbol	**Meaning**
0	Required digit. Do not suppress leading or terminating 0s in this position.
#	Optional digit. Do not include a leading or terminating digit that is 0.

.	Decimal point.
,	Comma separator.
$	Dollar sign.
%	Multiply by 100 and append a percentage sign.

Description

Once we have instantiated a *DecimalFormat* object, we format a number by passing it as an argument to the *format* method, shown in Table 3.4. **Example 3.7** demonstrates the use of the *DecimalFormat* patterns and calling the *format* method. The output for this program is shown in **Figure 3.12**.

Example 3.7 Demonstrating the *DecimalFormat* Class

```java
/* Demonstrating the DecimalFormat class
   Anderson, Franceschi
*/

// import the DecimalFormat class from the java.text package
import java.text.DecimalFormat;

public class DemoDecimalFormat
{
  public static void main( String [ ] args )
  {
    // first, instantiate a DecimalFormat object specifying a
    // pattern for currency
    DecimalFormat pricePattern = new DecimalFormat( "$0.00" );

    double price1 = 78.66666666;
    double price2 = 34.5;
    double price3 = .3333333;
    int price4 = 3;
    double price5 = 100.23;

    // then print the values using the pattern
    System.out.println( "The first price is: "
                  + pricePattern.format( price1 ) );
    System.out.println( "\nThe second price is: "
                  + pricePattern.format( price2 ) );
    System.out.println( "\nThe third price is: "
                  + pricePattern.format( price3 ) );
    System.out.println( "\nThe fourth price is: "
                  + pricePattern.format( price4 ) );
    System.out.println( "\nThe fifth price is: "
                  + pricePattern.format( price5 ) );

    // instantiate another new DecimalFormat object
    // for printing percentages
    DecimalFormat percentPattern = new DecimalFormat( "0.0#%" );

    double average1 = .98;
    System.out.println( "\nThe first average is: "
                  + percentPattern.format( average1 ) );
    double average2 = .98748;
    System.out.println( "\nThe second average is: "
                  + percentPattern.format( average2 ) );

    // now instantiate another new DecimalFormat object
    // for printing time as two digits
    DecimalFormat timePattern = new DecimalFormat( "00" );

    int hours = 5, minutes = 12, seconds = 0;
    System.out.println( "\nThe time is "
                  + timePattern.format( hours ) + ":"
                  + timePattern.format( minutes ) + ":"
                  + timePattern.format( seconds ) );

    // now instantiate another DecimalFormat object
    // for printing numbers in the millions.
    DecimalFormat bigNumber = new DecimalFormat( "#,###" );

    int millions = 1234567;
    System.out.println( "\nmillions is "
                  + bigNumber.format( millions ) );
  }
}
```

Description

Figure 3.12 Output from Example 3.7

Description

In Example 3.7, line 14 instantiates the *DecimalFormat* object, *pricePattern*, which will be used to print prices. In the pattern

```
"$0.00"
```

Description

the first character of this pattern is the dollar sign ($), which we want to precede the price. The 0 specifies that there should be at least one digit to the left of the decimal point. If there is no value to the left of the decimal point, then insert a zero. The two 0s that follow the decimal point specify that exactly two digits should be to the right of the decimal point; that is, if more than two digits are to the right of the decimal point, round to two digits; if the last digit is a 0, include the zero, and if there is no fractional part to the number, include two zeroes. Using this pattern, we see that in lines 23–24, *price1* is printed to two decimal places. In lines 25–26, *price2* is printed with a zero in the second decimal place.

In lines 29–30, we print *price4*, which is an integer. The *format* method API calls for a *double* as the argument; however, because all numeric data types can be promoted to a *double*, any numeric data type can be sent as an argument. The result is that two zeroes are added to the right of the decimal point.

COMMON ERROR TRAP

When using a % symbol to *format* a percentage, do not multiply the value by 100. The *format* method will do that for you.

Finally, we use the *pricePattern* pattern to print *price5* in lines 31–32, which needs no rounding or padding of extra digits.

Next, line 36 instantiates a *DecimalFormat* object, *percentPattern*, for formatting percentages to one or two decimal places (`"0.0#%"`). Lines 38–40 and 41–43 define the variables *average1* and *average2* then print them using the *format* method in an output statement. Notice that we do not multiply the averages by 100 before we format the percentage. A % in the pattern signals to the *format* method that it should multiply the value by 100 before converting the number to a *String*.

REFERENCE POINT

You can read more about the *DecimalFormat* class on Oracle's Java website: *www.oracle.com/technetwork/java*.

Line 47 defines another pattern, `"00"`, which is useful for printing the time with colons between the hour, minutes, and seconds. When the time is printed on lines 50–53, the hours, minutes, and seconds are padded with a leading zero, if necessary.

Line 57 defines our last pattern, `"#,###"`, which can be used to insert commas into integer values in the thousands and above. Lines 60–61 print the variable *millions* with commas separating the millions and thousands digits. Notice that the pattern is extrapolated for a number that has more digits than the pattern.

```
The die roll is 2
The random number between 20 and 200 is 117
```

3.9 Generating Random Numbers with the *Random* Class

Random numbers come in handy for many operations in a program, such as rolling dice, dealing cards, timing the appearance of a nemesis in a game, or other simulations of seemingly random events.

There's one problem in using random numbers in programs, however: Computers are **deterministic**. In essence, this means that given a specific input to a specific set of instructions, a computer will always produce the same output. The challenge, then, is generating random numbers while using a deterministic system. Many talented computer scientists have worked on this problem, and some innovative and complex solutions have been proposed.

The *Random* class, which is in the *java.util* package, uses a mathematical formula to generate a sequence of numbers. The constructor generates a **seed** value, which determines where in that sequence the set of *random* numbers will begin. As such, the *Random* class generates numbers that appear to be, but are not truly, random. These numbers are called **pseudorandom** numbers, and they work just fine for our purposes.

Table 3.6 shows a constructor for the *Random* class and a method for retrieving a random integer. The default constructor creates a random number generator using a seed value. Once the random number generator is created, we can ask for a random number by calling the *nextInt* method. Other methods, *nextDouble*, *nextBoolean*, *nextByte*, and *nextLong*, which are not shown in Table 3.6, return a random *double, boolean, byte*, or *long* value, respectively.

A *Random* Class Constructor and the *nextInt*

Method

Random Class Constructor

`Random( )`

creates a random number generator with a seed generated using the system time

The *nextInt* Method

Return value	Method name and argument list
`int`	`nextInt( int number )` returns a random integer ranging from 0 up to, but not including, *number* in uniform distribution

Description

To demonstrate how to use the random number generator, let's take rolling a die as an example. To simulate the roll of a six-sided die, we need to simulate random occurrences of the numbers 1 through 6. If we call the *nextInt* method with an argument of 6, it will return an integer between 0 and 5. To get randomly distributed numbers from 1 to 6, we can simply add 1 to the value returned by the *nextInt* method. Thus, if we have instantiated a *Random* object named *random*, we can generate random numbers from 1 to 6 by calling the *nextInt* method in this way:

```
int die = random.nextInt( 6 ) + 1;
```

In general, assuming than *n* is smaller than *m*, if we want to generate random numbers from *n* to *m*, we should call the *nextInt* method with the number of possible random values (*m* – *n* + 1), and then add the first value of our sequence (*n*) to the returned value. Thus, this statement generates a random number between 10 and 100 inclusive:

```
int randomNumber = random.nextInt( 100 - 10 + 1 ) + 10;
```

Line 18 of **Example 3.8** generates a random number between 20 and 200 inclusive.

Example 3.8 A Demonstration of the *Random* Class

```
/*A demonstration of the Random class
  Anderson, Franceschi
*/
import java.util.Random;

public class RandomNumbers
{
  public static void main( String [ ] args )
  {
    Random random = new Random( );

    // simulate the roll of a die
    int die = random.nextInt( 6 ) + 1;
    System.out.println( "\nThe die roll is " + die );

    // generate a random number between 20 and 200
    int start = 20, end = 200;
    int number = random.nextInt( end - start + 1 ) + start;
    System.out.println( "\nThe random number between " + start
                        + " and " + end + " is " + number );
  }
}
```

Description

REFERENCE POINT

You can read more about the *Random* class on Oracle's Java website: *www.oracle.com/technetwork/java*.

When the *RandomNumbers* program executes, it will produce output similar to **Figure 3.13**. The output will vary from one execution of the program to the next because different random numbers will be generated.

Figure 3.13 Output from Example 3.8

Description

```
Enter your first name > Syed
Your name is Syed

Enter your age as an integer > 21
Your age is 21

Enter your GPA > 3.875
Your GPA is 3.875
```

```
Enter your age as an integer >21
```

```
Enter your middle initial > A
Your middle initial is A
```

```
Enter a sentence > Scanner is useful.
You said: "Scanner is useful."

3.10 Input from the Console Using the *Scanner* Class

As our programs become more complex, we will need to allow the users of our programs to input data. User input can be read into our program in several ways:

- from the keyboard
- from a file
- through a Graphical User Interface (GUI)

The Java Class Library provides classes for all types of data input. In this chapter, we will concentrate on inputting data from the keyboard.

The *Scanner* class provides methods for reading *byte, short, int, long, float, double*, *boolean*, and *String* data types from the keyboard. These methods are shown in **Table 3.7**.

Selected Methods of the *Scanner* Class

A *Scanner* Class Constructor

`Scanner( InputStream dataSource )`

creates a Scanner object that will read from the InputStream dataSource . To read from the keyboard, we will use the predefined InputStream System.in .

Selected Methods of the *Scanner* Class

Return value	Method name and argument list
`byte`	`nextByte( )` returns the next input as a *byte*
`short`	`nextShort( )` returns the next input as a *short*
`int`	`nextInt( )` returns the next input as a *int*
`long`	`nextLong( )` returns the next input as a *long*
`float`	`nextFloat( )` returns the next input as a *long*
`double`	`nextDouble( )` returns the next input as a *double*
`boolean`	`nextBoolean( )` returns the next input as a *boolean*
`String`	`next( )` returns the next token in the input line as a *String*
`String`	`nextLine( )` returns the unread characters of the input line as a *String*

Description

The *Scanner* class is defined in the *java.util* package, so we need to include the following *import* statement:

```
import java.util.Scanner;
```

In order to use the *Scanner* class, we must first instantiate a *Scanner* object and associate it with a data source. We will use the *System.in* input stream, which by default is tied to the keyboard. Thus, our data source for input will be *System.in*. The following statement will instantiate a *Scanner* object named *scan* and associate the keyboard as its data source.

```
Scanner scan = new Scanner( System.in );
```

Once the *Scanner* object has been instantiated, we can use it to call any of the *next*. . . methods to input data from the keyboard. The specific *next*. . . method we call depends on the type of input we want from the user. Each of the *next*. . . methods returns a value from the input stream, that is, the value the user types into the keyboard. We need to assign the return value from the *next*. . . methods to a variable to complete the data input. Obviously, the data type of our variable must match or be compatible with the data type of the value returned by the *next*. . . method.

The *next*. . . methods just perform input. They do not tell the user what data to enter. Before calling any of the *next* methods, therefore, we need to prompt the user for the input we want. We can print a prompt using *System.out.print*, which is similar to using *System.out.println*, except that the cursor remains after the printed text rather than advancing to the next line.

When writing a prompt for user input, we should keep several things in mind. First, our prompt should be specific. If we want the user to enter his or her full name, then our prompt should say just that:

```
Please enter your first and last names.
```

If the input should fall within a range of values, then we should tell the user which values will be valid, for example:

```
Please enter an integer between 0 and 10.
```

We should also keep in mind that users are typically not programmers. It’s important to phrase a prompt using language the user understands. Many times, programmers write a prompt from their point of view, as in this bad prompt:

```
Please enter a String:
```

Users don’t know, and don’t care, about *Strings* or any other data types, for that matter. Users want to know only what they need to enter to get the program to do its job.

When our prompts are clear and specific, the user makes fewer errors and therefore feels more comfortable using our program.

SOFTWARE ENGINEERING TIP

Provide the user with clear prompts for input. Prompts should be phrased using words the user understands and should describe the data requested and any restrictions on input values.

Line 13 of **Example 3.9** prompts the user to enter his or her first name. Line 14 captures the user input and assigns the word entered by the user to the *String* variable *firstName*, which is printed in line 15. Similarly, line 17 prompts for the user’s age, line 18 captures the integer entered by the user and assigns it to the *int* variable *age*, and line 19 outputs the value of *age*. Reading other primitive data types follows the same pattern. Line 21 prompts for the user’s grade point average (a *float* value). Line 22 captures the number entered by the user and assigns it to the *float* variable *gpa*, and line 23 outputs the value of *gpa*.

Example 3.9 Reading from the Keyboard Using *Scanner*

```
/* A demonstration of reading from the keyboard using Scanner
   Anderson, Franceschi
*/

import java.util.Scanner;

public class DataInput
{
  public static void main( String [ ] args )
  {
    Scanner scan = new Scanner( System.in );

    System.out.print( "Enter your first name > " );
    String firstName = scan.next( );
    System.out.println( "Your name is " + firstName );

    System.out.print( "\nEnter your age as an integer > " );
    int age = scan.nextInt( );
    System.out.println( "Your age is " + age );

    System.out.print( "\nEnter your GPA > " );
    float gpa = scan.nextFloat( );
    System.out.println( "Your GPA is " + gpa );
  }
}
```

Description

When this program executes, the prompt is printed on the console and the cursor remains at the end of the prompt. **Figure 3.14** shows the output when these statements are executed and the user enters Syed, presses *Enter*, enters 21, presses *Enter*, and enters 3.875, and presses *Enter* again.

Figure 3.14 Data Input with Example 3.9

Description

SOFTWARE ENGINEERING TIP

End your prompts with some indication that input is expected, and include a trailing space for better readability.

The methods *nextByte, nextShort, nextLong, nextDouble*, and *nextBoolean* can be used with the same pattern as *next, nextInt*, and *nextFloat*.

Note that we end our prompt with a space, an angle bracket, and another space. The angle bracket indicates that we are waiting for input, and the spaces separate the prompt from the input. Without the trailing space, the user's input would immediately follow the prompt, which is more difficult to read, as we show in **Figure 3.15**.

Figure 3.15 Prompt and Input Running Together

As you review Table 3.7, you may notice that the *Scanner* class does not provide a method for reading a single character. To do this, we can use the *next* method, which returns a *String*, then extract the first character from the *String* using the *charAt(0)* method call, as shown in **Example 3.10**. Line 14 inputs a *String* from the user and assigns it to the *String* variable *initialS*, then line 15 assigns the first character of *initialS* to the *char* variable *initial*; *initial* is then printed at line 16 as shown in **Figure 3.16**.

Example 3.10 Using *Scanner* for Character Input

```
 1 /* A demonstration of how to get character input using Scanne
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6
 7 public class CharacterInput
 8 {
 9   public static void main( String [ ] args )
10   {
11     Scanner scan = new Scanner( System.in );
12
13     System.out.print( "Enter your middle initial > " );
14     String initialS = scan.next( );
15     char initial = initialS.charAt( 0 );
16     System.out.println( "Your middle initial is " + initial )
17   }
18 }
```

Description

Figure 3.16 Output of Example 3.10

Description

A *Scanner* object divides its input into sequences of characters called **tokens**, using **delimiters**. The default delimiters are the standard **white space** characters, which among others include the space, tab, and *newline* characters. The complete set of Java white space characters is shown in **Table 3.8**.

Java White Space Characters

Character	**Unicode Equivalents**
space	`\u00A0, \u2007, \u202F`
tab	`\u0009, \u000B`
line feed	`\u000A`
form feed	`\u000C`
carriage return	`\u000D`
file, group, unit, and record separators	`\u001C, \u001D, \u001E, \u001F`

Description

By default, when a *Scanner* object tokenizes the input, it skips leading white space, then builds a token composed of all subsequent characters until it encounters another delimiter. Thus, if we have this code,

```
System.out.print( "Enter your age as an integer > " );
int age = scan.nextInt( );
```

Description

and the user types, for example, three spaces and a tab, *21*, and a newline:

```
<space><space><space><tab>21<newline>
```

Description

then the *Scanner* object skips the three spaces and the tab, starts building a token with the character *2*, then adds the character *1* to the token, and stops building the token when it encounters the *newline* character. Thus, *21* is the resulting token, which the *nextInt* method returns and which is then assigned to the *age* variable.

An input line can contain more than one token. For example, if we prompt the user for his or her name and age, and the user enters the following line, then presses *Enter*:

```
<tab>Jon<space>Olsen,<space>21<space>
```

Description

then, the leading white space is skipped and the *Scanner* object creates three tokens:

- *Jon*
- *Olsen,*
- *21*

Note that commas are not white space, so the comma is actually part of the second token. To input these three tokens, our program would use two calls to the *next* method to retrieve the two *String* tokens and a call to *nextInt* to retrieve the age.

To capture a complete line of input from the user, we use the method *nextLine*. Unlike other *Scanner* methods, the *nextLine* method returns a *String* containing any leading and trailing white space, except for the *newline* character, which is the *nextLine* method's only delimiter. **Example 3.11** shows how *nextLine* can be used in a program. **Figure 3.17** shows a sample run of the program with the user entering data.

Example 3.11 Using the *nextLine* Method

```
/* A demonstration of using Scanner's nextLine method
   Anderson, Franceschi
*/

import java.util.Scanner;

public class InputALine
{
  public static void main( String [ ] args )
  {
    Scanner scan = new Scanner( System.in );

    System.out.print( "Enter a sentence > " );
    String sentence = scan.nextLine( );
    System.out.println( "You said: \"" + sentence + "\"" );
  }
}
```

Description

Figure 3.17 Output of Example 3.11

Description

REFERENCE POINT

You can read more about the *Scanner* class on Oracle's Java website: *www.oracle.com/technetwork/java*.

If the user's input (that is, the next token) is not compatible with the data type of the *next*. . . method call, then an *InputMismatchException* is generated and the program stops. **Figure 3.18** demonstrates Example 3.9 when the program calls the *nextInt* method and the user enters a letter, rather than an integer. It is possible to avoid this exception, and we show how when we discuss looping.

Figure 3.18 An Exception When Input Is Not the Expected Data Type

Description

If the user doesn't type anything when prompted, or if the user types some characters but doesn't press *Enter*, the program will simply wait until the user does press *Enter*.

3.11 Calling *Static* Methods and Using *Static* Class Variables

Classes can also define ***static* methods**, which can be called without instantiating an object. These are also called **class methods**. The API of these methods has the keyword *static* before the return type:

```
static dataType methodName( arg1, arg2, . . . )
```

One reason a class may define *static* methods is to provide some quick, one-time functionality without requiring the client to instantiate an object. For example, as part of a larger calculation, we might want to calculate the square root of a number. Creating an object just to calculate a square root is a waste of memory and processor time. Fortunately, the *Math* class provides a *static* method that finds the square root of a number.

Class, or *static*, methods are invoked using the class name, rather than an object reference, as in the following syntax:

```
ClassName.staticMethodName( argumentList );
```

For example, in this statement:

```
absValue = Math.abs( someNumber );
```

the class name is *Math*, and the *static* method is *abs*, which returns the absolute value of the argument (*someNumber*). We use the class name rather than an object reference, because *static* methods can be called without instantiating an object. Later in this chapter, we will explore some *static* methods of the *Math* class in greater detail.

Because *static* methods can be called without an object being instantiated, *static* methods cannot access the instance variables of the class (because instance variables are object data and exist only after an object has been instantiated). *Static* methods can access ***static* data**, however, and classes often declare *static* data to be used with *static* methods. *Static* data belong to the class, rather than to a particular object, or instance, of the class.

A common use of *static* class variables is to define constants for commonly used values or for parameters for the *static* class methods. For example, the *Math* class defines two *static* constants to facilitate the use of pi and the natural logarithm, e.

Like *static* methods, *static* constants are also accessed using the class name and dot operator, as in this syntax:

```
ClassName.staticConstant
```

Thus, the *static* constant representing the value of pi can be accessed this way:

```
Math.PI
```

At first, this may appear to go against our earlier discussion of encapsulation and the restrictions on clients directly accessing object data. Remember we said that the client needed to use accessor methods (getters) and mutator methods (setters) to access object data. The reasoning behind encapsulation is to protect the object data from corruption by the client. However, in this case, the *static* data is constant, so the client is unable to change it. For the client, directly accessing the class constant is easier and faster than calling a method.

```
Combine the arguments using concatenation
A double: 23.7, and an int: 78

Java is case sensitive: a is different from A

Create a variable and print its value
The grade is 3.81
```

3.12 Using *System.in* and *System.out*

In order to print program output to the screen, we have been using statements like

```
System.out.println( "The value of b is " + b );
```

and

```
System.out.print( "Enter your first name > " );
```

And to instantiate a *Scanner* object, we used this statement:

```
Scanner scan = new Scanner( System.in );
```

It is now time to look at these statements in depth and understand them completely.

System is an existing Java class in the *java.lang* package. One of its fields is a *static* constant, *out*, which represents the Java console by default. Another of its fields is a *static* constant, *in*, which represents the keyboard by default. Because *in* and *out* are *static*, we refer to them using the class name, *System*, and the dot notation:

```
System.out
System.in
```

Table 3.9 shows these *static* constants as well as the *static* *exit* method, which can be used to terminate a program. Calling *exit* at the end of a program is optional. After the last instruction is executed, the program will end in any case. However, the *exit* method of the *System* class can be useful if we want to stop execution at a place other than the usual end of the program.

***Static* Constants of the *System* Class and the *exit* Method**

Constant	**Value**
`in`	*static* constant that represents the standard input stream, by default the keyboard
`out`	*static* constant that represents the standard output stream, by default the Java console

A Useful *System* Method

Return value	**Method name and argument list**
`void`	`exit( int exitStatus )` *static* method that terminates the Java Virtual Machine. A value of 0 for *exitStatus* indicates a normal termination. Any other values indicate an abnormal termination and are used to signal that the program ended because an error occurred.

Description

System.out is an object of the *PrintStream* class, which is also an existing Java class; it can be found in the *java.io* package. The *out* object refers to the **standard output device**, which by default is the Java console.

The methods *print* and *println* belong to the *PrintStream* class and take arguments of any primitive type, a *String*, or an object reference. The only difference between *print* and *println* is that *println* will also print a *newline* character after it writes the output. **Table 3.10** shows some methods of the *PrintStream* class, which can be used with *System.out*.

PrintStream Methods for Use with *System.out*

	Useful *PrintStream* Methods
Return value	**Method name and argument list**
`void`	`print( argument )` prints *argument* to the standard output device. The argument can be any primitive data type, a *String* object, or another object reference.
`void`	`println( argument )` prints *argument* to the standard output device, then prints a *newline* character. The argument can be any primitive data type, a *String*, or another object reference.
`void`	`println( )` prints a *newline* character. This method is useful for skipping a line in the program's output.

Description

Example 3.12 demonstrates various ways to use the *print* and *println* methods:

Example 3.12 Demonstrating the *print* and *println* Methods

```
 1 /* Testing the print and println methods
 2    Anderson, Franceschi
 3 */
 4
 5 public class PrintDemo
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     System.out.println( "Combine the arguments using concatenation" );
10     System.out.println( "A double: " + 23.7 + ", and an int: " + 78 );
11
12     System.out.print( "\nJava is case sensitive: " );
13     System.out.println( 'a' + " is different from " + 'A' );
14
15     System.out.println( "\nCreate a variable and print its value" );
16     String s = new String( "The grade is" );
17     double grade = 3.81;
18     System.out.println( s + " " + grade );
19
20     System.exit( 0 ); // optional
21   }
22 }
```

Description

Lines 10 and 13 show how *print* or *println* can be used with various data types such as *double, int*, and *char*. Variables and expressions can also be used instead of literals, as shown in line 18, where two *Strings* and the *double* variable *grade* are output.

REFERENCE POINT

You can read more about the *System* and *PrintStream* classes on Oracle's Java website: *www.oracle.com/technetwork/java*.

The output of Example 3.12 is shown in **Figure 3.19**. We terminate the program by calling the *exit* method of the *System* class.

Figure 3.19 The Output from Example 3.12

Description

```
The value of e is 2.718281828459045
The value of pi is 3.141592653589793

The absolute value of 6.7 is 6.7

The absolute value of -6.7 is 6.7
```

```
The log of 5 is 1.6094379124341003

The square root of 9 is 3.0

4 to the power 3 is 64.0

43.5 to the power 3.4 is 372274.65827529586
```

```
23.4 rounded is 23

23.49 rounded is 23

23.5 rounded is 24

23.51 rounded is 24

23.6 rounded is 24
```

```
The smaller of 8 and 2 is 2

The larger of 8 and 2 is 8

The smallest of 8, 5, and 12 is 5
```

3.13 The *Math* Class

The *Math* class is also part of the *java.lang* package. As such, it is automatically available to any Java program; we do not need to use the *import* statement. The *Math* class provides two *static* constants (*E* and *PI*), as well as a number of *static* methods that save the programmer from writing some complex mathematical code.

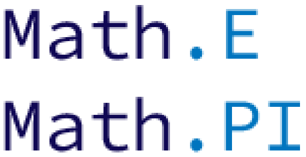
The two constants, *E* and *PI*, are both *doubles* and represent, respectively, ***e*** (the base of the natural logarithm, i.e., log e = 1) and ***pi***, the ratio of the circumference of a circle to its diameter. Approximate values of *e* and *pi*, as we know them, are 2.78 and 3.14, respectively. These constants are shown in **Table 3.11**.

***Static* Constants of the *Math* Class**

Constant	**Value**
`E`	*e*, the base of the natural logarithm
`PI`	*pi*, the ratio of the circumference of a circle to its diameter

Description

Because *E* and *PI* are *static* data members of the *Math* class, they are referenced using the name of the *Math* class and the dot notation as follows:



```
Math.E
Math.PI
```

Description

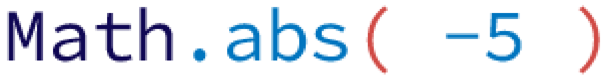
Useful methods of the *Math* class are shown in **Table 3.12**. All the methods of the *Math* class are *static*; so they are called using the class name, *Math*, and the dot notation as follows:

Useful Methods of the *Math* Class

Math Class Method Summary

Return value	Method name and argument list
`dataTypeOfArg`	`abs( arg )` *static* method that returns the absolute value of the argument *arg,* which can be a *double, float, int,* or *long*.
`double`	`log( double arg )` *static* method that returns the natural logarithm (in base *e*) of its argument, *arg*. For example, log(1) returns 0 and log(*Math.E)* returns 1.
`dataTypeOfArgs`	`min( argA, argB )` *static* method that returns the smaller of the two arguments. The arguments can be *doubles, floats, ints,* or *longs*.
`dataTypeOfArgs`	`max( argA, argB )` *static* method that returns the larger of the two arguments. The arguments can be *doubles, floats, ints,* or *longs*.
`double`	`pow( double base, double exp` *static* method that returns the value of *base* raised to the *exp* power.
`long`	`round( double arg )` *static* method that returns the closest integer to its argument, *arg.*
`double`	`sqrt( double arg )` *static* method that returns the positive square root of *arg*.

Description



```
Math.abs( -5 )
```

Description

Example 3.13 demonstrates how the *Math* constants and the *abs* method can be used in a Java program. In lines 9 and 10, we print the values of *e* and *pi* using the *static* constants of the *Math* class. Then in lines 12 and 15, we call the *abs* method, which returns the absolute value of its argument.

Example 3.13 *Math* Class Constants and the *abs* Method

```
 1 /* A demonstration of the Math class methods and constants
 2    Anderson, Franceschi
 3 */
 4
 5 public class MathConstants
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     System.out.println( "The value of e is " + Math.E );
10     System.out.println( "The value of pi is " + Math.PI );
11
12     double d1 = Math.abs( 6.7 ); // d1 will be assigned 6.7
13     System.out.println( "\nThe absolute value of 6.7 is " + d1 );
14
15     double d2 = Math.abs( -6.7 ); // d2 will be assigned 6.7
16     System.out.println( "\nThe absolute value of -6.7 is " + d2 );
17   }
18 }
```

Description

We then print the results in lines 13 and 16. The output of Example 3.13 is shown in Figure 3.20.

Figure 3.20 Output from Example 3.13

Description

The operation and usefulness of most *Math* class methods are obvious. But several methods—*pow*, *round*, and *min/max*—require a little explanation.

The *pow* Method

Example 3.14 demonstrates how some of these *Math* methods can be used in a Java program.

Example 3.14 A Demonstration of Some *Math* Class Methods

```
 1 /* A demonstration of some Math class methods
 2    Anderson, Franceschi
 3 */
 4
 5 public class MathMethods
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     double d2 = Math.log( 5 );
10     System.out.println( "\nThe log of 5 is " + d2 );
11
12     double d4 = Math.sqrt( 9 );
13     System.out.println( "\nThe square root of 9 is " + d4 );
14
15     double fourCubed = Math.pow( 4, 3 );
16     System.out.println( "\n4 to the power 3 is " + fourCubed );
17
18     double bigNumber = Math.pow( 43.5, 3.4 );
19     System.out.println( "\n43.5 to the power 3.4 is " + bigNumber );
20   }
21 }
```

Description

The *Math* class provides the *pow* method for raising a number to a power. The *pow* method takes two arguments; the first is the base and the second is the exponent.

Although the argument list for the *pow* method specifies that the base and the exponent are both *doubles*, we can, in fact, send arguments of any numeric type to the *pow* method because all numeric types can be promoted to a *double*. No matter what type the arguments are, however, the return value is always a *double*. Thus, when line 15 calls the *pow* method with two integer arguments, the value of *fourCubed* will be 64.0. If we prefer that the return value be 64, we can cast the return value to an *int*.

Line 18 shows how to use the *pow* method with arguments of type *double*. The output of Example 3.14 is shown in **Figure 3.21**.

Figure 3.21 Output from Example 3.14

Description

The *round* Method

The *round* method converts a *double* to its nearest integer using these rules:

- Any fractional part .0 to .4 is rounded down.
- Any fractional part .5 and above is rounded up.

Lines 9–13 in **Example 3.15** use the *round* method with various numbers. **Figure 3.22** shows the output.

Example 3.15 A Demonstration of the *Math round* Method

```
 1 /* A demonstration of the Math round method
 2    Anderson, Franceschi
 3 */
 4
 5 public class MathRounding
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     System.out.println( "23.4 rounded is " + Math.round( 23.4 ) );
10     System.out.println( "23.49 rounded is " + Math.round( 23.49 ) );
11     System.out.println( "23.5 rounded is " + Math.round( 23.5 ) );
12     System.out.println( "23.51 rounded is " + Math.round( 23.51 ) );
13     System.out.println( "23.6 rounded is " + Math.round( 23.6 ) );
14   }
15 }
```

Description

Figure 3.22 Output from Example 3.15

Description

The *min* and *max* Methods

The *min* and *max* methods return the smaller or larger of their two arguments, respectively. **Example 3.16** demonstrates how the *min* and *max* methods can be used in a Java program. **Figure 3.23** shows the output. Thus, the statement on line 9 of Example 3.16 will assign 2 to the *int* variable *smaller*. At line 12, a similar statement using the *max* method will assign 8 to the *int* variable *larger*.

Example 3.16 A Demonstration of the *min* and *max* Methods

```
 1 /* A demonstration of min and max Math class methods
 2    Anderson, Franceschi
 3 */
 4
 5 public class MathMinMaxMethods
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     int smaller = Math.min( 8, 2 );
10     System.out.println( "The smaller of 8 and 2 is " + smaller );
11
12     int larger = Math.max( 8, 2 );
13     System.out.println( "The larger of 8 and 2 is " + larger );
14
15     int a = 8, b = 5, c = 12;
16     int tempSmaller = Math.min( a, b ); // find smaller of a & b
17     int smallest = Math.min( tempSmaller, c ); // compare result to c
18     System.out.println( "The smallest of " + a + ", " + b + ", and "
19                          + c + " is " + smallest );
20   }
21 }
```

Description

Figure 3.23 Output from Example 3.16

Description

REFERENCE POINT

You can read more about the *Math* class on Oracle's Java website: *www.oracle.com/technetwork/java*.

The *min* method can also be used to compute the smallest of three variables. After declaring and initializing the three variables (*a, b*, and *c*) at line 15, we assign to a temporary variable named *tempSmaller* the smaller of the first two variables, *a* and *b*, at line 16. Then, at line 17, we compute the smaller of *tempSmaller* and the third variable, *c*, and assign that value to the variable *smallest*, which is output at lines 18 and 19.

The pattern for finding the largest of three numbers is similar, and we leave that as an exercise at the end of the chapter.

3.14 Formatting Output with the *NumberFormat* Class

Like the *DecimalFormat* class, the *NumberFormat* class can also be used to format numbers for output. The *NumberFormat* class, however, provides specialized *static* methods for creating objects specifically for formatting currency and percentages.

The *NumberFormat* class is part of the *java.text* package, so we need to include the following *import* statement at the top of our program.

```
import java.text.NumberFormat;
```

Description

The *static* methods of the *NumberFormat* class to format currency and percentages are shown in **Table 3.13**.

Useful Methods of the *NumberFormat* Class

	***NumberFormat* Method Summary**
Return value	**Method name and argument list**
`NumberFormat`	`getCurrencyInstance( )` *static* method that creates a format object for money
`NumberFormat`	`getPercentInstance( )` *static* method that creates a format object for percentages
`String`	`format( double number )`

	returns a *String* representation of *number* formatted as a currency or percentage, depending on the object used to call the method

Description

As we can see from the first two method headers, their return type is a *NumberFormat* object. These *static* methods, called **factory methods**, are used instead of constructors to create objects. Thus, instead of using the *new* keyword and a constructor, we will call one of these methods to create our formatting object.

The *getCurrencyInstance* method returns a formatting object that reflects the local currency. In the United States, that format is a leading dollar sign and is two digits to the right of the decimal place. The *getPercentInstance* method returns a formatting object for printing a fraction as a percentage by multiplying the fraction by 100, rounding to the nearest whole percent, and adding a percent sign (%).

We then use the *format* method from the *NumberFormat* class to display a value either as money or a percentage. The *format* method takes one argument, a *double,* which is the variable or value that we want to print; it returns the formatted version of the value as a *String* object, which we can then print.

Example 3.17 is a complete program illustrating how to use these three methods.

Example 3.17 Demonstrating the *NumberFormat* Class

```java
/* Demonstration of currency and percentage formatting
   using the NumberFormat class.
   Anderson, Franceschi
*/

// we need to import the NumberFormat class from java.text
import java.text.NumberFormat;

public class DemoNumberFormat
{
  public static void main( String [ ] args )
  {
    double winningPercentage = .675;
    double price = 78.9;

    // get a NumberFormat object for printing a percentage
    NumberFormat percentFormat = NumberFormat.getPercentInstance( );

    // call format method using the NumberFormat object
    System.out.print( "The winning percentage is " );
    System.out.println( percentFormat.format( winningPercentage ) );

    // get a NumberFormat object for printing currency
    NumberFormat priceFormat = NumberFormat.getCurrencyInstance( );

    // call format method using the NumberFormat object
    System.out.println( "\nThe price is: "
                        + priceFormat.format( price ) );
  }
}
```

Description

The output of this program is shown in **Figure 3.24**. As with *DecimalFormat*, the *NumberFormat format* method multiples the fraction to be formatted by 100. Note that the winning percentage is formatted as a rounded whole number. If we wanted to print the fraction .675 as 67.5%, we would need to use a *DecimalFormat* object.

Figure 3.24 Output from Example 3.17

Description

```
The int is 42
The Integer object is 42
Their sum is 84

The value of i1 is 76
The value of i2 is 76

The value of d1 is 58.32
The value of d2 is 58.32
```

```
Enter a character > d
The Unicode decimal value of d is: 100

d is a digit: false

d is a letter: true
d is uppercase: false
d is lowercase: true

d in uppercase is: D
d in lowercase is: d
```

3.15 The *Integer, Double, Character,* and Other Wrapper Classes

Most programs use a combination of primitive data types and objects. Some class methods, however, will accept only objects as arguments, so we need some way to convert a primitive data type into an object. Conversely, there are times when we need to convert an object into a primitive data type. For example, let’s say we have a GUI where we ask users to type their age into a text box or a dialog box. We expect the age to be an *int* value; however, text boxes and dialog boxes return their values as *Strings*. To perform any calculations on an age in our program, we will need to convert the value of that *String* object into an *int*.

For these situations, Java provides **wrapper classes**. A wrapper class “wraps” the value of a primitive type, such as *double* or *int*, into an object. These wrapper classes define an instance variable of that primitive data type, and also provide useful constants and methods for converting between the objects and the primitive data types. **Table 3.14** lists the wrapper classes for each primitive data type.

Wrapper Classes for Primitive Data Types

Primitive Data Type	Wrapper Class
double	Double
float	Float
long	Long
int	Integer
short	Short
byte	Byte
char	Character
boolean	Boolean

Description

All these classes are part of the *java.lang* package. So, the *import* statement is not needed in order to use wrapper classes in a program.

Java provides special support for converting between a primitive numeric type and its wrapper class. For example, we can simply assign an *int* variable to an *Integer* object reference. Java will automatically provide the conversion for us. This conversion is called **autoboxing**. In **Example 3.18**, the conversion is illustrated in lines 9 and 10. The *int* variable, *intPrimitive*, and the *Integer* object, *integerObject*, are output at lines 12 and 13 and have the same value (42). The output is shown in **Figure 3.25**.

Example 3.18 A Demonstration of the Wrapper Classes

```
 1 /* A demonstration of the Wrapper classes and methods
 2    Anderson, Franceschi
 3 */
 4
 5 public class DemoWrapper
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     int intPrimitive = 42;
10     Integer integerObject = intPrimitive;
11
12     System.out.println( "The int is " + intPrimitive );
13     System.out.println( "The Integer object is " + integerObject );
14
15     int sum = intPrimitive + integerObject;
16     System.out.println( "Their sum is " + sum );
17
18     int i1 = Integer.parseInt( "76" );    // convert "76" to an int
19     Integer i2 = Integer.valueOf( "76" ); // convert "76" to Integer
20     System.out.println( "\nThe value of i1 is " + i1 );
21     System.out.println( "The value of i2 is " + i2 );
22
23     double d1 = Double.parseDouble( "58.32" );
24     Double d2 = Double.valueOf( "58.32" );
25     System.out.println( "\nThe value of d1 is " + d1 );
26     System.out.println( "The value of d2 is " + d2 );
27   }
28 }
```

Description

Figure 3.25 Output from Example 3.18

Description

Similarly, when an *Integer* object is used as an *int*, Java also provides this conversion, which is called **unboxing**. Thus, when we use an *Integer* object in an arithmetic expression, the *int* value is automatically used. Line 15 of Example 3.18 uses the *Integer* object *integerObject* in an arithmetic expression, adding the *Integer* object to the *int* variable *intPrimitive*. As shown in Figure 3.25, the result is the same as if both operands were *int* variables.

REFERENCE POINT

You can read more about the wrapper classes on Oracle's Java website: *www.oracle.com/technetwork/java*.

Similar operations are possible using other numeric primitives and their associated wrapper classes.

In addition to automatic conversions between primitive types and wrapper objects, the *Integer* and *Double* classes provide methods, shown in **Table 3.15**, that allow us to convert *Strings* to numbers.

Methods of the *Integer* and *Double* Wrapper Classes

Useful Methods of the *Integer* Wrapper Class

Return value	Method name and argument list
`int`	`parseInt( String s )` *static* method that converts the *String s* to an *int* and returns that value
`Integer`	`valueOf( String s )` *static* method that converts the *String s* to an *Integer* object and returns that object

Useful Methods of the *Double* Wrapper Class

Return value	Method name and argument list
`double`	`parseDouble( String s )` *static* method that converts the *String s* to an *double* and returns that value
`Double`	`valueOf( String s )` *static* method that converts the *String s* to an *Double* object and returns that object

Description

The *parseInt*, *parseDouble*, and *valueOf* methods are *static* and are called using the *Integer* or *Double* class name and the dot notation. The *parse* methods convert a *String* to a primitive type, and the *valueOf* methods convert a *String* to a wrapper object. For example, line 18 of Example 3.18 converts the *String* “76” to the *int* value 76. Line 19 converts the *String* “76” to an equivalent *Integer* object.

Similarly, line 23 converts the *String* “58.32” to a *double*, and line 24 converts the same *String* to an equivalent *Double* object.

Because a *char* is a primitive type, we can’t call methods on a *char* variable. By wrapping a *char* variable into an object, however, the *Character* class provides some helpful methods for dealing with *chars*. Often, we may want to determine whether a character is a digit or a letter. For example, if we are checking whether a password is secure, we may want to determine whether the password has at least one digit, or we may want to change the case of a *char* variable. **Table 3.16** shows some useful methods of the *Character* class. All these methods are *static*, so we call them using the *Character* class name instead of an object reference. The first four methods test whether a *char* is a digit, a letter, lowercase, or uppercase. For each of these methods, we send the *char* variable as an argument and the method returns *true* or *false*. The next two methods, *toLowerCase* and *toUpperCase*, convert the *char* argument to lower- or uppercase if the *char* is a letter. We send the *char* variable to the method, and it returns a copy of the *char* variable after converting its case, if possible.

Useful Methods of the *Character* Wrapper Classes

Useful *static* Methods of the *Character* Wrapper Class

Return value	**Method name and argument list**
`boolean`	`isDigit( char c )` returns true if *c* is a character from ‘0’ to ‘9’ or a digit in other languages; false, otherwise
`boolean`	`isLetter( char c )` returns true if *c* is a letter; false, otherwise
`boolean`	`isLowerCase( char c )` returns true if *c* is a lowercase letter; false, otherwise
`boolean`	`isUpperCase( char c )`

	returns true if *c* is an uppercase letter; false, otherwise
`char`	`toLowerCase( char c )` returns the lowercase version of *c* if *c* is a letter; otherwise it returns *c* unchanged
`char`	`toUpperCase( char c )` returns the uppercase version of *c* if *c* is a letter; otherwise it returns *c* unchanged

Description

Example 3.19 demonstrates the use of these methods.

Example 3.19 Character Methods

```
 1 /*  Character Methods
 2     Anderson, Franceschi
 3 */
 4 import java.util.Scanner;
 5
 6 public class CharacterMethods
 7 {
 8   public static void main( String [ ] args )
 9   {
10     Scanner scan = new Scanner( System.in );
11
12     System.out.print( "Enter a character > " );
13     String input = scan.next( );
14     char c = input.charAt( 0 );
15
16     System.out.println( "The Unicode decimal value of " + c + " is: "
17                                  + ( int ) c );
18
19     System.out.println(  "\n" + c + " is a digit: "
20                                  + Character.isDigit( c ) );
21
22     System.out.println(  "\n" + c + " is a letter: "
23                                  + Character.isLetter( c ) );
24     System.out.println(  c + " is uppercase: "
25                                  + Character.isUpperCase( c ) );
26     System.out.println(  c + " is lowercase: "
27                                  + Character.isLowerCase( c ) );
28
29     System.out.println(  "\n" + c + " in uppercase is: "
30                                  + Character.toUpperCase( c ) );
31     System.out.println(  c + " in lowercase is: "
32                                  + Character.toLowerCase( c ) );
33   }
34 }
```

Description

Lines 12–14 prompt the user for a character to test or convert. Remember that *Scanner* does not have a *nextChar* method, so we need to use the *next* method to read a *String* and then extract the first character of the inputted *String* using the *charAt* method.

Lines 16–17 output the decimal Unicode value of the *char* variable by type casting it to an *int*.

At lines 19–20, we test whether the *char* is a digit by calling the *isDigit* method and output the returned value of *true* or *false*. Similarly, at lines 22–23, we test whether the *char* is a letter by calling the *isLetter* method and output the returned value of *true* or *false*.

At lines 24–27, we test whether the *char* is an uppercase or lowercase letter, again outputting the return value of *true* or *false*.

Finally, at lines 29–32, we attempt to convert the *char* to an uppercase letter and then to a lowercase letter. If *c* is not a letter, or if it is already an uppercase or lowercase letter, the methods return the value unchanged.

Figure 3.26 shows the output of the program when the user enters *d*.

Figure 3.26 Output from Example 3.19

Description

3.18.1	Multiple Choice Exercises Question 12
3.18.3	Fill In the Code Question 33
3.18.4	Identifying Errors in Code Question 35
3.18.5	Debugging Area Question 44
3.18.8	Technical Writing Questions 71, 72

```
Enter your first name > Esmerelda
Hello, Esmerelda
Your name has 9 letters.

In what year were you born? 2002
This year, you will be 18 years old.
So far, you have lived 22.9% of your expected life span.

I'm thinking of a number between 1 and 20
What is your guess? 15
The secret number was 2
Your guess was 13 away.
```

3.16 Programming Activity 2: Using Predefined Classes

In this Programming Activity, you will write a short program using some of the classes and methods discussed in this chapter. Your program will perform the following operations:

1. a. Prompt the user for his or her first name
   b. Print a message saying hello to the user
   c. Tell the user how many characters are in his or her name
2. a. Ask the user for the year of his or her birth
   b. Calculate and print the age the user will be this year
   c. Declare a constant for average life expectancy; set its value to 78.94
   d. Print a message that tells the user the percentage of his or her expected life lived so far formatted to one decimal place
3. a. Generate a random number between 1 and 20 inclusive
   b. Output a message telling the user that the program is thinking of a number between 1 and 20 and ask for a guess
   c. Output a message telling the user the number and how far away from the number the user's guess was

To complete this Programming Activity, copy the contents of this chapter's Programming Activity 2 folder in the supplied code accompanying this text. Open the *PracticeMethods.java* file and look for four sets of five asterisks (*****), where you will find instructions to write *import* statements and items 1, 2, and 3 for completing the Programming Activity.

Example 3.20 shows the *PracticeMethods.java* file, and **Figure 3.27** shows the output from a sample run after you have completed the Programming Activity. Your output might vary from that shown because we use 2020 as the current year for calculating age and because item 3 generates a random number.

Example 3.20 *PracticeMethods.java*

```
/* Chapter 3 Programming Activity 2
   Calling class methods
   Anderson, Franceschi
 */

// ***** 1. add your import statements here

public class PracticeMethods
{
  public static void main( String [ ] args )
  {
    //*****
    // 2.  a. Create a Scanner object to read from the keyboard.
    //     b. Prompt the user for their first name.
    //     c. Print a message that says hello to the user.
    //     d. Print a message that says how many letters
    //               are in the user's name.
    // Your code goes here

    //*****
    // 3.  a. Skip a line, then prompt the user for the year
    //            they were born.
    //     b. Declare a constant for the current year.
    //     c. Calculate and print the age the user will be this year.
    //     d. Declare a constant for average life expectancy,
    //            set its value to 78.94.
    //     e. Calculate and print the percentage
    //            of the user's expected life they've lived.
    //        Use the DecimalFormat class to format the percentage
    //            to one decimal place.
    // Your code goes here

    //*****
    // 4.  a. Generate a secret random integer between 1 and 20
    //     b. Skip a line, then ask the user for a guess.
    //     c. Print a message telling the user the secret number
    //         and how far from the number the user's guess was
    //         (hint: use Math.abs).
    // Your code goes here

  }
}
```

Description

Figure 3.27 Console Output from a Sample Run of Programming Activity 2

Description

DISCUSSION QUESTIONS

1. Which methods of the *Scanner* class did you choose for reading the user’s name and birth year? Explain your decisions.
2. How would you change your code to generate a random number between 10 and 20?

CHAPTER REVIEW

3.17 Chapter Summary

- Object-oriented programming entails writing programs that use classes and objects. Using prewritten classes shortens development time and creates more reliable programs. Programs that use prewritten classes are called clients of the class.
- Benefits of object-oriented programming include encapsulation, reusability, and reliability.
- Classes consist of data, plus instructions that operate on that data. Objects of a class are created using the class as a template. Creating an object is called instantiating an object, and the object is an instance of the class. The *new* keyword is used to instantiate an object.
- The object reference is the variable name for an object and points to the data of the object.
- The data of a class are called fields and consist of instance variables and *static* variables. The instructions of the class are called methods. Methods of a class get or set the values of the data or provide other services of the class.
- The name of a method, along with its argument list and return value, is called the Application Programming Interface (API) of that method. Methods that are declared to be *public* can be called by any client of the class.

- By convention, class names in Java start with a capital letter. Method names, instance variables, and object names start with a lowercase letter. In all these names, embedded words begin with a capital letter.
- When our program makes a method call, control transfers to the instructions in the method until the method finishes executing. Then control is transferred back to our program.
- Instance methods are called using the object reference and the dot notation.
- A constructor is called when an object is instantiated. A constructor has the same name as the class and its job is to initialize the object's data. Classes can have multiple constructors.
- A method's data type is called the method's return type. If the data type is anything other than the keyword *void*, the method returns a value to the program. When a value-returning method finishes executing, its return value replaces the method call in the expression.
- When an object reference is first declared, its value is *null*. Attempting to use a *null* object reference to call a method generates an error.
- The garbage collector runs occasionally and deletes objects that have no object references pointing to them.
- Java packages are groups of classes arranged according to functionality. Classes in the *java.lang* packages are automatically available to Java programs. Other classes need to be imported.
- The *String* class can be used to create objects consisting of a sequence of characters. *String* constructors accept *String* literals, *String* objects, or no argument, which creates an empty *String*. The *length* method returns the number of characters in the *String* object. The *toUpperCase* and *toLowerCase* methods return a *String* in upper or lower case. The *charAt* method extracts a character from a *String*, while the *substring* method extracts a *String* from a *String*. The *indexOf* method searches a *String* for a character or substring.
- The *DecimalFormat* class, in the *java.text* package,

provides methods to format numeric output. For example, we can specify the number of digits to display after the decimal point or add dollar signs and percentage signs (%).

- The *Random* class, in the *java.util* package, provides methods to generate random numbers.
- The *Scanner* class, in the *java.util* package, provides methods for reading input from the keyboard. Methods are provided for reading primitive data types and *Strings*.
- When prompting the user for input, phrase the prompt in language the user understands. Describe the data requested and any restrictions on valid input values.
- *Static* methods, also called class methods, can be called without instantiating an object. *Static* methods can access only the *static* data of a class.
- *Static* methods are called using the class name and the dot notation.
- *System.out.println* prints primitive data types or a *String* to the Java console and adds a *newline* character. *System.out.println* with no argument skips a line. *System.out.print* prints the same data types to the Java console, but does not add a *newline.* Classes provide a *toString* method to convert objects to a *String* in order to be printed.
- The *Math* class provides *static* constants *PI* and *E* and *static* methods to perform common mathematical calculations, such as finding the maximum or minimum of two numbers, rounding values, and raising a number to a power.
- The *NumberFormat* class, in the *java.text* package, provides *static* methods for creating objects to format numeric output as currency or a percentage.
- Wrapper classes provide an object interface for a primitive data type. The *Integer* and *Double* wrapper classes provide *static* methods for converting between *ints* and *doubles* and *Strings*.
- The *Character* wrapper class provides methods for testing whether a character is a digit or a letter, and for converting letters to upper- or lowercase.

3.18 Exercises, Problems, and Projects

3.18.1 Multiple Choice Exercises

1. If you want to use an existing class from the Java Class Library in your program, what keyword should you use?

    - `use`
    - `import`
    - `export`
    - `include`

6. A constructor has the same name as the class name.

    - true
    - false

9. A given class can have more than one constructor.

    - true
    - false

12. What is the keyword used to instantiate an object in Java?

    - `make`
    - `construct`
    - `new`
    - `static`

17. In a given class named *Quiz*, there can be only one method with the name *Quiz*.

- true
- false

20. A *static* method is

- a class method.
- an instance method.

23. In the *Quiz* class, the *foo* method has the following API:

```
public static double foo( float f )
```

Description
What can you say about *foo?*

- It is an instance method.
- It is a class field.
- It is a class method.
- It is an instance variable.

28. In the *Quiz* class, the *foo* method has the following API:

```
public static void foo( )
```

Description
How would you call that method?

- `Quiz.foo( );`
- `Quiz.foo( 8 );`
- `Quiz( foo( ) );`

32. In the *Quiz* class, the *foo* method has the following API:

```
public double foo( int i, String s, char c )
```

Description
How many arguments does *foo* take?

- 0
- 1
- 2
- 3

37. In the *Quiz* class, the *foo* method has the following API:

```
public double foo( int i, String s, char c )
```

Description
What is the return type of method *foo*?

- `double`
- `int`
- `char`
- `String`

42. *String* is a primitive data type in Java.

- true
- false

45. Which one of the following is not an existing wrapper class?

- `Integer`
- `Char`
- `Float`
- `Double`

50. What is the proper way of accessing the constant *E* of the *Math* class?

- `Math.E( )x;`

- `Math.E;`
- `E;`
- `Math( E );`

3.18.2 Reading and Understanding Code

1. What is the output of this code sequence?

   
   ```
   String s = new String( "HI" );
   System.out.println( s );
   ```

   Description

2. What is the output of this code sequence?

   
   ```
   String s = "A" + "BC" + "DEF" + "GHIJ";
   System.out.println( s );
   ```

   Description

3. What is the output of this code sequence?

   
   ```
   String s = "Hello";
   s = s.toLowerCase( );
   System.out.println( s );
   ```

   Description

4. What is the output of this code sequence?

   
   ```
   int a = Math.min( 5, 8 );
   System.out.println( a );
   ```

   Description

5. What is the output of this code sequence?

   
   ```
   System.out.println( Math.sqrt( 4.0 ) );
   ```

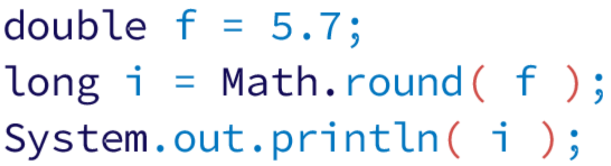
Description

6. What is the output of this code sequence? (You will need to actually compile this code and run it in order to have the correct output.)

```
System.out.println( Math.PI );
```

Description

7. What is the output of this code sequence?



```
double f = 5.7;
long i = Math.round( f );
System.out.println( i );
```

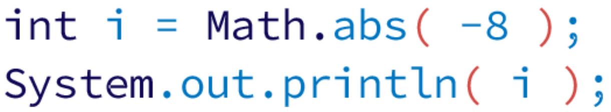
Description

8. What is the output of this code sequence?

```
System.out.print( Math.round( 3.5 ) );
```

Description

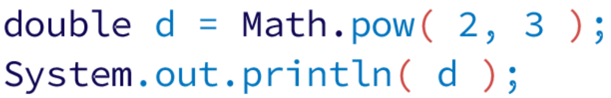
9. What is the output of this code sequence?



```
int i = Math.abs( -8 );
System.out.println( i );
```

Description

10. What is the output of this code sequence?



```
double d = Math.pow( 2, 3 );
System.out.println( d );
```

Description

3.18.3 Fill In the Code

1. This code concatenates the three *Strings* “Intro ”, “to”, “ Programming” and outputs the resulting *String*. (Your output should be *Intro to Programming*.)

   
   ```
   String s1 = "Intro ";
   String s2 = "to";
   String s3 = " Programming";
   // your code goes here
   ```

   Description

2. This code prints the number of characters in the *String* “Hello World”.

   
   ```
   String s = "Hello World";
   // your code goes here
   ```

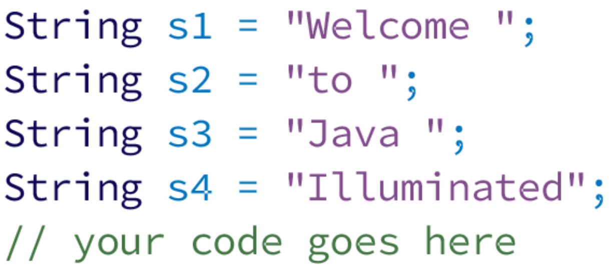
   Description

3. This code prompts the user for a *String*, then prints the *String* and the number of characters in it.

   
   ```
   // your code goes here
   ```

   Description

4. This code uses only a single line *System.out.println*. . . statement in order to print “Welcome to Java Illuminated” on one line using the following variables and the *String* concatenation operator:



```
String s1 = "Welcome ";
String s2 = "to ";
String s3 = "Java ";
String s4 = "Illuminated";
// your code goes here
```

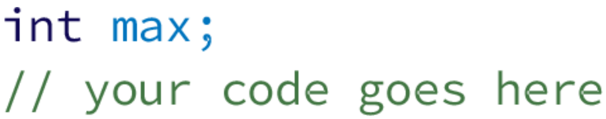
Description

5. This code uses exactly four *System.out.print* statements in order to print “Welcome to Java Illuminated” on the same output line.

```
// your code goes here
```

Description

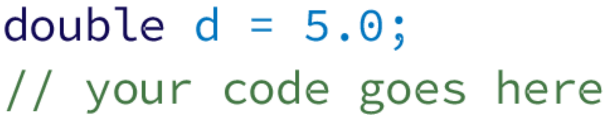
6. This code assigns the maximum of the values 3 and 5 to the *int* variable *max* and outputs the result.



```
int max;
// your code goes here
```

Description

7. This code calculates the square root of 5 and outputs the result.



```
double d = 5.0;
// your code goes here
```

Description

8. This code asks the user for two integer values, then calculates the minimum of the two values and prints it.

```
// your code goes here
```

Description

9. This code asks the user for three integer values, then calculates the maximum of the three values and prints it.

```
// your code goes here
```

Description

10. This code prompts the user for a single character and prints “true” if the character is a letter and “false” if it is not a letter.

```
// your code goes here
```

Description

11. This code asks the user for a *double*, then prints the square of that number using the *pow* method of the *Math* class.

```
// your code goes here
```

Description

3.18.4 Identifying Errors in Code

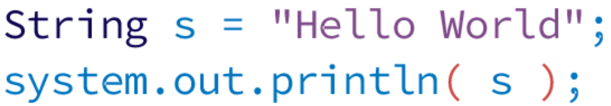
1. Where is the error in this statement?

```
import text.NumberFormat;
```

2. Where is the error in this statement?

```
import java.util.DecimalFormat;
```

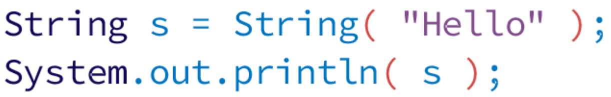
3. Where is the error in this code sequence?



```
String s = "Hello World";
system.out.println( s );
```

Description

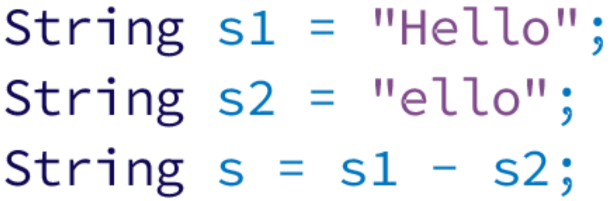
4. Where is the error in this code sequence?



```
String s = String( "Hello" );
System.out.println( s );
```

Description

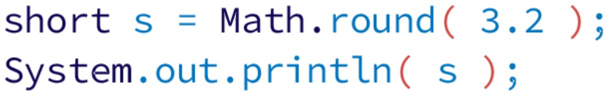
5. Where is the error in this code sequence?



```
String s1 = "Hello";
String s2 = "ello";
String s = s1 - s2;
```

Description

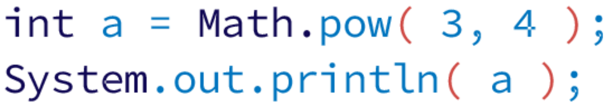
6. Where is the error in this code sequence?



```
short s = Math.round( 3.2 );
System.out.println( s );
```

Description

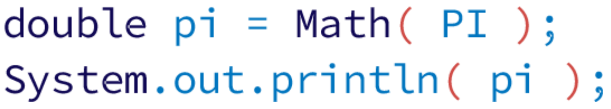
7. Where is the error in this code sequence?



```
int a = Math.pow( 3, 4 );
System.out.println( a );
```

Description

8. Where is the error in this code sequence?



```
double pi = Math( PI );
System.out.println( pi );
```

Description

9. Where is the error in this code sequence?

```
String s = 'H';
System.out.println( "s is " + s );
```

Description

3.18.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

1. You coded the following program in the file *Test.java:*

```
public class Test
{
  public static void main( String [ ] args )
  {
    int a = 6;
    NumberFormat nf = NumberFormat.getCurrencyInstance( );
  }
}
```

Description

When you compile, you get the following message:

```
Test.java: 6: error: cannot find symbol
    NumberFormat nf = NumberFormat.getCurrencyInstance( );
    ^
  symbol : class NumberFormat
  location: class Test
Test.java: 6: error: cannot find symbol
    NumberFormat nf = NumberFormat.getCurrencyInstance( );
                      ^
  symbol : variable NumberFormat
  location: class Test
2 errors
```

Description

Explain what the problem is and how to fix it.

2. You coded the following on lines 10–12 of class *Test.java:*

```
String s;                    // line 10
int l = s.length( );         // line 11
System.out.println( "length is " + l );      // line 12
```

Description

When you compile, you get the following message:

```
Test.java:11: error: variable s might not have been initialized.
    int l = s.length( );     // line 11
            ^
1 error
```

Description

Explain what the problem is and how to fix it.

3. You coded the following on lines 10 and 11 of class *Test.java:*

```
double d = math.sqrt( 6 );          // line 10
System.out.println( "d = " + d );   // line 11
```

Description

When you compile, you get the following message:

```
Test.java: 10: error: cannot find symbol
    double d = math.sqrt( 6 ); // line 10
               ^
    symbol : variable math
    location: class Test
1 error
```

Description

Explain what the problem is and how to fix it.

4. You coded the following on lines 10 and 11 of class *Test.java:*

```
double d = Math.PI( );             // line 10
System.out.println ( "d = " + d ); // line 11
```

Description

When you compile, you get the following message:

```
Test.java:10: error: cannot find symbol
    double d = Math.PI( );   // line 10
                   ^
    symbol : method PI( )
    location: class Math
1 error
```

Description

Explain what the problem is and how to fix it.

5. You coded the following on lines 10 and 11 of class *Test.java:*

```
double d = Math.e;                   // line 10
System.out.println( "d = " + d ); // line 11
```

Description

When you compile, you get the following message:

```
Test.java:10: error: cannot find symbol
    double d = Math.e;                      // line 10
                   ^
    symbol : variable e
    location: class Math
1 error
```

Description

Explain what the problem is and how to fix it.

6. You imported the *DecimalFormat* class and coded the following in the class *Test.java:*

```
double grade = .895;
DecimalFormat percent =
  new DecimalFormat( "#.0%" );

System.out.println( "Your grade is " + grade );
```

Description

The code compiles properly and runs, but the result is not what you expected. You expect this output:

```
Your grade is 89.5%
```

Description

But instead, the output is

```
Your grade is 0.895
```

Description

Explain what the problem is and how to fix it.

3.18.6 Write a Short Program

1. Write a program that reads two words representing passwords from the keyboard and outputs the number of characters in the smaller of the two. For example, if the two words are *open* and *sesame*, then the output should be *4*, the length of the shorter word, *open*.
2. Write a program that prompts the user for a domain name. Your program should then concatenate that name with *www.* and *.com* in order to form an Internet domain name and output the result. For instance, if the name entered by the user is *yahoo*, then the output will be *www.yahoo.com*.
3. Write a program that reads a word from the keyboard. Your program should output the word in uppercase letters only, output that word in lowercase letters only, and then, at the end, output the original word.
4. Write a program that generates two random numbers between 0 and 100 and prints the smaller of the two numbers.
5. Write a program that takes a *double* as an input, then computes and outputs the cube of that number using the *pow* method of the *Math* class.
6. Write a program that reads a file name from the keyboard. You should expect that the file name has one . (dot) character in it, separating the file name from the file extension. Retrieve the file extension and output it. For instance, if the user inputs *index.html*, you should output *html*; if the user inputs *MyClass.java*, you should output *java*.
7. Write a program that reads a full name (first name and last name) from the keyboard as a single line; you should expect the first name and the last name to be separated by a space. Retrieve and output the first and last names.

3.18.7 Programming Projects

1. Write a program that reads three integer values from the keyboard representing, respectively, a number of quarters, dimes, and nickels. Convert the total coin amount to dollars and output the result with a dollar notation.
2. Write a program that reads from the keyboard the radius of a circle. Calculate and output the area and the circumference of that circle. You can use the following formulas:

   $$\text{area} = \pi * \text{r}^2$$
   $$\text{circumference} = 2 * \pi * \text{r}$$

   Description
3. Write a program that generates five random integers between 60 and 100 and calculates the smallest of the five numbers.
4. Write a program that generates three random integers between 0 and 50, calculates the average, and prints the result to one decimal place.
5. Write a program that reads two integers from the keyboard: one representing the number of shots taken by a basketball player, the other representing the number of shots made by the same player. Calculate the shooting percentage and output it with the percent notation.
6. Write a program that reads three *double* numbers from the keyboard representing, respectively, the three coefficients *a*, *b*, and *c* of a quadratic equation. Solve the equation using the following formulas:

   $\text{x1} = (-b + \text{square root } (b^2 - 4ac))/(2a)$

   $\text{x2} = (-b - \text{square root } (b^2 - 4ac))/(2a)$

Description

Run your program on the following sample values:

$a = 1.0$, $b = 3.0$, $c = 2.0$
$a = 0.5$, $b = 0.5$, $c = 0.125$
$a = 1.0$, $b = 3.0$, $c = 10.0$

Description

Discuss the results for each program run, in particular what happens in the last case.

7. Write a program that reads two numbers from the keyboard representing, respectively, an investment and an interest rate (you will expect the user to enter a number such as .065 for the interest rate, representing a 6.5% interest rate). Your program should calculate and output (in $ notation) the future value of the investment in 5, 10, and 20 years using the following formula:

   $\text{future value} = \text{investment} * (1 + \text{interest rate})^{\text{year}}$

   We will assume that the interest rate is an annual rate and is compounded annually.

8. Write a program that reads from the keyboard the (x,y) coordinates for two points in the plane. You can assume that all numbers are integers. Using the *Point* class from the Java Class Library (you may need to look it up on the Web), instantiate two *Point* objects with your input data, then output the data for both *Point* objects.

9. Write a program that reads an email address. Assuming that the email address contains one at sign (@), extract and print the username and the domain name of the email address.
10. Write a program that reads a telephone number from the keyboard as a *String* of 10 digits. You should output that same telephone number formatted as (nnn) nnn-nnnn.
11. Write a program that reads a sentence from the keyboard. The sentence has been encrypted so that the message consists of only the first five characters with even-numbered indexes. All other characters should be discarded. Decrypt the sentence and output the result. For example, if the user inputs “Hiejlzl3ow”, your output should be *Hello*.
12. Write a program that reads a commercial website URL from the keyboard; you should expect that the URL starts with *www.* and ends with *.com*. Retrieve the name of the site

and output it. For instance, if the user inputs *www.yahoo.com*, you should output *yahoo*.

3.18.8 Technical Writing

1. At this point, we have written and debugged many examples of code. When you compile a Java program with the Java compiler, you get a list of all the errors in your code. Do you like the Java compiler? Do the error messages it displays when your code does not compile help you determine what’s wrong? How?
2. Computers, computer languages, and application programs existed before object-oriented programming. However, OOP has become an industry standard. Discuss the advantages of using OOP compared to using only basic data types in a program.
3. Explain and discuss a situation where you would use the method *parseInt* of the class *Integer*.
4. In addition to the basic data types (*int*, *float*, *char*, *boolean*, …), Java provides many prewritten classes, such as *Math*, *NumberFormat*, and *DecimalFormat*. Why is this an advantage? How does this impact the way a programmer approaches a programming problem in general?

3.18.9 Group Project (for a group of 1, 2, or 3 students)

1. Write a program that calculates a monthly mortgage payment; we will assume that the interest rate is compounded monthly.
   You will need to do the following:
    - Prompt the user for a *double* representing the annual

interest rate. For example, 3.5% would be entered as .035.

- Prompt the user for the number of years the mortgage will be held (typical input here is 10, 15, or 30).
- Prompt the user for a number representing the mortgage amount borrowed from the bank.
- Calculate the monthly payment using the following formulas:
  - Monthly payment = (mIR * M) / (1 − (1 / (1 + mIR)$^{(12*nOY)}$)), where:
    - mIR = monthly interest rate = annual interest rate / 12
    - nOY = number of years
    - M = mortgage amount
- Output a summary of the mortgage problem, as follows:
  - the annual interest rate in percent notation
  - the mortgage amount in dollars
  - the monthly payment in dollars, with only two significant digits after the decimal point
  - the total payment over the years, with only two significant digits after the decimal point
  - the overpayment, i.e., the difference between the total payment over the years and the mortgage amount, with only two significant digits after the decimal point
  - the overpayment as a percentage (in percent notation) of the mortgage amount

Introduction

Graphical output is an integral part of many programs today. One compelling reason for using graphics in a program is the ability to present data in a format that is easy to comprehend. For example, our application could output average monthly temperatures as text, as shown in **Figure 4.1**.

Figure 4.1 Outputting Monthly Temperatures as Text

Description

Or we could produce the bar chart shown in **Figure 4.2**.

Figure 4.2 Bar Chart of Monthly Temperatures

Description

The bar chart presents the same information as the text output, but it adds a visual component that makes it easier to compare the monthly temperatures—for example, to find the highest or lowest temperature or to spot temperature trends throughout the year. The colors also add information, with the low temperatures shown in blue, the moderate temperatures in yellow, and the high temperatures in red.

In this chapter, we use JavaFX to write programs that produce graphical output.

4.1 JavaFX Application Structure

Over the years, Java has provided several incarnations of graphics systems. The first was Abstract Window Toolkit (AWT), which was subsequently replaced by Swing. Java's current system for building graphics applications is JavaFX. JavaFX makes it possible to create rich user interfaces with animations and special effects. In this chapter, we concentrate on JavaFX's features for creating graphical output for applications.

In order to use JavaFX, you need to download the JavaFX SDK. It can be downloaded as a bundle with the Java SDK, or separately if one has already downloaded the Java SDK. At the time of this edition, Oracle has open sourced JavaFX. It can be downloaded at *https://openjfx.io/*.

Oracle provides tutorial information on JavaFX at *http://docs.oracle.com/javafx/2/get_started/jfxpub-get_started.htm* and documentation for all the JavaFX classes is included with the latest Java documentation.

JavaFX uses a mixed performance/art metaphor. We start with a stage (a window) to which we add one or more scenes. To produce graphical output, we add a canvas to our scene, and we draw shapes and text on the canvas. When our application begins, the window opens and displays whatever we have drawn on the canvas.

REFERENCE POINT

For a tutorial on JavaFX, visit Oracle's website at *http://docs.oracle.com/javafx/2/get_started/jfxpub-get_started.htm*

We, the authors, are providing two classes to get you started. First, we provide a utility program, *JIGraphicsUtility.java*, to manage some of the common code needed to set up a JavaFX application. Second, we provide *ShellGraphicsApplication.java*, which provides a framework for adding your custom drawing code. The *JIGraphicsUtility.java* class, shown in **Example 4.1**, has one *static* method, *setUpGraphics*, which is designed to be called from our graphics application to set up our window title and size. We show the *JIGraphicsUtility* class here for completeness, but we do not need to make any modifications to this file. All we need to do is include this file in the same folder as our graphics application and call the *setUpGraphics* method from our application. The *setUpGraphics* method has the API shown in **Table 4.1**. In our graphics application, we use the *GraphicsContext* object returned from the *setUpGraphics* method to call methods that draw shapes and text on the window.

Example 4.1 *JIGraphicsUtility* Class

```java
/* JIGraphicsUtility
   Utility class for building JavaFX graphics applications
   Anderson, Franceschi
*/

import javafx.scene.Group;
import javafx.scene.canvas.Canvas;
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.Scene;
import javafx.stage.Stage;

 public class JIGraphicsUtility
{
     public static GraphicsContext setUpGraphics( Stage stage,
                          String title, int height, int width )
     {
        stage.setTitle( title );
        Canvas canvas = new Canvas( height, width );
        GraphicsContext gc = canvas.getGraphicsContext2D( );
        Group root = new Group( canvas );
        stage.setScene( new Scene( root ) );
        stage.show( );
        return gc;
     }
}
```

Description

The *static setUpGraphics* Method

Return Value	**Method Name and Argument List**
`GraphicsContext`	`setUpGraphics( Stage`

	`stage, String title, int width, int height )` initializes a scene on the *stage*, sets the title of the window to *title*, and adds a canvas with the *width* and *height* specified; returns a *GraphicsContext* object

Description

Example 4.2 shows the *ShellGraphicsApplication* class. This class provides skeleton code for an application. We create a new application by modifying this code.

Example 4.2 *ShellGraphicsApplication.java*

```
 1 /* A Shell for creating graphics applications
 2    Anderson, Franceschi
 3 */
 4
 5 import javafx.application.Application;
 6 import javafx.scene.canvas.GraphicsContext;
 7 import javafx.stage.Stage;
 8
 9 public class ShellGraphicsApplication extends Application
10 {
11     @Override
12     public void start( Stage stage )
13     {
14         // set up window title and size
15         GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
16                   stage, "Shell Graphics Application", 700, 400 );
17
18         // your drawing code goes here
19     }
20
21     public static void main( String [ ] args )
22     {
23         launch( args );
24     }
25 }
```

Description

Lines 5–7 import the minimum classes needed for a JavaFX application. Notice that all the package names begin with *javafx*.

We define our application name in line 9. Here the name is *ShellGraphicsApplication*. For each new application we write, we will change this name to reflect the application’s purpose. The phrase “*extends Application*” means that we inherit basic functionality and methods from the JavaFX *Application* class.

One of the methods we inherit is the *start* method, which the JavaFX platform calls automatically when the application begins. It receives one parameter, *stage*, which represents the application’s window. We need to write our own version of the *start* method (lines 11–19), however, in which we put our method calls to draw shapes and text on the window. We use the *@Override* annotation in line 11 to indicate that our *start* method replaces the *start* method in the *Application* class.

Our first order of business is to call the *setUpGraphics* method (lines 14–16). Because *setUpGraphics* is a *static* method, we call it using the *JIGraphicsUtility* class name. Here we send as arguments the stage representing our window; a title for the window; and a size for the window, in this case a width of 700 pixels and a height of 400 pixels. For our applications, we can change the title to something appropriate and alter the window size as needed.

Line 18 indicates where we add code to create our graphics.

In lines 21–24 we define the *main* method. Its only job is to launch the JavaFX application by calling the *launch* method of the *Application* class, passing through any arguments that were sent to the *main* method. Because this code will be the same for every application, we place *main* at the end of the program.

Thus, to run a JavaFX graphics application, we alter the *ShellGraphicsApplication.java* class to add our custom graphics code, and we put the *JIGraphicsUtility.java* class and our custom class in the same folder. We then compile both classes and execute our custom class.

On the author’s computer, the JavaFX version is 17.0.1 and is installed in the *C:\Program Files\JavaFX* folder.

To compile a JavaFX program from the command line, type:

```
javac --module-path <path of JavaFX lib folder> --add-modules
javafx.controls ApplicationClassName.java
```

Description

On the author’s computer, it would be:

```
javac --module-path "C:\Program Files\JavaFX\javafx-sdk-17.0.1\lib"
--add-modules javafx.controls ApplicationClassName.java
```

Description

To compile the *ShellGraphicsApplication* class from the command line, it would be:

```
javac --module-path "C:\Program Files\JavaFX\javafx-sdk-17.0.1\lib"
--add-modules javafx.controls ShellGraphicsApplication.java
```

Description

After compilation, to run a JavaFX from the command line, type:

```
java --module-path <path of JavaFX lib folder> --add-modules
javafx.controls ApplicationClassName
```

Description

On the author's computer, it would be:

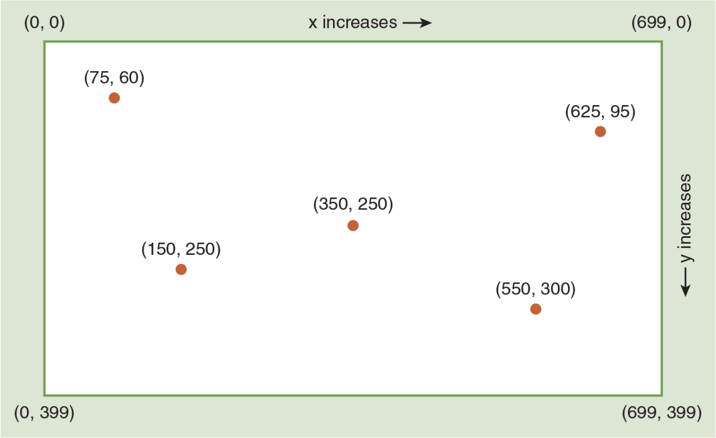
```
java --module-path "C:\Program Files\JavaFX\javafx-sdk-17.0.1\lib"
--add-modules javafx.controls ApplicationClassName
```

Description

To run the *ShellGraphicsApplication* from the command line, it would be:

```
java --module-path "C:\Program Files\JavaFX\javafx-sdk-17.0.1\lib"
--add-modules javafx.controls ShellGraphicsApplication
```

Description



4.2 The Graphics Coordinate System and Color

JavaFX's *GraphicsContext* class, in the *javafx.scene.canvas* package, provides methods to draw figures such as rectangles, circles, and lines; to set the colors for drawing; and to write text in a window.

To draw on the window, we specify the location where we want to put our shapes and the color we want the shapes to have.

A window is composed of pixels, which can be thought of as colored dots. A window with a width of 700 pixels and a height of 400 pixels has a total of 28,000 (700 * 400) pixels. Each pixel has a location expressed using an (*x*, *y*) coordinate system. The *x* coordinate specifies the horizontal position, beginning at 0 on the left side of the window and increasing as you move to the right. The *y* coordinate specifies the vertical position, starting at 0 at the top of the window and increasing as you move down. Thus, for a window that is 700 pixels wide and 400 pixels high, the coordinate (0, 0) corresponds to the upper-left corner; (699, 0) is the upper-right corner; (0, 399) is the lower-left corner; and (699, 399) is the lower-right corner. **Figure 4.3** shows a window with a few sample pixels and their (*x*, *y*) coordinates.

Figure 4.3 The *GraphicsContext* Coordinate System

Description

Each pixel also has a color. When a window opens, all pixels are set to the **background color**, which by default is white. Any drawing we perform is done in the **foreground colors**, which are the **stroke color** and the **fill color**. Most of the drawing methods have a stroke and a fill version, where the stroke version draws an outlined shape in the current stroke color and the fill version draws a solid shape in the current fill color. By default, both the stroke color and fill color are black, but we can set either to any color we prefer. The values set for the colors remain in effect until we set either the stroke color or the fill color to another color. For example, if we set the stroke color to blue and the fill color to red, then draw an outlined rectangle and a line, as well as a solid oval, the rectangle and line will be drawn in blue and the oval will be drawn in red. Then if we set the fill color to yellow and draw a solid rectangle, that rectangle will be drawn in yellow.

To set the foreground colors, we call the *setFill* or *setStroke* methods of the *GraphicsContext* class as shown in **Table 4.2**. These methods take as an argument, a *Paint* object. Because objects of the *Color* class are also *Paint* objects, we can send *Color* objects as arguments to the *setFill* and *setStroke* methods.

Methods of the *GraphicsContext* Class to Set the Foreground Colors

Return Value	**Method Name and Argument List**
`void`	`setStroke( Paint color )` sets the current outline color to *color*
`void`	`setFill( Paint color )` sets the current fill color to *color*

Description

The *Color* class, which is in the *javafx.scene.paint* package, defines colors using the RGB (red, green, blue) system. Any RGB color is composed of red, green, and blue components. Each component's value can range from 0 to 255 (00 to FF in hexadecimal); the higher the value, the higher the concentration of that component in the color. For example, a color with red 5 255, green 5 0, and blue 5 0 is pure red, and a color with red 5 0, green 5 0, and blue 5 255 is pure blue.

The color white is (255, 255, 255): its red, green, and blue components have the maximum value. Black is (0, 0, 0): its red, green, and blue components have the minimum value. Gray consists of equal amounts of each component. The higher the value of the components, the lighter the color of gray. This makes sense because the closer a color gets to white, the lighter that color will be. Similarly, the closer the gray value gets to 0, the darker the color of gray, because the color is approaching black.

For convenience in setting stroke and fill colors, the *Color* class provides approximately 150 *static Color* constants. **Table 4.3** lists some *Color* constants for common colors and their corresponding red, green, and blue components in hexadecimal. For a complete list of *Color* constants, see the documentation for the *Color* class in the Java Class Library.

Selected *Color* Constants and Their Red, Green, and Blue Components

Color Constant	Red	Green	Blue
■ Color.BLACK	00	00	00
■ Color.BLUE	00	00	FF
■ Color.CYAN	00	FF	FF
■ Color.DARKGRAY	A9	A9	A9
■ Color.GRAY	80	80	80
■ Color.GREEN	00	FF	00
■ Color.LIGHTGRAY	D3	D3	D3
■ Color.MAGENTA	FF	00	FF
■ Color.ORANGE	FF	A5	00
■ Color.PINK	FF	C0	CB
■ Color.RED	FF	00	00
□ Color.WHITE	FF	FF	FF
■ Color.YELLOW	FF	FF	00

Description

Each color constant is a predefined *Color* object, so you can simply assign the constant to your *Color* object reference. *Color* constants can be used wherever a *Color* or *Paint* object is expected. For example, assuming that *gc* is a *GraphicsContext* reference, this statement sets the current stroke color to orange:

```
gc.setStroke( Color.ORANGE );
```

If none of these 150 predefined colors meets our needs, we can create a custom color using any of the 16.7 million possible combinations of the component values. The *Color* class has a number of methods for creating colors, but for our purposes we'll need only the *static* factory method shown in **Table 4.4**.

A *Color* Class *static* Factory Method

Return Value	Method Name and Argument List

`Color`	`rgb( int rr, int gg, int bb )` creates a *Color* object with an *rr* red component, *gg* green component, and *bb* blue component

4.3 Drawing Shapes and Text

Now we're ready to create some graphics. Let's start with drawing lines.

Table 4.5 shows some useful methods of the *GraphicsContext* class for drawing shapes and displaying text in a window.

Drawing Methods of the *GraphicsContext* Class

Return Value	**Method Name and Argument List**
`void`	`strokeLine( double xStart, double yStart, double xEnd, double yEnd )` draws a line starting at (*xStart*, *yStart*) and ending at (*xEnd*, *yEnd*)
`void`	`strokeRect( double x, double y, double width, double height )` draws the outline of a rectangle with its top-left corner at (*x*, *y*), with the specified *width* and *height* in pixels
`void`	`fillRect( double x, double y, double width, double height )` draws a solid rectangle with its top-left corner at (*x*, *y*), with the specified *width* and *height* in pixels
`void`	`clearRect( double x, double y, double width, double height )` draws a solid rectangle in the current background color with its top-left corner at (*x*, *y*), with the specified *width* and *height* in pixels
`void`	`strokeOval( double x, double y, double width, double height )` draws the outline of an oval inside an invisible bounding rectangle with the specified *width* and *height* in pixels; the top-left

	corner of the bounding rectangle is (*x, y*)
`void`	`fillOval( double x, double y, double width, double height )` draws a solid oval inside an invisible bounding rectangle with the specified *width* and *height* in pixels; the top-left corner of the bounding rectangle is (*x, y*)
`void`	`strokeText( String s, double x, double y )` displays the *String s* with the (*x, y*) coordinate indicating the lower-left corner of the first character; the text is drawn in the current stroke color and line width
`void`	`fillText( String s, double x, double y )` displays the *String s* with the (*x, y*) coordinate indicating the lower-left corner of the first character; the text is drawn in the current fill color
`void`	`setLineWidth( double width )` sets the current stroke line width to *width* pixels
`void`	`setFont( Font f )` sets the font to *f* for displaying text

Description

As you can see, all these methods have a *void* return type, so they do not return a value. Method calls to these methods should be stand-alone statements.

The pattern for the method names is simple. The *draw* methods render the outline of the figure, while the *fill* methods render solid figures. The *clearRect* method draws a rectangle in the background color, which effectively erases anything drawn within that rectangle.

Figure 4.4 shows the relationship among the method arguments and the figures drawn.

Figure 4.4 The Arguments for Drawing Lines, Rectangles, Ovals, and Text

Description

Example 4.3 shows a graphics application that draws some lines, and **Figure 4.5** shows the output from this application. For this application, we have modified *ShellGraphicsUtility.java*, renamed it to *DrawingLines.java*, and placed our application and *JIGraphicsUtility.java* in the same folder.

Example 4.3 *DrawingLines.java*

```
/* Drawing Lines
   Anderson, Franceschi
*/

import javafx.application.Application;
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;
import javafx.stage.Stage;

import java.util.Random;

public class DrawingLines extends Application
{
    @Override
    public void start( Stage stage )
    {
        final int WIDTH = 700;
        final int HEIGHT = 400;
        // set up window title and size
        GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
                    stage, "Drawing Lines", WIDTH, HEIGHT );

        // draw a vertical black line
        gc.strokeLine( 100, 125, 100, 300 );

        // draw a horizontal red line
        gc.setStroke( Color.RED );
        gc.setLineWidth( 5 ); // widen the line
        gc.strokeLine( 300, 75, 550, 75 );

        // draw a diagonal line in a random color
        Random rand =  new Random( );
        int red = rand.nextInt( 0xFF );
        int green = rand.nextInt( 0xFF );
        int blue = rand.nextInt( 0xFF );
        Color randomColor = Color.rgb( red, green, blue );
        gc.setStroke( randomColor );

        gc.strokeLine( 0, 0, WIDTH - 1, HEIGHT - 1 );
    }

    public static void main( String [ ] args )
    {
        launch( args );
    }
}
```

Description

Figure 4.5 Output from *DrawingLines.java*

Description

Lines 5–8 import the JavaFX classes we use in this application, including the *Color* class. We also import the *Random* class from the standard Java Class Library on line 10.

In the call to the *setUpGraphics* method (lines 19–21), we specify the window title to be “Drawing Lines” and set the size of the window to be 700 by 400 pixels.

On lines 23–24, we draw a line by calling the *strokeLine* method, sending as arguments the start and end coordinates of the line. The line is horizontal because the *y* values for the start and end coordinates are the same. The line’s color is the default stroke color, black.

Next we draw a vertical red line (lines 26–29). We first set the stroke color to red, using the predefined *Color* constant, *Color.RED*. We make the line 5 pixels wide by calling the *setLineWidth* method with an argument of 5. This line width will stay in effect until we set the line width to a different value. The line is vertical because the *x* values for the start and end coordinates are the same.

Finally, we generate a random value for the stroke color (lines 31–37) by generating random values for the red, green, and blue components, then we use those values to create a *Color* object using the *rgb* factory method. We send FF to the *nextInt* method of the *Random* class because each red, green, and blue component’s value can range from 00 to FF in hexadecimal. Note that preceding an integer literal value with 0x indicates that the value is hexadecimal. Line 39 draws a diagonal line in this random color from the top-left corner of the window to the bottom-right corner, using the width and height of the window defined in lines 17 and 18.

Example 4.4 shows how to use the *GraphicsContext* methods for drawing shapes, and **Figure 4.6** shows the output of this application. To draw a rectangle, we call the *strokeRect* or *fillRect* methods with the (*x*, *y*) coordinate of the upper-left corner, as well as the width in pixels and the height in pixels. As you might expect, to draw a square, we specify equal values for the width and height. Line 23 draws an outlined rectangle with an upper-left corner at the coordinate (100, 50) and is 80 pixels wide and 200 pixels high; line 24 draws a solid square with an upper-left corner at the coordinate (275, 75) with sides that are 160 pixels in length.

Example 4.4 *DrawingShapes.java*

```java
/* Drawing Shapes
   Anderson, Franceschi
*/

import javafx.application.Application;
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;
import javafx.stage.Stage;

public class DrawingShapes extends Application
{
    @Override
    public void start( Stage stage )
    {
        // set up window title and size
        GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
                  stage, "Drawing Shapes", 700, 400 );
        // specify colors
        gc.setFill( Color.CYAN );
        gc.setStroke( Color.ORANGE );

        // draw rectangles
        gc.strokeRect( 100, 50, 80, 200 );  // outlined rectangle
        gc.fillRect( 275, 75, 160, 160 );   // solid square

        // draw ovals
        gc.fillOval( 100, 50, 80, 200 );    // oval inside rectangle
        gc.strokeOval( 100, 275, 200, 80 );  // outlined oval

        // draw circle using center point and radius
        gc.setFill( Color.MEDIUMSEAGREEN );
        int centerX = 550, centerY = 275;
        int radius = 75;
        gc.fillOval( centerX - radius, centerY - radius,
                     radius * 2, radius * 2 );
    }

    public static void main( String [ ] args )
    {
        launch( args );
    }
}
```

Description

Figure 4.6 Output from *DrawingShapes.java*

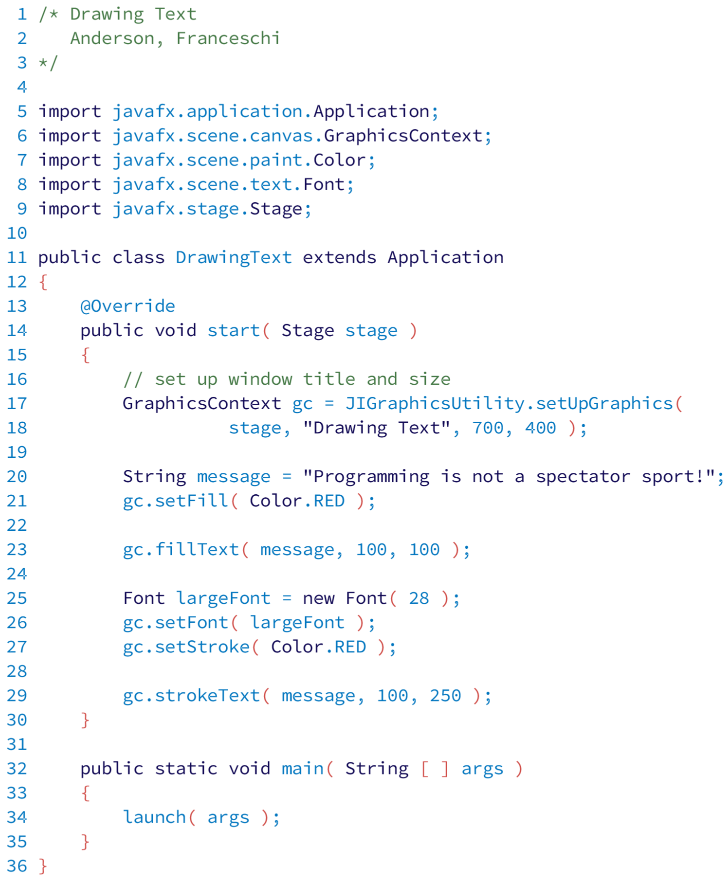
Description

Drawing an oval or a circle is a little more complex. As you can see in Figure 4.4, we need to imagine a rectangle bounding all sides of the oval or circle. Then the (*x*, *y*) coordinate we specify in the *strokeOval* or *fillOval* method is the location of the upper-left corner of the bounding rectangle. Accordingly, the width and height are the width and height of the bounding rectangle. Line 27 in Example 4.4 draws a filled oval whose upper-left corner is at coordinate (100, 50) and is 80 pixels wide and 200 pixels high. These are the same arguments we sent to the *strokeRect* method in line 23; thus, that rectangle at line 23 is the bounding rectangle for this oval, and we see that the filled oval is drawn exactly inside that rectangle. Line 28 draws an outlined oval 200 pixels wide and 80 pixels high, the same dimensions as the oval drawn at line 27 but rotated 90 degrees.

We draw a circle by calling the *strokeOval* or *fillOval* methods, specifying equal values for the width and height. Sometimes it seems more natural to identify circles by giving a center point and a radius. In this case, we can convert the center point and radius into the arguments for the *strokeOval* or *fillOval* methods as done in lines 32–35.

Example 4.5 shows how to use display text using the *fillText* method. The coordinate we specify is the lower-left corner of the first character in the *String*. The first call to *fillText* (line 23) displays our message in the default font. As you can see in **Figure 4.7**, the default text size is quite small. To display a message in a larger font, we can use the *setFont* method of the *GraphicsContext* class as shown in **Table 4.5**. First, however, we need to create a *Font* (line 25) using the *Font* constructor shown in Table 4.6. Its only argument is a requested point size for the font; in this case, we request a font size of 28. We then set the font in line 26. Line 29 redisplays the message in the larger font with a call to *strokeText* so that the text is outlined.

Example 4.5 *DrawingText.java*



```
/* Drawing Text
   Anderson, Franceschi
*/

import javafx.application.Application;
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;
import javafx.scene.text.Font;
import javafx.stage.Stage;

public class DrawingText extends Application
{
    @Override
    public void start( Stage stage )
    {
        // set up window title and size
        GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
                  stage, "Drawing Text", 700, 400 );

        String message = "Programming is not a spectator sport!";
        gc.setFill( Color.RED );

        gc.fillText( message, 100, 100 );

        Font largeFont = new Font( 28 );
        gc.setFont( largeFont );
        gc.setStroke( Color.RED );

        gc.strokeText( message, 100, 250 );
    }

    public static void main( String [ ] args )
    {
        launch( args );
    }
}
```

Description

Figure 4.7 Output from *DrawingText.java*

Description

A *Font* Class Constructor

Font Constructor

`Font( double size )`

creates a *Font* object with a height of *size* in the default typeface

Description

What happens if the (*x*, *y*) coordinate you specify for a figure isn't inside the window? If a figure's coordinates are outside the bounds of the window, no error will be generated, but the portion of the figure outside the window bounds won't be visible.

COMMON ERROR TRAP

If you want the whole drawing to be visible, be careful to ensure that all parts of your shape are enclosed within the bounds of the window.

CODE IN ACTION

Within the online resources, you will find a movie illustrating step-by-step how to use the *GraphicsContext* drawing methods. Click on the link to start the movie.

© Hemera Technologies/Photos.com/Thinkstock

Putting all this together, we can now write an application that draws a sprite, which is a graphics object that can be positioned and drawn as a unit. **Example 4.6** shows the code to do that, and **Figure 4.8** shows our sprite.

Example 4.6 *DrawingASprite.java*

```
/* Drawing a Sprite
   Anderson, Franceschi
*/

import javafx.application.Application;
import javafx.scene.canvas.Canvas;
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;
import javafx.stage.Stage;

public class DrawingASprite extends Application
{
    @Override
    public void start( Stage stage )
    {
        // set up window title and size
        GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
                  stage, "Drawing a Sprite", 700, 400 );

       // drawing the sprite
       int sX = 275;
       int sY = 100;
       gc.setFill( Color.CORAL ); // body
       gc.fillOval( sX, sY + 20, 120, 160 );
       gc.setFill( Color.DARKGOLDENROD ); // hat
       gc.fillRect( sX + 30, sY, 60, 30 );
       gc.setStroke( Color.DARKGOLDENROD ); // hat brim
       gc.setLineWidth( 3 );
       gc.strokeLine( sX, sY + 30, sX + 120, sY + 30 );
       gc.setFill( Color.CHOCOLATE ); // eye
       gc.fillOval( sX + 80, sY + 60, 24, 16 );
       gc.setFill( Color.DARKSALMON ); // feet
       gc.setLineWidth( 1 );
       gc.fillOval( sX + 64, sY + 166, 60, 16 );
       gc.strokeOval( sX + 64, sY + 166, 60, 16 );
       gc.fillOval( sX + 36, sY + 170, 60, 16 );
       gc.strokeOval( sX + 36, sY + 170, 60, 16 );
    }

    public static void main( String [ ] args )
    {
        launch( args );
    }
}
```

Description

Figure 4.8 Output from *DrawingASprite.java with the Anchor Point Indicated*

Description

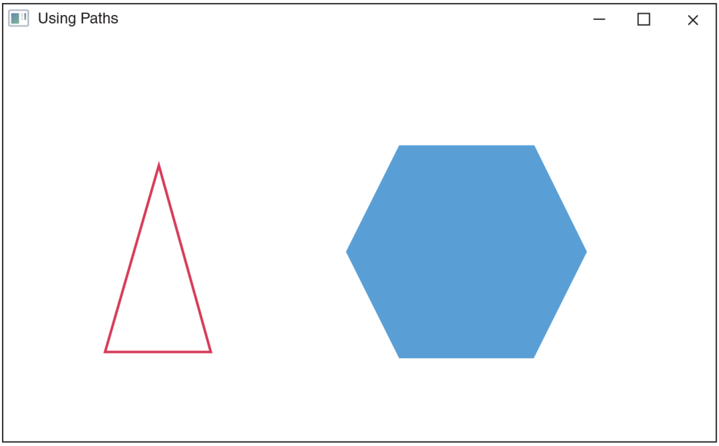
To draw our sprite, we use ovals for the body, eye, and feet, and we use a rectangle and line for the hat. We use various line widths to draw the hat brim, and we outline ovals to help define the feet.

It's important to realize that the rendering of the shapes occurs in the order in which the *stroke* or *fill* methods are executed. Any new shape that occupies the same space as a previously drawn shape will overwrite the previously drawn shape. In this drawing, we intentionally draw the eye and hat after drawing the body; and for the feet, we draw the filled ovals first, then outline the feet using stroked ovals.

In lines 21–22, we declare and initialize two variables, *sX* and *sY*. These define an **anchor point** for drawing the sprite. As indicated in Figure 4.8, the anchor point is the top-left point of the sprite's bounding rectangle. When we send *x* and *y* arguments to the *fillRect*, *strokeLine*, *fillOval*, and *strokeOval* methods, we specify those values relative to this starting (*sX*, *sY*) coordinate, or anchor point. By specifying these values relative to the anchor point—for example, *sX* 1 60—we are using **offsets**. By using offsets, we can easily change the position of the sprite on the window by simply changing the values of *sX* and *sY*. We don't need to change any of the arguments sent to the *GraphicsContext* methods. To demonstrate this, try changing the values of *sX* and *sY* and rerunning the application.

SOFTWARE ENGINEERING TIP

When drawing a figure using graphics, specify coordinates as offsets from a starting (*x*, *y*) coordinate.



4.4 Drawing Custom Shapes

To draw custom shapes we create a path, which consists of a series of coordinates between which the JavaFX platform should draw lines. Our resulting shape can be displayed either outlined or filled. Only one path can be defined at a time. **Table 4.7** shows the methods we use to create and display a path.

Path Drawing Methods of the *GraphicsContext* Class

Return Value	Method Name and Argument List
`void`	`beginPath( )` sets the drawing path to empty
`void`	`moveTo( double x, double y )` moves to the (*x*, *y*) location without adding a line to the path
`void`	`lineTo( double x, double y )` adds a line to the current path from the previous location to (*x*, *y*)

`void`	`closePath( )` closes the path by adding a line from the previous location to the first location of the path
`void`	`stroke( )` draws the path using the current stroke color
`void`	`fill( )` draws the path using the current fill color

Description

In **Example 4.7**, we illustrate drawing paths by creating an outlined triangle and a filled hexagon.

Example 4.7 *DrawingPaths.java*

```
/* Drawing Shapes Using Paths
   Anderson, Franceschi
*/

import javafx.application.Application;
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;
import javafx.stage.Stage;

public class DrawingPaths extends Application
{
    @Override
    public void start( Stage stage )
    {
        // set up window title and size
        GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
                  stage, "Using Paths", 700, 400 );

        // drawing a triangle
        // 1. create the path
        int startX = 175;
        int startY = 120;
        gc.beginPath( );
        gc.moveTo( startX, startY );
        gc.lineTo( startX - 50, startY + 175 );
        gc.lineTo( startX + 50, startY + 175 );
        gc.closePath( );

        // 2 draw the path
        gc.setStroke( Color.CRIMSON );
        gc.stroke( );

        // draw a hexagon
        // 1. create the path
        startX = 350;
        startY = 200;
        gc.beginPath( );
        gc.moveTo( startX, startY );
        gc.lineTo( startX + 50, startY - 100 );
        gc.lineTo( startX + 175, startY - 100 );
        gc.lineTo( startX + 225, startY );
        gc.lineTo( startX + 175, startY + 100 );
        gc.lineTo( startX + 50, startY + 100 );
        gc.closePath( );

        // 2. draw the path
        gc.setFill( Color.CORNFLOWERBLUE );
        gc.fill( );
    }

    public static void main( String [ ] args )
    {
        launch( args );
    }
}
```

Description

To draw our outlined triangle, we start by defining our anchor point coordinates (lines 21–22), which is the top point of the triangle. Then we call the *beginPath* method (line 23) to create an empty path. Next, we call the *moveTo* method (line 24) to set the origin of our drawing at the top point of the triangle, which is our anchor point. Of course, we could begin at any of the triangle's three points. We call the *lineTo* method (lines 25–26) twice to specify one line from the origin to the lower-left point and a second line from that location to the lower-right point.

COMMON ERROR TRAP

Forgetting to close the path could result in an incomplete shape.

We call the *closePath* method (line 27) to finish the shape; this method adds a line from our current position to the origin. Optionally, we could complete the shape by writing a third *lineTo* method call that creates a line from the lower-right point to the origin. In either case, once the path is fully defined, we draw the triangle by setting the stroke color and calling the *stroke* method (lines 29–31).

Drawing the hexagon is similar. We define coordinates for an anchor point (the leftmost point of the hexagon), begin a new path, move to our anchor point, define five lines of the hexagon using *lineTo* method calls, and close the path to finish the shape (lines 35–44). We display the filled hexagon by setting the fill color and calling the *fill* method (lines 46–49).

The resulting figures are shown in **Figure 4.9**.

4.5 Programming Activity 1: Writing an Application with Graphics

In this programming activity, you will create an application that uses graphics to draw a picture of your own design. The objective of this programming activity is to gain experience with the window coordinate system, the *stroke* and *fill* graphics methods, and using colors.

1. Start with the *ShellGraphicsApplication* class, change the name of the class to represent the figure you will draw, and add an *import* statement for the *Color* class. Remember to include the *JIGraphicsUtility.java* file in the same folder.
2. Create a drawing of your own design. It's helpful to sketch the drawing on graph paper first, then translate the drawing into the coordinates of the application window. Your drawing should define an anchor point, and include at least two each of rectangles, ovals, and lines, plus a path. Your drawing should also use at least three colors, one of which is a custom color.
3. Label your drawing using the *fillText* method.

Be creative and have fun with your drawing!

DISCUSSION QUESTIONS

1. If you define the starting (*x*, *y*) coordinate of the drawing as (800, 400), you might not be able to see the drawing. Explain why.
2. What is the advantage to drawing a figure using a starting (*x*, *y*) coordinate as an anchor point?

© Lois GoBe/Shutterstock.

CHAPTER REVIEW

4.6 Chapter Summary

- Graphical applications, which extend the JavaFX *Application* class, open a window and allow us to create graphical output.
- JavaFX applications use a performance/art metaphor with a stage corresponding to the window and a scene on which we can place a canvas.
- We put the code to draw shapes and text in the *start* method, which is called automatically when the application begins.
- The *GraphicsContext* class provides methods to draw on a canvas. Methods are provided for drawing figures, such as rectangles, ovals, custom shapes, and lines; to set the colors for drawing; and to display text in a window.
- An (*x*, *y*) coordinate system is used to specify locations in the window. Each coordinate corresponds to a pixel (or picture element). The *x* value specifies the horizontal position, beginning at 0 on the left-hand side of the window and increasing as you move right across the window. The *y* value specifies the vertical position, starting at 0 at the top of the window and increasing as you move down the window.
- All drawing on a graphics window is done in the current

stroke or fill foreground color, which are changed using the *setStroke* and *setFill* methods, respectively. The stroke color is used for lines and outlined shapes; the fill color is used for drawing solid shapes. Either the stroke or fill color can be used for text.

- Objects of the *Color* class can be used to set the current stroke or fill color. The *Color* class provides *static* constants for convenience in using colors.
- Custom *Color* objects can be instantiated by using the *rgb* factory method and specifying the red, green, and blue components of the color.
- When displaying text, we can set the size of the text by instantiating a *Font* object and calling the *setFont* method of the *GraphicsContext* class.
- A custom shape can be drawn using a path. We start by creating a new path and moving to our origin. We then define points to which lines should be drawn. When finished, we close the path, then either fill the path as a solid figure or stroke the path as an outlined figure.
- A sprite is a graphics object composed of shapes that is intended to move as a unit. When drawing a sprite, define a starting (x, y) coordinate as an anchor point and specify all x and y values for the drawing methods as offsets from the starting coordinate.

4.7 Exercises, Problems, and Projects

4.7.1 Multiple Choice Exercises

1. What package does the *GraphicsContext* class belong to?

    - *javafx.scene.paint*
    - *javafx.scene.canvas*
    - *javafx.stage*
    - *javafx.application*

6. If a window is 400 by 800 pixels, how many pixels does the window contain?

    - 1,200 pixels
    - 32,000 pixels
    - 320,000 pixels

10. A JavaFX graphical application opens a window.

    - true
    - false

13. In JavaFX graphical applications, the *start* method is called automatically; the programmer does not code the method call.

    - true
    - false

16. Look at the following code:

```
Color c = Color.BLUE;
```

What is *BLUE?*

- a *static* constant of the class *Color*
- an instance variable of the class *Color*
- a *static* method of the class *Color*
- an instance method of the class *Color*

21. What can be stated about the line drawn by the following code?

```
gc.strokeLine( 100, 200, 300, 200 );
```

Description

- The line is vertical.
- The line is horizontal.
- The line is diagonal.
- None of the above.

26. What do the arguments 10, 20 represent in the following statement?

```
gc.strokeRect( 10, 20, 100, 200 );
```

Description

- the (*x*, *y*) coordinate of the upper-left corner of the rectangle we are drawing
- the width and height of the rectangle we are drawing
- the (*x*, *y*) coordinate of the center of the rectangle we are drawing
- the (*x*, *y*) coordinate of the lower-right corner of the rectangle we are drawing

31. What do the arguments 100, 200 represent in the following statement?

```
gc.strokeRect( 10, 20, 100, 200 );
```

Description

- the (*x*, *y*) coordinate of the upper-left corner of the rectangle we are drawing
- the width and height of the rectangle we are drawing
- the height and width of the rectangle we are drawing
- the (*x*, *y*) coordinate of the lower-right corner of the rectangle we are drawing

36. How many arguments does the *fillOval* method take?

    - 0
    - 2
    - 4
    - 5

41. In RGB format, a gray color can be coded as *A A A,* where the first *A* represents the amount of red in the color, the second *A* the amount of green, and the third *A* the amount of blue. *A* can vary from 0 to 255, including both 0 and 255; how many possible gray colors can we have?

    - 1
    - 2
    - 255
    - 256
    - 257

4.7.2 Reading and Understanding Code

In questions 11 through 15, assume that *gc* is a *GraphicsContext* reference.

1. In what color will the rectangle be drawn?

```
gc.setFill( Color.BLUE );
gc.fillRect( 10, 20, 100, 200 );
```

Description

2. What is the length of the line being drawn?

```
gc.strokeLine( 50, 20, 50, 350 );
```

Description

3. What is the width of the rectangle being drawn?

```
gc.fillRect( 10, 20, 250, 350 );
```

Description

4. What is the (*x*, *y*) coordinate of the upper-right corner of the rectangle being drawn?

```
gc.fillRect( 10, 20, 250, 350 );
```

Description

5. What is the (*x*, *y*) coordinate of the lower-right corner of the rectangle being drawn?

```
gc.strokeRect( 10, 20, 250, 350 );
```

Description

4.7.3 Fill In the Code

1. This code sets the current fill color to red and the current stroke color to green.

```
// assume you have a GraphicsContext object named gc
// your code goes here
```

2. This code draws the *String* “Fill In the Code” with the lower-left corner of the first character (the *F*) being at the coordinate (100, 250).

```
// assume you have a GraphicsContext object named gc
// your code goes here
```

3. This code draws a filled rectangle with a width of 100 pixels and a height of 300 pixels, starting at the coordinate (50, 30).

```
// assume you have a GraphicsContext object called gc
// your code goes here
```

4. This code draws a filled rectangle starting at (50, 30) for its upper-left corner with a lower-right corner at (100, 300).

```
// assume you have a GraphicsContext object called gc
// your code goes here
```

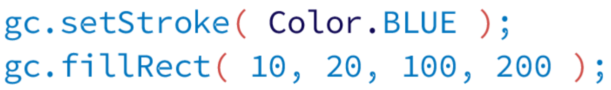
5. This code draws a circle of radius 100 with its center located at (200, 200).

```
// assume you have a GraphicsContext object called gc
// your code goes here
```

4.7.4 Identifying Errors in Code

In questions 21 through 25, assume that *gc* is a *GraphicsContext* reference.

1. Where is the logic error in this code sequence that attempts to draw a solid blue rectangle?



```
gc.setStroke( Color.BLUE );
gc.fillRect( 10, 20, 100, 200 );
```

Description

2. Where is the error in this code sequence?

```
gc.fillText( 'Find the bug', 100, 200 );
```

Description

3. Where is the error in this code sequence?

```
gc.setFill( GREEN );
```

Description

4. Where is the error in this code sequence?

```
gc.setColor( Color.RED );
```

Description

5. Where is the error in this code sequence?

```
gc.color = Color.RED;
```

Description

6. Where is the error in this statement?

```
import java.GraphicsContext;
```

Description

7. Where is the error in this statement?

```
import java.stage.Stage;
```

Description

4.7.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

1. You coded the following program in the file *MyDrawingApp.java*.

```
import javafx.application.Application;
import javafx.scene.canvas.GraphicsContext;
import javafx.stage.Stage;
public class MyDrawingApp extends Application
{
    @Override
    public void start( Stage stage )
    {
        GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
                   stage, "Tester", 700, 400 );
        gc.strokeRect( 725, 200, 50, 50 );
    }

    public static void main( String [ ] args )
    {
       launch( args );
    }
}
```

Description

You get no compiler errors, but when you run the program, the rectangle doesn't appear. Explain what the problem is and how to fix it.

2. You imported the *Color* class and coded the following on line 10 of the class *MyApplication.java*:

```
Color c = Color.rgb( 1.4, 234, 23 );    // line 10
```

Description

When you compile, you get the following message:

```
MyApplication.java:10: error: incompatible types: possible
lossy conversion from double to int
Color c = Color.rgb( 1.4, 234, 23 );    // line 10
                     ^
1 error
```

Description

Explain what the problem is and how to fix it.

3. You coded the following on line 10 of the class *MyApplication.java*:

```
Color c = Color.Blue;    // line 10
```

Description

When you compile, you get the following message:

```
MyAppliction.java:10: error: cannot find symbol
     Color c = Color.Blue;    // line 10
                    ^
symbol : variable Blue
location : class Color
1 error
```

Description

Explain what the problem is and how to fix it.

4.7.6 Write a Short Program

1. Write an application that displays the five Olympic rings.
2. Write an application that displays a tic-tac-toe board. Include a few Xs and Os.
3. Write an application that displays a rhombus (i.e., a parallelogram with equal sides). Your rhombus should not be a square.

4.7.7 Programming Projects

1. Write an application that displays two eyes. An eye can be drawn using an oval, a filled circle, and lines. On the window, write a word or two about these eyes.
2. Write an application that displays the following coins: a quarter, a dime, and a nickel. These three coins should be drawn as basic circles (of different diameters) with the currency value displayed inside the coin (for example, “25¢”). (Hint: Use the Unicode currency symbols chart to find the encoding for a cent sign.)

3. Write an application that displays a basic house made up of lines (and possibly rectangles). Your house should have multiple colors. Display a title for the house (for instance, “Java House”).

4. Write an application that displays four concentric circles. Each circle should have a lighter shade of the same color. (Hint: Look up the *brighter* method in the *Color* class.)

4.7.8 Technical Writing

1. Explain some advantages to displaying data visually as charts. Also, explain the role that color can play in communicating data values.
2. If the *strokeRect* method did not exist, but you still had the *strokeLine* method available, explain how you would be able to draw a rectangle.

4.7.9 Group Project (for a group of 1, 2, or 3 students)

1. Write an application that displays the following:
   - a drawing of two or three chessboard pieces as sprites; use a path for at least part of the drawing

- a description of one of the chessboard pieces (for instance, a rook) and its main legal moves

In order to make the description visually appealing, use several colors and several fonts.

Introduction

The order of a program's instructions, called the **flow of control** of the program, is critical to producing correct results. There are essentially four types of flow of control: sequential execution, method calls, selection, and looping. Most programs use a combination of all types of flow of control.

With sequential execution in an application, the JVM executes each instruction in order. Whenever one of the instructions includes a method call, control transfers to the method, where its instructions are executed. When the method completes, we resume execution of the original instructions in order.

Sometimes, however, we don't want to execute every instruction. Some instructions should be executed only for certain input values, but not for others. For example, we may want to count only the odd numbers or perform only the operation that the user selects from a menu. For these applications, we need a way to determine at run time the input values we have and, therefore, which instructions we should execute.

In this chapter, we'll discuss **selection**, which gives us a way to test for certain conditions and to select the instructions to execute based on the results of the test. To perform selection, Java provides a number of alternatives: *if*, *if/else*, *if/else if*, the conditional operator (?:), and *switch*.

```
75 > 18 && 75 < 65 is false
75 < 65 && 75 > 18 is false
75 > 65 || 75 < 18 is true
75 > 65 || 75 < 18 && false is true
( 75 > 65 || 75 < 18 ) && false is false
```

5.1 Forming Conditions

Often in a program, we need to compare variables or objects. For instance, to determine whether someone can shop online, we want to know if the person's age is at least 18. Or, if we are adding students to the honor roll, we want to add only those students with averages of 90 or better. Similarly, if we are sending warnings to students, we want to send those warnings only to students whose averages are below 60.

Java provides equality, relational, and logical operators to evaluate and test whether an expression is true or false. It also provides selection statements to transfer control to a different part of the program depending on the result of that test.

5.1.1 Equality Operators

A common operation is to compare two variables or values of the same data type to determine if their values are equal. For example, we need to compare the user's input to a 'y' to determine whether he or she wants to play a game again. Or if we want to print a list of students who will continue next year, we need to eliminate the students who are graduating seniors.

To compare values of primitive data types, Java provides the **equality operators** shown in **Table 5.1**. Both are binary operators, meaning that they take two operands. The operands may be expressions that evaluate to a primitive numeric or *boolean* type or an object reference. The result of an expression composed of a relational operator and its two operands is a *boolean* value, that is, *true* or *false*.

Equality Operators

Equality Operator	**Type**	**Meaning**
==	binary	is equal to
!=	binary	is not equal to

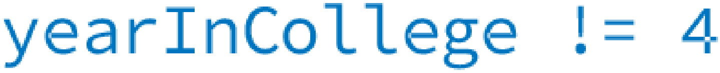
Description

For instance, if an *int* variable *age* holds the value 32, then

the expression `( age == 32 )` will evaluate to *true*, and

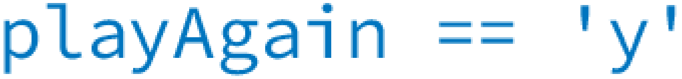
the expression `( age != 32 )` will evaluate to *false*.

The following expression can be used to eliminate seniors by testing whether the value of the *int* variable *yearInCollege* is not equal to 4:



```
yearInCollege != 4
```

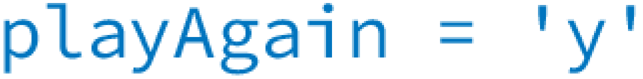
The following expression can be used in a game program to determine whether the user wants to play again:



```
playAgain == 'y'
```

Assuming the user’s input is stored in the *char* variable *playAgain*, then if the user typed ‘y’, the expression evaluates to *true*; with any other input value, the expression evaluates to *false*.

A common error is to use the assignment operator instead of the equality operator. For example:



```
playAgain = 'y'
```

actually **assigns** the value *y* to the variable *playAgain*.

COMMON ERROR TRAP

Do not confuse the equality operator == (double equal signs) with the assignment operator = (one equal sign).

Although the equality operators can be used to compare object references, these operators cannot be used to compare object data. We discuss the comparison of objects later in the chapter.

5.1.2 Relational Operators

To compare values of primitive numeric types, Java provides the **relational operators** shown in **Table 5.2**. These operators are binary, meaning that they take two operands, each of which is an expression that evaluates to a primitive numeric type. The relational operators cannot be used with *boolean* expressions or with object references.

Relational Operators

Relational Operator	Type	Meaning
<	binary	is less than
<=	binary	is less than or equal to
>	binary	is greater than
>=	binary	is greater than or equal to

Description

Again, if an *int* variable *age* holds the value 32, then

the expression `( age < 32 )` will evaluate to *false*,

the expression `( age <= 32 )` will evaluate to *true*,

the expression `( age > 32 )` will evaluate to *false*, and

the expression `( age >= 32 )` will evaluate to *true*.

This expression tests whether an *int* variable *testScore* is at least 90:

```
testScore >= 90
```

Description

This code tests whether that test score is less than 60:

```
testScore < 60
```

5.1.3 Logical Operators

A common operation in a program is to test whether a combination of conditions is true or false. For these operations, Java provides the **logical operators** !, &&, and ||, which correspond to the Boolean logic operators NOT, AND, and OR. These operators, which are shown in **Table 5.3**, take *boolean* expressions as operands. A *boolean* expression can be a combination of variables, operators, and method calls that result in a *boolean* value.

Logical Operators

Logical Operator	Type	Meaning
`!`	unary	NOT
`&&`	binary	AND
`||`	binary	OR

Description

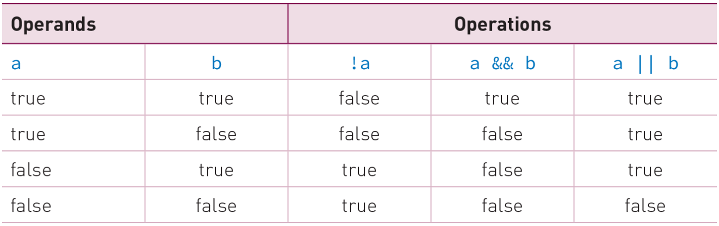
The NOT operator (!) takes one *boolean* expression as an operand and inverts the value of that operand. If the operand is *true*, the result will be *false*; and if the operand is *false*, the result will be *true*.

The AND operator (&&) takes two *boolean* expressions as operands; if both operands are *true*, then the result will be *true*; otherwise, the result will be *false*.

The OR operator (||) also takes two *boolean* expressions as operands. If both operands are *false*, then the result will be *false*; otherwise, it will be *true*. The OR operator consists of two vertical bars with no intervening space. On the PC keyboard, the vertical bar is the shifted character above the *Enter* key.

The truth table for these logical operators is shown in **Table 5.4**.

Truth Table for Logical Operators



Operands		Operations		
a	b	!a	a && b	a || b
true	true	false	true	true
true	false	false	false	true
false	true	true	false	true
false	false	true	false	false

Description

REFERENCE POINT

The complete Operator Precedence Chart is provided in Appendix B.

The order of precedence of the relational and logical operators is shown in **Table 5.5**, along with the arithmetic operators. Note that the Unary NOT operator (!) has the highest precedence of the relational and logical operators, followed by the relational operators, then the equality operators, then AND (&&), then OR (||).

Operator Precedence

Operator Hierarchy	Order of Same-Statement Evaluation	Operation
`( )`	left to right	parentheses for explicit grouping
`++, --`	right to left	shortcut postincrement/ postdecrement
`++, --, !`	right to left	shortcut preincrement/ predecrement, logical

		unary NOT
`*, /, %`	left to right	multiplication, division, modulus
`+, -`	left to right	addition or *String* concatenation, subtraction
`<, <=, >, >=`	left to right	relational operators: less than, less than or equal to, greater than, greater than or equal to
`==, !=`	left to right	equality operators: equal to and not equal to
`&&`	left to right	logical AND
`||`	left to right	logical OR
`=, +=, -=, *=, /=, %=`	right to left	Assignment operator and shortcut assignment operators

Description

Example 5.1 shows these operators at work.

Example 5.1 How Logical Operators Work

```
 1 /* Using Logical Operators
 2    Anderson, Franceschi
 3 */
 4
 5 public class LogicalOperators
 6 {
 7  public static void main( String [ ] args )
 8  {
 9   int age = 75;
10   boolean test;
11
12   test = ( age > 18 && age < 65 );
13   System.out.println( age + " > 18 && " + age + " < 65 is " + test );
14
15   // short circuitry with AND
16   test = ( age < 65 && age > 18 );
17   System.out.println( age + " < 65 && " + age + " > 18 is " + test );
18
19   // short circuitry with OR
20   test = ( age > 65 || age < 18 );
21   System.out.println( age + " > 65 || " + age + " < 18 is " + test );
22
23   // AND has higher precedence than OR
24   test = ( age > 65 || age < 18  && false );
25   System.out.println( age + " > 65 || " + age
26                       + " < 18 && false is " + test );
27
28   // use of parentheses to force order of execution
29   test = ( ( age > 65 || age < 18 )  && false );
30   System.out.println( "( " + age + " > 65 || " + age
31                       + " < 18 ) && false is " + test );
32  }
33 }
```

Description

Line 12 evaluates whether the variable *age* is greater than 18 and less than 65 and assigns the result to the *boolean* variable *test*. Since line 9 set the value of *age* to 75, the first operand (*age . 18*) evaluates to *true*. The second operand (*age , 65*) evaluates to *false*; finally,

```
true && false
```

evaluates to *false*, and *false* is assigned to *test*, which is printed at line 13. Line 16 evaluates the same expression as in line 12, but in reverse order. Now the first operand (*age , 65*) evaluates to *false*, and therefore, since the operator is the logical AND, the overall expression evaluates to *false*, independently of the value of the second operand. Because (*false* && something) always evaluates to *false*, the second operand (*age . 18*) will never be evaluated by the JVM. This is called **short-circuit**

evaluation.

Line 20 shows an example of short-circuit evaluation for the logical OR operator. The first operand (*age > 65*) evaluates to *true*, resulting in the overall expression evaluating to *true*, independently of the value of the second operand. Because (*true* || something) always evaluates to *true*, the second operand will never be evaluated by the JVM.

As shown in Table 5.5, the logical AND operator has higher precedence than the logical OR operator. Thus, the expression in line 24 is not evaluated from left to right; rather, the second part of the expression (*age , 18* && *false*) is evaluated first, which evaluates to *false*. Then (*age . 65* || *false*) evaluates to *true*, which is assigned to *test*, and then output at lines 25–26. If we want to evaluate the expression from left to right, we have to use parentheses to force this, as in line 29. Then, (*age > 65* || *age , 18*) is evaluated first and evaluates to *true*; (*true* && *false*) is evaluated next and evaluates to *false*.

Figure 5.1 shows the output of Example 5.1.

Figure 5.1 Output from Example 5.1

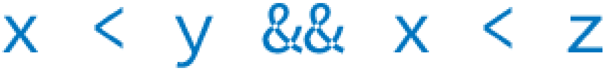
Description

Suppose we have three *ints: x, y*, and *z*, and we want to test if *x* is less than both *y* and *z*. A common error is to express the condition this way:

```
x < y && z // incorrect comparison of x to y and z
```

Description

Because *z* is not a *boolean* variable, this statement will generate a compiler error. Both operands of the logical AND and logical OR operators must evaluate to a *boolean* expression. The correct expression is the following:



```
x < y && x < z
```

Description

COMMON ERROR TRAP

Be sure that both operands of the logical AND and logical OR operators are *boolean* expressions. Expressions such as `x < y && z`, with *x, y,* and *z* being numeric types, are illegal. Instead, use the expression `x < y && x < z`

There are often several ways to express the same condition using the Java logical operators. For instance, suppose we have two boolean variables called *flag1* and *flag2*, and we want to test if at least one of them is *false*.

In plain English, we would translate it as *flag1* is *false* OR *flag2* is *false*.

Table 5.6 provides several equivalent expressions for the preceding test.

Examples of Equivalent Expressions

Equivalent Expressions	English Meaning
`( flag1 == false ) || ( flag2 == false )`	*flag*1 is false OR *flag*2 is false
`!flag1 || !flag2`	!*flag*1 is true OR !*flag*2 is true
`! ( flag1 && flag2 )`	not both *flag*1 and *flag*2 are true

Description

Although all the expressions in Table 5.6 are equivalent, the first expression, which is the simplest translation of the condition to test, is the easiest to understand and would be the best selection for readability.

DeMorgan’s Laws

Thanks to the work of the British mathematician Augustus DeMorgan, we have a set of rules to help develop expressions that are equivalent. DeMorgan, who is known for his work in Boolean algebra and set theory, developed what are known as DeMorgan’s Laws. They are the following:

1. `NOT( A AND B ) = ( NOT A ) OR ( NOT B )`
2. `NOT( A OR B ) = ( NOT A ) AND ( NOT B )`

Description

In Java, therefore, using the first law, we see that

`!( a && b )` is equivalent to `!a || !b`

Description

Using the second law, we see that

`!( a || b )` is equivalent to `!a && !b`

Description

These laws are illustrated in the extended truth table shown in **Table 5.7**.

Truth Table for DeMorgan's Laws

a	b	!a	!b	a && b	a || b	!(a && b)	!a || !b	!(a || b)	!a && !b
true	true	false	false	true	true	false	false	false	false
true	false	false	true	false	true	true	true	false	false
false	true	true	false	false	true	true	true	false	false
false	false	true	true	false	false	true	true	true	true

Description

Thus, to use DeMorgan's Laws, we change the AND operator to OR and change the OR operator to AND, and apply the NOT operator (!) to each operand of a logical operator. When the operands are expressions using relational or equality operators, the negated expressions are shown in **Table 5.8**.

The Logical NOT Operator Applied to Relational and Equality Operators

Expression	! (Expression)
a == b	a != b
a != b	a == b
a < b	a >= b
a >= b	a < b
a > b	a <= b
a <= b	a > b

Description

SOFTWARE ENGINEERING TIP

Compose Boolean expressions so that they are easy to read and understand.

For instance, suppose we have an *int* variable named *age*, representing the age of a person, and we want to assess whether *age* is less than or equal to 18 or greater than or equal to 65.

Table 5.9 provides several equivalent expressions for the preceding test.

Again, although all the expressions in Table 5.9 are equivalent, the first expression, which is the simplest translation of the condition to test, is the easiest to read.

More Examples of Equivalent Expressions

Equivalent Expressions	English Meaning
`( age <= 18 || age >= 65 )`	*age* is less than or equal to 18 or *age* is greater than or equal to 65
`!( age > 18 && age < 65 )`	*age* is not between 18 and 65
`!( age > 18 ) || !( age < 65 )`	*age* is not greater than 18 or *age* is not less than 65

Description

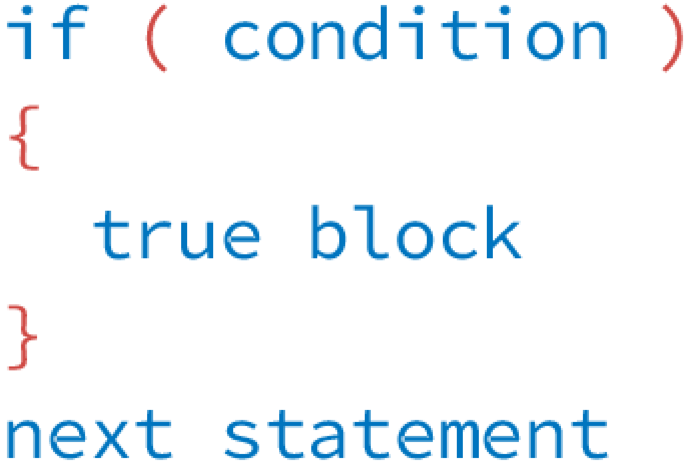
condition?
false
true
true block
next statement

```
Enter your test grade > 85
Enter your extra credit > 10
Your final test grade is 95
```

```
Enter your test grade > 85
Enter your extra credit > 0
Your final test grade is 85
```

5.2 Simple Selection with *if*

The simple selection pattern is appropriate when our program needs to perform an operation for one set of data, but not for all other data. For this situation, we use a simple *if* statement, which has this pattern:



```
if ( condition )
{
   true block
}
next statement
```

Description

The true block can contain one or more statements and is executed only if the condition evaluates to *true*. After the true block executes, the instruction following the *if* statement is executed. If the condition is *false*, the true block is skipped and execution picks up at the next instruction after the *if* statement. If the true block contains only one statement, the curly braces are optional. **Figure 5.2** illustrates the flow of control of a simple *if* statement.

Figure 5.2 Flow of Control of a Simple *if* Statement

Description

In **Example 5.2**, we first prompt the user to enter a grade at lines 12–13. Then we prompt the user for any extra credit points at lines 15–16. At line 18, we test whether the extra credit points are greater than 0. If so, we add the extra credit points to the test grade at line 19. Then, no matter what the extra credit was, lines 21–22 are executed, which print the final grade. **Figures 5.3** and **5.4** show two runs of the program, one with extra credit greater than 0, and one with no extra credit.

Example 5.2 Working with *if* Statements

```
 1 /* Using if to calculate a final test grade
 2    Anderson, Franceschi
 3 */
 4 import java.util.Scanner;
 5
 6 public class TestGrade
 7 {
 8   public static void main( String [ ] args )
 9   {
10     Scanner scan = new Scanner( System.in );
11
12     System.out.print( "Enter your test grade > " );
13     int grade = scan.nextInt( );
14
15     System.out.print( "Enter your extra credit > " );
16     int extraCredit = scan.nextInt( );
17
18     if ( extraCredit > 0 )
19         grade += extraCredit;
20
21     System.out.println( "Your final test grade is "
22                   + grade );
23   }
24 }
```

Description

Figure 5.3 Output of Example 5.2 with 10 Extra Credit Points

Description

Figure 5.4 Output of Example 5.2 with No Extra Credit

Description

Notice the indentation of the true block (line 19). Indenting clarifies the structure of the program. It's easy to see that we add the extra credit to the test grade only if the condition is true. Notice also that we skipped a line after the end of the *if* statement; this further separates the true block from the instruction that follows the *if* statement, making it easier to see the flow of control.

SOFTWARE ENGINEERING TIP

Indent the true block in an *if* statement for clarity.

Many software engineers believe it's a good practice to include the curly braces even if only one statement is included in the true block, because it increases clarity and ease of maintenance. The curly braces increase clarity because they highlight the section of code to be executed when the condition is *true*. Program maintenance is easier because if the program requirements change and we need to add a second statement to the true block, the curly braces are already in place.

Note that there is no semicolon after the condition. If we place a semicolon after the condition, as in this **incorrect** statement,

```
if ( grade >= 60 ); // incorrect to place semicolon here
      System.out.println( "You passed" );
```

Description

COMMON ERROR TRAP

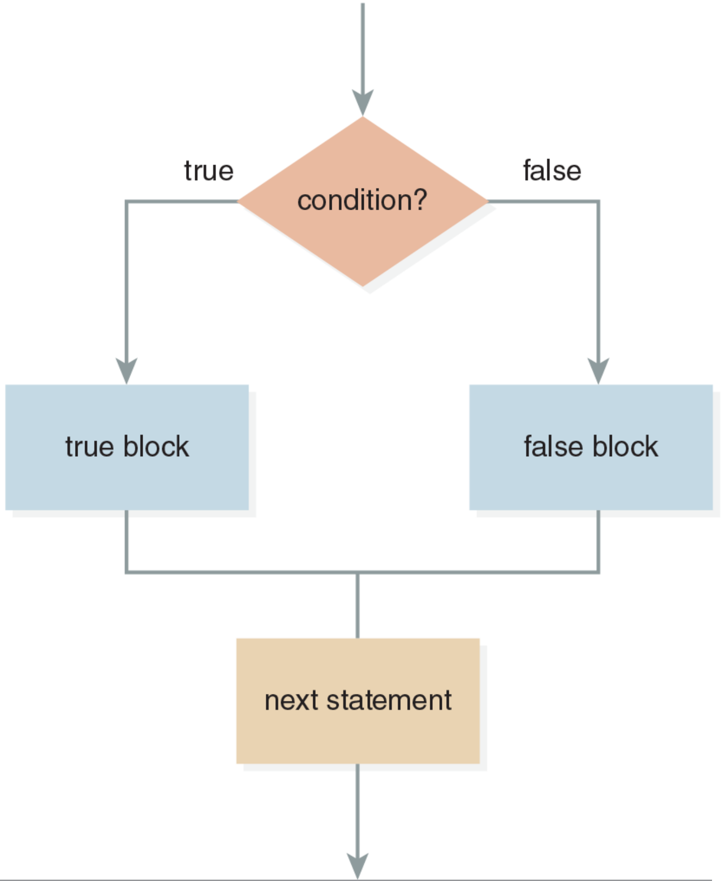
Adding a semicolon after the condition of an *if* statement indicates that the true block is empty and can cause a logic error at run time.

the compiler will not generate an error. Instead, it will consider the semicolon to indicate that the true block of the *if* statement is empty, because a semicolon by itself indicates a statement that does nothing. In this case, the compiler concludes that there is no instruction to execute when the condition is *true*. As a result, when the program runs, the statement

```
System.out.println( "You passed" );
```

Description

is treated as though it follows the *if* statement, and therefore, the message `“You passed”` will be printed regardless of the value of *grade*.



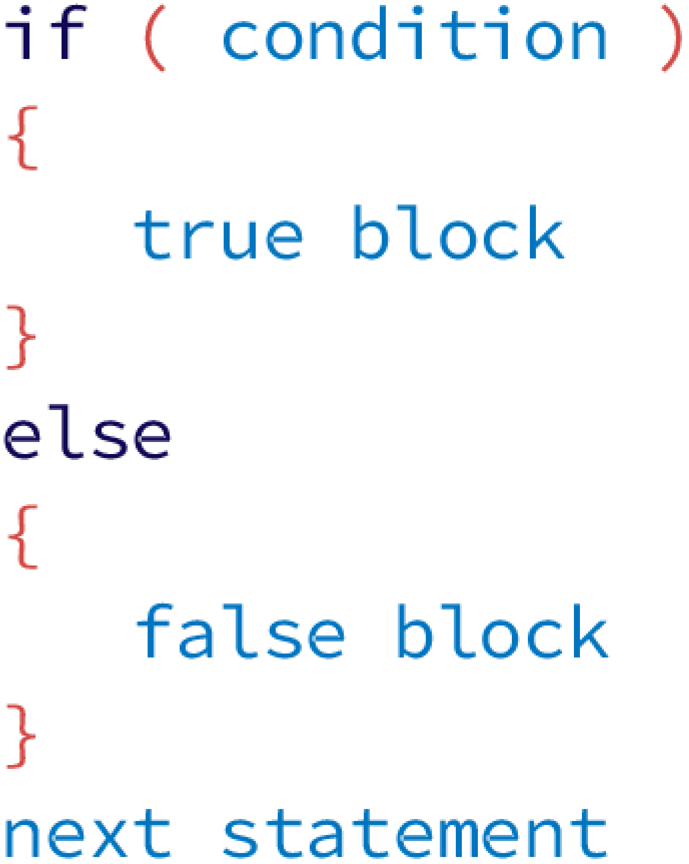
true
condition?
false
true block
false block
next statement

```
Enter a grade > 60
You passed
```

```
Enter a grade > 59
You failed
```

5.3 Selection Using *if/else*

The second form of an *if* statement is appropriate when the data falls into two mutually exclusive categories and different instructions should be executed for each category. For these situations, we use an *if/else* statement, which has the following pattern:



```
if ( condition )
{
    true block
}
else
{
    false block
}
next statement
```

Description

If the condition evaluates to *true*, the true block is executed and the false block is skipped. If the condition evaluates to *false*, the true block is skipped and the *false* block is executed. In either situation, the statement following the *if* statement is executed next. **Figure 5.5** illustrates the flow of control of an *if/else* statement.

Figure 5.5 Flow of Control of an *if/else* Statement

Description

If the true or false block contains only one statement, the curly braces are optional for that block.

Again, notice the indentation of the true and false blocks and that the *else* and curly braces line up under the *if*. This coding style makes it easy to see which statements belong to the true block and which belong to the false block. If the indentation is incorrect, a reader of our program may misunderstand which statements will be executed. In any event, the compiler ignores the indentation; the indentation is designed only to make it easier for humans to understand the logic of the code.

In **Example 5.3**, we test a grade to determine whether it is a passing grade (.5 60) or a failing grade (any other value). This is a case where the data is mutually exclusive: either the grade is a passing grade or it is not. We want to print a different message depending on the grade. After prompting the user for a numeric grade, we declare a *String* to hold the appropriate message (line 16), which will be determined in our *if/else* statement. If the *if* condition, `(grade >= 60)`, is true, then we assign “You passed” to *message*. If the condition is false, we assign “You failed” to *message*. On line 22, after the *if/else* statement completes, we print whatever *String* we have assigned to *message*. **Figures 5.6** and **5.7** show two runs of the program, first with a grade greater than or equal to 60, and then with a grade less than 60.

Example 5.3 Working with *if/else* Statements

```
/* Using if/else
   Anderson, Franceschi
*/

import java.util.Scanner;

public class PassingGrade
{
 public static void main( String [ ] args )
 {
    Scanner scan = new Scanner( System.in );

    System.out.print( "Enter a grade > " );
    int grade = scan.nextInt( );

    String message;
    if ( grade >= 60 )
     message = "You passed";
    else
     message = "You failed";

    System.out.println( message );
 }
}
```

Description

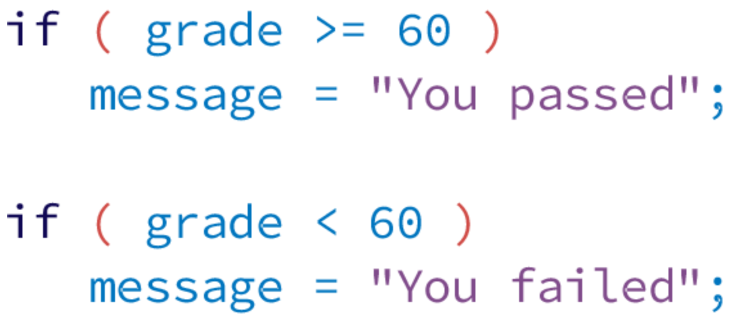
Figure 5.6 Output from Example 5.3 with *grade* >= 60

Description

Figure 5.7 Output from Example 5.3 with *grade* < 60

Description

Note that we could have used two sequential *if* statements, as in:



```
if ( grade >= 60 )
   message = "You passed";

if ( grade < 60 )
   message = "You failed";
```

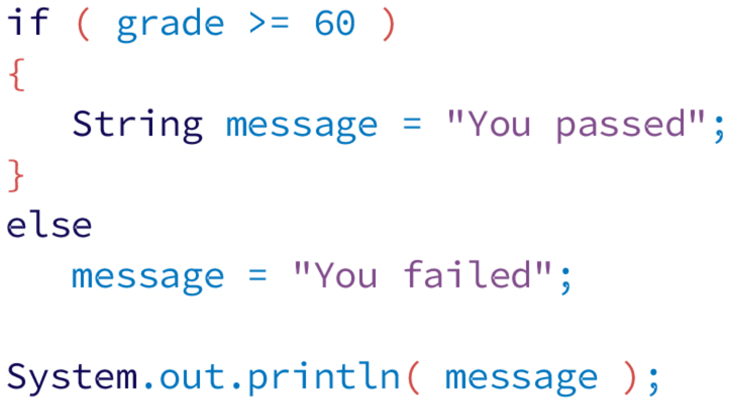
Description

However, if the first condition, `(grade >= 60)`, is false, the second condition, `(grade < 60)`, must be true. So an *if/else* simplifies our processing and avoids unnecessarily testing two conditions when only one of the conditions can be true.

Block Scope

The **scope** of a variable is the region within a program where the variable can be **referenced**, or used. When we declare a variable, its scope extends from the point at which it is declared until the end of the block in which we declared it. A method, such as *main*, is a block. Thus, in Example 5.3, the scope of the object reference *scan* extends from line 11 through the end of *main*. Thus, we can legally reference *scan* on line 14. Similarly, the scope of *grade* extends from its declaration (line 14) through the end of *main*, and we can legally reference it on line 17 in the *if* condition. Finally, the scope of the *String message* extends from line 16 through the end of *main*, and thus we can legally reference *message* on lines 18, 20, and 22.

The true blocks and false blocks for *if* statements are also blocks. Thus, if instead of declaring the *String message* on line 16, we declare it inside the true block of the *if* statement as in the following,



```
if ( grade >= 60 )
{
   String message = "You passed";
}
else
   message = "You failed";

System.out.println( message );
```

Description

then the scope of *message* extends from its declaration only until the end of the true block. In this case, the compiler will generate “cannot find symbol” error messages for the references to *message* inside the false block and for the *System.out.println* statement after the *if* statement because *message* is out of scope outside of the true block.

CODE IN ACTION

Within the online resources, you will find a movie illustrating step-by-step how to use an *if/else* statement. Click on this chapter’s link to start the movie.

condition n?
true
false
true block for condition n
false block (optional)
next statement

```
Enter your test grade: 83
Your test grade of 83 is a letter grade of B
```

5.4 Selection Using *if/else if*

The last form of an *if* statement is appropriate when the data falls into more than two mutually exclusive categories and the appropriate instructions to execute are different for each category. For this situation, Java provides the *if/else if* statement.

The *if/else if* statement follows this pattern:

```
if ( condition 1 )
{
      true block for condition 1
}
else if ( condition 2 )
{
      true block for condition 2
}
. . .
else if ( condition n )
{
      true block for condition n
}
else
{
      false block for all conditions being false
}
next statement
```

Description

The flow of control for this form of the *if* statement is shown in **Figure 5.8**.

Figure 5.8 Flow of Control of an *if/else if* Statement

Description

There can be any number of conditions in an *if/else if* statement. As we can see, once a condition evaluates to *true* for any value, control moves to the true block for that condition, then skips the remainder of the conditions, continuing execution at any statement that follows the *if/else if* statement. The final false block (along with the final *else*) is optional and is executed only when none of the conditions evaluates to *true*. Note that if the final *else* is used, then the condition it covers is not coded. The *else* stands alone on the line.

We can use the *if/else if* statement to determine a student's letter grade based on his or her numeric grade. **Example 5.4** demonstrates a Java application that prompts a student for a test grade and translates that grade into a letter grade.

Example 5.4 A Demonstration of *if/else if*

```java
/* A program to translate a numeric grade into a letter grade
   Anderson, Franceschi
*/

import java.util.Scanner;

public class LetterGrade
{
  public static void main( String [ ] args )
  {
    Scanner scan = new Scanner( System.in );

    char letterGrade;

    System.out.print( "Enter your test grade: " );
    int grade = scan.nextInt( );

    if ( grade >= 90 )
         letterGrade = 'A';

    else if ( grade >= 80 )
         letterGrade = 'B';

    else if ( grade >= 70 )
         letterGrade = 'C';

    else if ( grade >= 60 )
         letterGrade = 'D';

    else  // grade fits none of the conditions
          letterGrade = 'F';

    System.out.println( "Your test grade of " + grade
                        + " is a letter grade of " + letterGrade );
  }
}
```

Description

COMMON ERROR TRAP

In an *if/else* or *if/else if/else* statement, do not specify a condition for the final *else*.

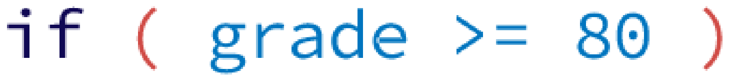
Figure 5.9 shows the output from the program when a student enters a grade of 83.

Figure 5.9 Output from Example 5.4

Description

Notice that each condition is a simple relational expression.

Even though we assign a *B* letter grade when the numeric grade is between 80 and 89, the condition for a *B* letter grade (line 21) is simply:



```
if ( grade >= 80 )
```

Description

We don’t need to write the condition as

```
if ( grade >= 80 && grade < 90 )
```

Description

because by the time the condition is tested at line 21, all numeric grades greater than or equal to 90 have been eliminated by the test condition at line 18. Any grade greater than or equal to 90 causes the condition at line 18, `( grade >= 90 )`, to evaluate to *true*. For those grades, the flow of control is to assign an *A* to *letterGrade* at line 19, then skip the remainder of the conditions, continuing execution at the statement following the *if/else if* statement, which is line 33 in this example. Thus, if the condition at line 21 is evaluated, we know that the *grade* must be less than 90. Note that in line 30, the final *else* covers the only other possibility: that the grade is less than 60. We do not code that condition; rather we include only the *else*.

CODE IN ACTION

5.14.1	Multiple Choice Exercises Question 8
5.14.2	Reading and Understanding Code

5.14.4

Question 15
Identifying Errors in Code
Questions 36, 37, 38

```
Enter the first integer: 6
Enter the second integer: 7
Enter the third integer: 5
The smallest is 5
```

```
I'm thinking of a number between 1 and 10. What is your guess? 2
The number was 10
You missed it by a mile!
Better luck next time.
```

5.5 Sequential and Nested *if/else* Statements

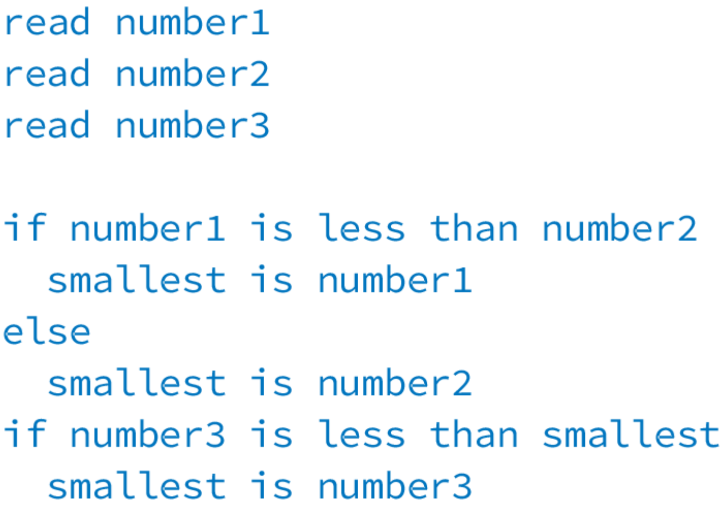
When we need the results of one *if* statement's processing before we can evaluate the next condition, we can write multiple *if* statements either sequentially or nested within other *if* statements.

5.5.1 Sequential *if/else* Statements

Finding the Minimum or Maximum Values

To illustrate sequential *if* statements, let's look at the problem of finding the smallest of three numbers.

We can use multiple, sequential *if* statements. First we find the smaller of the first two numbers, then we find the smaller of that result and the third number. The pseudocode for this application is:



```
read number1
read number2
read number3

if number1 is less than number2
  smallest is number1
else
  smallest is number2
if number3 is less than smallest
  smallest is number3
```

Description

Translating the pseudocode into Java, we get the application in **Example 5.5**, which prompts the user for three integers and outputs the smallest of the three numbers. In this application, we use two sequential *if* statements. The first *if* statement (lines 23–26) uses an *if/else* statement to find the smaller of the first two integers and stores that value into the variable *smallest*. Then, the second *if* statement (lines 28–29) compares the third integer to the value stored in *smallest*. In the second *if* statement, we don’t use an *else* clause, because we need to change the value in *smallest* only if the condition is *true*, that is, if the third number is less than *smallest*. Otherwise, the smallest value is already stored in *smallest*.

Example 5.5 An Application with Sequential *if* Statements

```
/* Find the smallest of three integers
   Anderson, Franceschi
*/

import java.util.Scanner;

public class FindSmallest
{
  public static void main( String [ ] args )
  {
       int smallest;
       int num1, num2, num3;

       Scanner scan = new Scanner( System.in );

       System.out.print( "Enter the first integer: " );
       num1 = scan.nextInt( );
       System.out.print( "Enter the second integer: " );
       num2 = scan.nextInt( );
       System.out.print( "Enter the third integer: " );
       num3 = scan.nextInt( );

       if ( num1 < num2 )
          smallest = num1;
       else
          smallest = num2;

       if ( num3 < smallest )
          smallest = num3;

       System.out.println( "The smallest is " + smallest );
  }
}
```

Description

When the program in Example 5.5 is run using 6, 7, and 5 for the three integers, the output is as shown in **Figure 5.10**.

Figure 5.10 Output from Example 5.5

Description

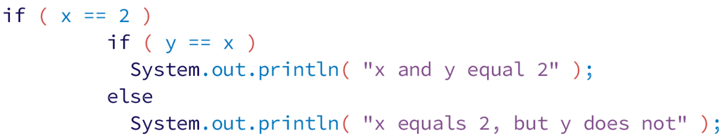
One more point. The code only checks that one number is less than another. What happens if two or more of the numbers are equal? The code still works! We only need to find the smallest value; we don’t care which of the variables holds that smallest value.

5.5.2 Nested *if/else* Statements

If statements can be written as part of the true or false block of another *if* statement. These are called nested *if* statements. Typically, we nest *if* statements when more information is required beyond the results of the first *if* statement.

One difficulty that arises with nested *if* statements is specifying which *else* clause pairs with which *if* statement, especially if some *if* statements have *else* clauses and others do not. The compiler matches any *else* clause with the most previous *if* statement that doesn't already have an *else* clause. If this matching is not what we want, we can use curly braces to specify the desired *if/else* pairing.

In this code, we have one *if* statement nested within another *if* statement.

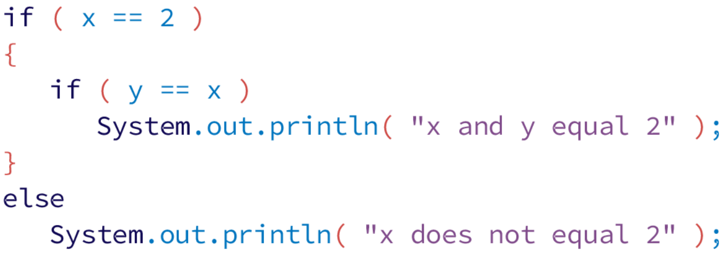


```
if ( x == 2 )
         if ( y == x )
           System.out.println( "x and y equal 2" );
         else
           System.out.println( "x equals 2, but y does not" );
```

Description

Without curly braces, the entire second *if* statement comprises the true block of the first condition `(x == 2)`, and the *else* is paired with the second condition `(y == x)`, because this is the most previous *if* condition that doesn't have an *else*.

However, we can force the *else* clause to be paired with the first condition by using curly braces, as follows:



```
if ( x == 2 )
{
   if ( y == x )
      System.out.println( "x and y equal 2" );
}
else
   System.out.println( "x does not equal 2" );
```

Description

With the curly braces added, the *if* condition `(y == x)`, along with its true block, becomes the complete true block for the condition `(x == 2)`, and the *else* clause now belongs to the first *if* condition `(x == 2)`.

Why can't we just alter the indentation to indicate our meaning? Remember that indentation increases the readability of the code for humans. The compiler ignores indentation and instead follows Java's syntactic rules.

Dangling else

A common error is writing *else* clauses that don't match any *if* conditions. This is called a **dangling else**. For example, the following code, which includes three *else* clauses and only two *if* conditions, will generate this compiler error:

```
'else' without 'if'
```

```
if ( x == 2 )

  if ( y == x )

     System.out.println( "x and y equal 2" );

  else // matches y==x
     System.out.println( "y does not equal 2" );

else // matches x==2
  System.out.println( "x does not equal 2" );

 else // no matching if!
  System.out.println( "x and y are not equal" );
```

Description

COMMON ERROR TRAP

Be sure that all *else* clauses match an *if* condition. Writing *else* clauses that don't match *if* conditions will generate an `'else' without 'if'` compiler error.

For a more complex and real-world example of nested *if* statements, let’s generate a random number between 1 and 10. After we generate the random number, we’ll prompt the user for a guess. First we’ll verify that the guess is between 1 and 10. If it isn’t, we’ll print an error message. Otherwise, we’ll check whether the user has guessed the number. If so, we’ll print a congratulatory message. If the user has not guessed the number, we’ll display the number, then determine whether the guess was close. We’ll define “close” as within three numbers. We’ll print a message informing the user whether the guess was close, then we’ll wish the user better luck next time. The pseudocode for this program looks like this:

```
generate a secret random number between 1 and 10
prompt the user for a guess

if guess is not between 1 and 10
    print message
else
  if guess equals the secret number
    print congratulations
  else
    print the secret number
    if guess is not within 3 numbers
     print "You missed it by a mile!"
    else
     print "You were close."
    print "Better luck next time."
```

Description

This pseudocode uses three *if* statements; the first determines if the guess is within the requested range of numbers. If it isn’t, we print a message. Otherwise, a nested *if* statement tests whether the user has guessed the secret number. If so, we print a congratulatory message. If not, we print the secret number, and our last nested *if* statement determines whether the guess was not within 3 numbers of the secret number. If not, we print “You missed it by a mile!”; otherwise, we print “You were close.” In either case, we print “Better luck next time.”

Example 5.6 is the result of translating this pseudocode into a Java application.

Example 5.6 Nested *if* statements

```
 1 /* Guess a number between 1 and 10
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.Random;
 6 import java.util.Scanner;
 7
 8 public class GuessANumber
 9 {
10   public static void main( String [ ] args )
11   {
12     Random random = new Random( );
13     int secretNumber = random.nextInt( 10 ) + 1;
14
15     Scanner scan = new Scanner( System.in );
16
17     System.out.print( "I'm thinking of a number"
18                 + " between 1 and 10. What is your guess? " );
19     int guess = scan.nextInt( );
20
21     if ( guess < 1 || guess > 10 )
22     {
23        System.out.println( "Well, if you're not going to try,"
24                                     + " I'm not playing." );
25     }
26     else
27     {
28       if ( guess == secretNumber )
29            System.out.println( "Hoorah. You win!" );
30       else
31       {
32            System.out.println( "The number was " + secretNumber );
33
34            if ( Math.abs( guess - secretNumber ) > 3 )
35                System.out.println( "You missed it by a mile!" );
36            else
37                System.out.println( "You were close." );
38
39            System.out.println( "Better luck next time." );
40       }
41     }
42   }
43 }
```

Description

On line 34, we used the *abs* method of the *Math* class to determine whether the guess was within three integers of the secret number. By taking the absolute value of the difference between the guess and the secret number, we don’t need to worry about which number is higher than the other; we will always receive a positive difference from the *abs* method.

Figure 5.11 shows the output of a sample run of this program.

Figure 5.11 Output from the *GuessANumber* Program in Example 5.6

Description

5.6 Testing Techniques for *if/else* Statements

When an application uses *if/else* statements, the application's flow of control depends on the user's input or other data values. For one input value, the application may execute the true block, while for another input value, the application may execute the false block. Obviously, running an application only once is no guarantee that the program is correct, because if the true block was executed, then the false block was not executed, and therefore, was not tested. Similarly, if the false block was executed, then the true block was not executed, and therefore was not tested.

To test an application for correctness, we could attempt to test all execution paths. To do this, we devise a **test plan** that includes running the application with different data values designed to execute all the statements in the application.

For example, an application that determines whether an integer is positive or negative might have this code:

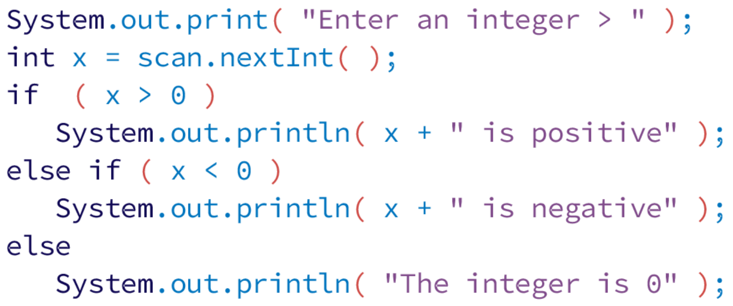
```
System.out.print( "Enter an integer > " );
int x = scan.nextInt( );
if  ( x > 0 )
   System.out.println( x + " is positive" );
else
   System.out.println( x + " is negative" );
```

Description

We could test this code by running the application twice, the first time entering the value 1, and the second time entering the value −1. We see that the results for those two values are correct: 1 is positive and −1 is negative. We have executed all the statements successfully, but can we say for certain that the program is correct? What if we entered the value 0, which is considered neither a positive nor a negative integer? As written, our program determines that 0 is negative, which is incorrect.

We see, then, that testing the true and false blocks is not sufficient; we need to test the condition of the *if/else* statement as well. There are three possibilities: *x* is less than 0, *x* is equal to 0, or *x* is greater than 0. To test the condition, we should run the application with input values that meet these three criteria. So we should run the application one more time with the input value of 0. This will show us that the program is incorrect, because our code identifies 0 as a negative number.

To correct the program, we should add another condition `(x < 0)` so we can separate 0 from the negative numbers. The code would then become:



```
System.out.print( "Enter an integer > " );
int x = scan.nextInt( );
if  ( x > 0 )
   System.out.println( x + " is positive" );
else if ( x < 0 )
   System.out.println( x + " is negative" );
else
   System.out.println( "The integer is 0" );
```

Description

Now if we retest the program with input values –1, 1, and 0, we get correct results for each of these values.

Notice that the test values we chose are –1, 0, and 1. We call these values the *boundary values* because they are the first possible values to cause the conditions (x > 0, and x < 0, and the implicit x == 0 condition) to evaluate to true. If we had incorrectly coded the first condition as x > 1 and we chose, for example, 2, to test our code, our test value of 2 would make the code appear to be correct. However, the code would not work correctly for the value 1. For this reason, we recommend using boundary values to test the execution paths in a program.

SOFTWARE ENGINEERING TIP

When testing your program, develop input values that test the boundary values for all execution paths and confirm that the logic implements the program specifications.

Another testing method is to treat the program like a black box, that is, as if the program's inner workings are unknown and unknowable to us. We devise our test plan based solely on the specifications of the program and develop input values that test the program logically. Thus, if our specifications are that we should determine whether an integer is positive or negative, we deduce that we should run the program with inputs that are a negative number, a positive number, and the special case, 0.

Both testing methods work together to ensure that a program is correct.

5.7 Programming Activity 1: Working with *if/else*

In this activity, you will write an *if/else* selection statement to decide how a golfer's score compares to par.

Copy to a folder on your computer all the files from the source code provided with this text for this chapter's Programming Activity 1.

Open the *SelectionPractice1Controller.java* source file. You will add your code to the *workWithIfElse* method. Part of the method has been coded for you. Search for ***** in the source file.

You should be positioned at the code shown in **Example 5.7.**

Example 5.7 The Student Code Portion of Programming Activity 1

```
public void workWithIfElse( int score )
{
        String result = "???";
        // ***** Student code starts here
        // If score is greater than 72, assign "over par" to result
        // If score is equal to 72, assign "par" to result
        // If score is less than 72, assign "below par" to result

        //
        // Student code ends here
        //

        animate( score, result );
}
```

Description

Where indicated in the code, you should write an *if/else* statement to perform the following function:

- In the method header of the method *workWithIfElse*, you see `( int score )`.
- The *int* variable *score* represents a golf score. This variable will be an input from the user; the text box that allows the user to enter the score has already been coded for you and stores the user's input in the variable *score*, which is available to your code as a parameter of the *workWithIfElse* method. Do not declare the variable *score* inside the method; just use it.
- We want to know if the golf score is "over par," "par," or "below par." Par is 72.
- Inside the *if/else* statement, you need to assign a value to the *String* variable named *result*, as follows:

  > If *score* is higher than 72, then assign "over par" to *result*; if score is exactly 72, assign "par" to *result*; and if score is lower than 72, assign "below par" to *result*.

- You do not need to write the code to call the method *animate*; that part of the code has already been written for you.

Animation: The application window will display the correct path of the *if/else* statement (in green), which may or may not be the same as your path, depending on how you coded the *if/else* statement. The animation will also assess your result, that is, the value of the variable *result*, and give you feedback on the correctness of your result.

To test your code, compile *SelectionPractice1Controller.java* and run *SelectionPractice1Application* and enter an integer in the text box. Try the following input values for *score*: 71, 72, and 73. Be sure your code produces the correct result for all input values.

When the program begins, you will see a graphics window with the text box of **Figure 5.12**, prompting you for an integer value.

Figure 5.12 The Beginning of the Application

Description

Figure 5.13 demonstrates the correct code path when the input value is 73 and assesses that the student’s code is correct.

Figure 5.13 A Correct *if/else* Statement

Description

Figure 5.14 again demonstrates the correct code path when the input value is 73, but in this case, the student’s code is incorrect.

Figure 5.14 An Incorrect *if/else* Statement

Description

DISCUSSION QUESTIONS

1. How many conditions did you use in the complete *if/else* statement?

2. Your code should be correct if the application gets correct results for the input values 71, 72, and 73. Explain why.

```
d1 = 1.0999999999999999
d2 = 1.1
d1 and d2 are not equal

piF = 3.1415927
pid = 3.141592653589793
piF and piD are not equal
```

```
d1 = 1.0999999999999999
d2 = 1.1
d1 and d2 are considered equal

piF = 3.1415927
pid = 3.141592653589793
piF and piD are considered equal
```

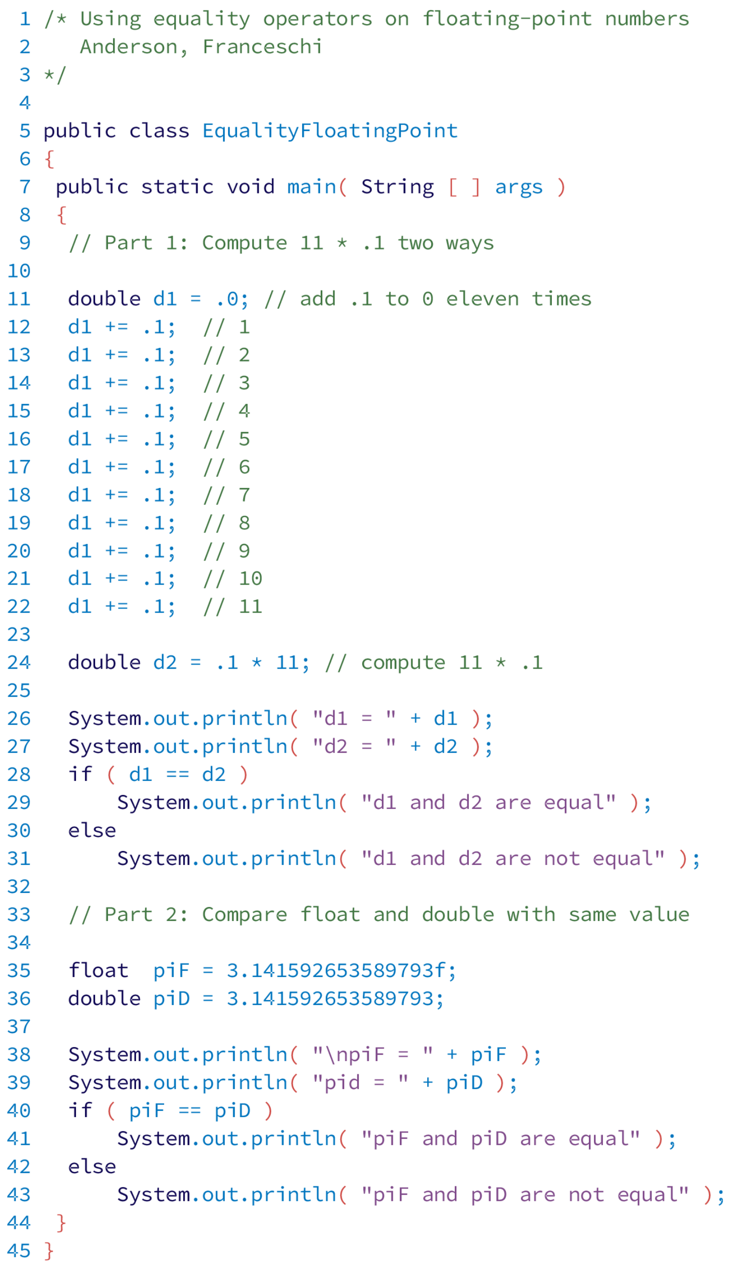
```
d1 = 1.1
d2 = 1.1
d1 and d2 are equal
```

5.8 Comparing Floating-Point Numbers

Java's *floats* and *doubles* are stored using IEEE 754 standard format. Because a finite number of bits (32 or 64) is used to store floating-point numbers, not all real-world values can be represented. As a result, minor rounding errors can be introduced when arithmetic is performed. That said, it is not advisable to simply rely on the equality operators to compare floating-point numbers.

Let's take a look at **Example 5.8**, which computes 11 * .1 two ways. First, at line 11, we assign .0 to a *double* variable, *d1*, and at lines 12–22 we add .1 to *d1* eleven times. Then, at line 24, we declare a second *double* variable, *d2*, and assign it the result of multiplying .1 times 11. We would expect, then, that *d1* and *d2* would have the same value. Not so, as the output of the program shows in **Figure 5.15**.

x**Example 5.8** Using the Equality Operator to Compare Floating-Point Numbers



```
/* Using equality operators on floating-point numbers
   Anderson, Franceschi
*/

public class EqualityFloatingPoint
{
 public static void main( String [ ] args )
 {
  // Part 1: Compute 11 * .1 two ways

  double d1 = .0; // add .1 to 0 eleven times
  d1 += .1;  // 1
  d1 += .1;  // 2
  d1 += .1;  // 3
  d1 += .1;  // 4
  d1 += .1;  // 5
  d1 += .1;  // 6
  d1 += .1;  // 7
  d1 += .1;  // 8
  d1 += .1;  // 9
  d1 += .1;  // 10
  d1 += .1;  // 11

  double d2 = .1 * 11; // compute 11 * .1

  System.out.println( "d1 = " + d1 );
  System.out.println( "d2 = " + d2 );
  if ( d1 == d2 )
      System.out.println( "d1 and d2 are equal" );
  else
      System.out.println( "d1 and d2 are not equal" );

  // Part 2: Compare float and double with same value

  float  piF = 3.141592653589793f;
  double piD = 3.141592653589793;

  System.out.println( "\npiF = " + piF );
  System.out.println( "pid = " + piD );
  if ( piF == piD )
      System.out.println( "piF and piD are equal" );
  else
      System.out.println( "piF and piD are not equal" );
 }
}
```

Description

Figure 5.15 Output from Example 5.8

Description

REFERENCE POINT

Binary representation of floating-point numbers is discussed in Appendix E.

We can also see the effects of rounding when comparing a *float* to a *double*. For example, at lines 35 and 36 of Example 5.8, we assign the same floating-point number (PI) to a double variable *piD* and to a float variable *piF*, then compare the two values at line 40. As we can see from the output in Figure 5.15, they do not compare as equal. The reason is that double-precision floating-point numbers are able to store a larger number of significant digits than single-precision floating-point numbers.

Instead of using the equality operator to compare floating-point numbers, it's better to compare the absolute value of the difference to a small value, called a *threshold*. The value of the threshold should be the difference we can tolerate and still consider the numbers equal. Let's redo Example 5.8. Instead of using the equality operator, we'll use the *Math.abs* method to compute a difference between the two numbers and compare the difference to a threshold value. We'll set the threshold at .0001, meaning that if the numbers differ by less than .0001, we'll consider them equal. The results of this approach are shown in **Example 5.9** and the output is given in **Figure 5.16**.

Example 5.9 Comparing Floating-Point Numbers Using a Threshold

```
/* Using a threshold to compare floating-point numbers
   Anderson, Franceschi
*/

public class ComparingFloatingPoint
{
 public static void main( String [ ] args )
 {
   final double THRESHOLD = .0001;

   // Part 1: Compute 11 * .1 two ways
   double d1 = .0; // add .1 to 0 eleven times
   d1 += .1;  // 1
   d1 += .1;  // 2
   d1 += .1;  // 3
   d1 += .1;  // 4
   d1 += .1;  // 5
   d1 += .1;  // 6
   d1 += .1;  // 7
   d1 += .1;  // 8
   d1 += .1;  // 9
   d1 += .1;  // 10
   d1 += .1;  // 11

   double d2 = .1 * 11; // compute 11 * .1

   System.out.println( "d1 = " + d1 );
   System.out.println( "d2 = " + d2 );
   if ( Math.abs( d1 - d2 ) < THRESHOLD )
        System.out.println( "d1 and d2 are considered equal" );
   else
        System.out.println( "d1 and d2 are not equal" );

   // Part 2: Compare float and double with same value
   float  piF = 3.141592653589793f;
   double piD = 3.141592653589793;

   System.out.println( "\npiF = " + piF );
   System.out.println( "piD = " + piD );
   if ( Math.abs( piF - piD ) < THRESHOLD )
        System.out.println( "piF and piD are considered equal" );
   else
        System.out.println( "piF and piD are not equal" );
 }
}
```

Description

Figure 5.16 Output of Example 5.9

Description

When we need exact precision in calculations with decimal numbers, we can use the *BigDecimal* class in the Java Class Library. The *BigDecimal* class, which is in the *java.math* package, provides methods that perform addition, subtraction, multiplication, and division of *BigDecimal* objects so that the results are exact, without the rounding errors caused by floating-point operations. **Table 5.10** shows a constructor of the *BigDecimal* class and several useful methods for performing calculations and comparing *BigDecimal* objects.

The *BigDecimal* Class API

BigDecimal Class Constructor Summary

`BigDecimal( String ddd )`

creates a *BigDecimal* object equivalent to the decimal number expressed as a *String*

***BigDecimal* Class Method Summary**

Return value	**Method name and argument list**
`BigDecimal`	`add( BigDecimal num )` returns a *BigDecimal* object equal to the current *BigDecimal* object plus *num*
`BigDecimal`	`subtract( BigDecimal num )` returns a *BigDecimal* object equal to the current *BigDecimal* object minus *num*
`BigDecimal`	`multiply( BigDecimal num )` returns a *BigDecimal* object equal to the current *BigDecimal* object times *num*
`BigDecimal`	`divide( BigDecimal num )` returns a *BigDecimal* object equal to the current *BigDecimal* object divided by *num*
`int`	`compareTo( BigDecimal`

	`num )` returns 0 if the current *BigDecimal* object is equal to *num*; –1 if the current *BigDecimal* object is less than *num*; and 1 if the current *BigDecimal* object is greater than *num*

Description

REFERENCE POINT

You can read more about the *BigDecimal* class on Oracle's Java website *www.oracle.com/technetwork/java*.

In **Example 5.10**, we perform the same calculations as in Example 5.9, but we use *BigDecimal* objects instead of *doubles*. On lines 11 and 12, we instantiate two *BigDecimal* objects: *d1* will hold the sum and is initialized to 0.0; *pointOne* is assigned the value 0.1 and will be repeatedly added to *d1*. Then on lines 16–26, we call the *add* method to add 0.1 to *d1* 11 times. We instantiate two more *BigDecimal* objects on lines 29 and 30, then call the *multiply* method to multiply 0.1 * 11. On line 35, we compare the resulting *BigDecimal* objects by calling the *compareTo* method, and find that the two results are in fact equal. The output of Example 5.10 is shown in **Figure 5.17**.

Example 5.10 Comparing Floating-Point Numbers Using *BigDecimal*

```
/* Using BigDecimal to compute precise decimal numbers
   Anderson, Franceschi
*/

import java.math.BigDecimal;

public class UsingBigDecimal
{
 public static void main( String [ ] args )
 {
   BigDecimal d1 = new BigDecimal( "0.0" );
   BigDecimal pointOne = new BigDecimal( "0.1" );

   // Compute 11 * .1 two ways
   // add .1 to d1 eleven times
   d1 = d1.add( pointOne ); // 1
   d1 = d1.add( pointOne ); // 2
   d1 = d1.add( pointOne ); // 3
   d1 = d1.add( pointOne ); // 4
   d1 = d1.add( pointOne ); // 5
   d1 = d1.add( pointOne ); // 6
   d1 = d1.add( pointOne ); // 7
   d1 = d1.add( pointOne ); // 8
   d1 = d1.add( pointOne ); // 9
   d1 = d1.add( pointOne ); // 10
   d1 = d1.add( pointOne ); // 11

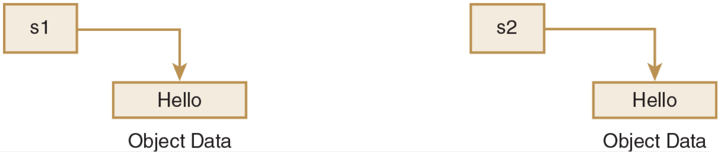
   // multiply .1 * 11
   BigDecimal d2 = new BigDecimal( "0.1" );
   BigDecimal eleven = new BigDecimal( "11" );
   d2 = d2.multiply( eleven );

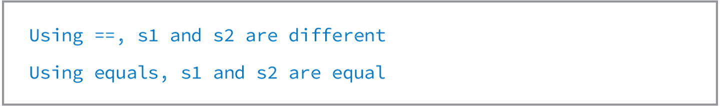
   System.out.println( "d1 = " + d1 );
   System.out.println( "d2 = " + d2 );
   if ( d1.compareTo( d2 ) == 0 )
        System.out.println( "d1 and d2 are equal" );
   else
        System.out.println( "d1 and d2 are not equal" );
 }
}
```

Description

Figure 5.17 Output of Example 5.10

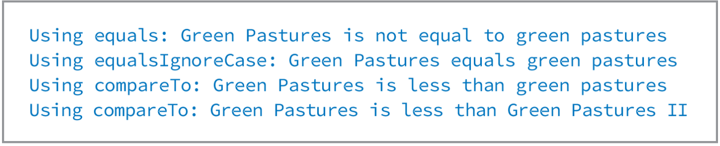
Description





```
Using ==, s1 and s2 are different

Using equals, s1 and s2 are equal
```



```
Using equals: Green Pastures is not equal to green pastures
Using equalsIgnoreCase: Green Pastures equals green pastures
Using compareTo: Green Pastures is less than green pastures
Using compareTo: Green Pastures is less than Green Pastures II
```

5.9 Comparing Objects

5.9.1 The *equals* Method

Often, we want to compare whether two objects are equal; typically, we will say that two objects are equal if they have the same data. If we use the equality operator (==) to compare object references, however, we are comparing the value of the object references. In other words, we are comparing whether the object references point to the same object, that is, the same memory location. To compare object data, we need to use the *equals* method, which all classes inherit from the *Object* class. Many classes provide a custom version of the *equals* method. The API of the *equals* method is the following:

```
public boolean equals( Object ob )
```

Description

Typically, the *equals* method returns *true* if the data in the parameter object matches the data in the object for which the method was called.

The program in **Example 5.11** creates the two *String* object references and objects shown in **Figure 5.18**. The program compares the object references using the equality operator and then compares the object data using the *equals* method. The output from this program is shown in **Figure 5.19**.

Example 5.11 Comparing Object Data

```
 1 /* Comparing Object References and Data
 2    Anderson, Franceschi
 3 */
 4 public class ComparingObjects
 5 {
 6   public static void main( String [] args )
 7   {
 8     String s1 = new String( "Hello" );
 9     String s2 = new String( "Hello" );
10
11     if( s1 == s2 )
12       System.out.println( "Using ==, s1 and s2 are equal" );
13     else
14       System.out.println( "Using ==, s1 and s2 are different" );
15
16     if( s1.equals( s2 ) )
17       System.out.println( "Using equals, s1 and s2 are equal" );
18     else
19       System.out.println( "Using equals, s1 and s2 are different" );
20   }
21 }
```

Description

Figure 5.18 *String* Objects and References

Description

Figure 5.19 Output from Example 5.11

Description

Lines 8 and 9 instantiate two *String* objects with the same data.

COMMON ERROR TRAP

Do not use the equality operators to compare object data; instead, use the *equals* method.

At line 11, when we compare *s1* and *s2* using the equality operator, the result is *false*, because the object references *s1* and *s2* point to two different objects.

We get different results using the *equals* method. When line 16 compares *s1* and *s2* using the *equals* method, the result is *true*, because *s1* and *s2* have identical data.

5.9.2 *String* Comparison Methods

In addition to the *equals* method, the *String* class provides two other methods, *equalsIgnoreCase* and *compareTo*, for comparing the values of *Strings*. These methods, along with the *equals* method are summarized in **Table 5.11**.

Comparison Methods of the *String* Class

String Methods for Comparing *String* Values

Return value	**Method name and argument list**
`boolean`	`equals ( String str )` compares the value of two *Strings*. Returns *true* if the *Strings* are equal; *false* otherwise.
`boolean`	`equalsIgnoreCase ( String str )` compares the value of two *Strings*, treating upper and lowercase characters as equal. Returns *true* if the *Strings* are equal; *false* otherwise.
`int`	`compareTo ( String str )` compares the value of the two *Strings* in lexicographic order. If the *String* object is less than the *String* argument, *str*, a negative integer is returned. If the *String* object is greater than the *String* argument, a positive number is returned; if the two *Strings* are equal, 0 is returned.

Description

The *equalsIgnoreCase* method is similar to the *equals* method, except that it is insensitive to case. Thus, the *equalsIgnoreCase* method returns *true* if the two *String* objects have the same sequence of characters, regardless of capitalization. For example, the *equalsIgnoreCase* method considers *ABC, AbC*, and *abc* to be equal.

REFERENCE POINT

The first 128 Unicode values are given in Appendix C.

The *compareTo* method returns an integer value, rather than a *boolean* value. The *compareTo* method's return value represents whether the *String* object is less than, equal to, or greater than the *String* argument passed to the *compareTo* method. The *compareTo* method uses lexicographic order—the Unicode collating sequence—to compare the *Strings*. Using the Unicode collating sequence means that a character with a lower Unicode numeric value is considered less than a character with a higher Unicode numeric value. Thus, an *a* is lower than a *b*; an *A* is lower than a *B*; and *0* is lower than *1*.

The *compareTo* method scans the two *Strings* from left to right. If it finds different characters in the same position in the two *Strings*, it immediately returns an integer value representing the difference between the Unicode values of those characters. For example, the distance between *a* and *c* is −2; the distance between *K* and *F* is 5.

If the *Strings* differ in length, but the characters they have in common are identical, then the *compareTo* method returns the difference in the length of the *Strings*.

In most cases, however, the exact return value is not important; it is sufficient to know whether the *String* object is less than, greater than, or equal to the *String* argument. In other words, all that we usually need to know is whether the return value is positive, negative, or 0.

Example 5.12 demonstrates how these methods can be used in a Java application to compare *Strings*. The output of the program is shown in **Figure 5.20**.

Example 5.12 Comparing Strings

```
 1 /* Demonstration of the String comparison methods
 2    Anderson, Franceschi
 3 */
 4
 5 public class ComparingStrings
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     String title1 = "Green Pastures";
10     String title2 = "Green Pastures II";
11     String title3 = "green pastures";
12
13     System.out.print( "Using equals: " );
14     if ( title1.equals( title3 ) )
15       System.out.println( title1 + " equals " + title3 );
16     else
17       System.out.println( title1 + " is not equal to " + title3 );
18
19     System.out.print( "Using equalsIgnoreCase: " );
20     if ( title1.equalsIgnoreCase( title3 ) )
21       System.out.println( title1 + " equals " + title3 );
22     else
23       System.out.println( title1 + " is not equal to " + title3 );
24
25     System.out.print( "Using compareTo: " );
26     if ( title1.compareTo( title3 ) > 0 )
27       System.out.println( title1 + " is greater than " + title3 );
28     else if ( title1.compareTo ( title3 ) < 0 )
29       System.out.println( title1 + " is less than " + title3 );
30     else
31       System.out.println( title1 + " is equal to " + title3 );
32
33     System.out.print( "Using compareTo: " );
34     if ( title1.compareTo( title2 ) > 0 )
35       System.out.println( title1 + " is greater than " + title2 );
36     else if ( title1.compareTo( title2 ) < 0 )
37       System.out.println( title1 + " is less than " + title2 );
38     else
39       System.out.println( title1 + " is equal to " + title2 );
40   }
41 }
```

Description

Figure 5.20 Output from Example 5.12

Description

In Example 5.12, we define three similar *Strings*: *title1 (Green Pastures), title2 (Green Pastures II)*, and *title3 (green pastures)*. When we compare *title1, Green Pastures, to title3, green pastures*, using the *equals* method (line 14), the result is *false*, because the *Strings* do not match in case. When we perform the same comparison using the *equalsIgnoreCase* method (line

20), however, the result is *true*, because except for capitalization, these two *Strings* are identical in character sequence and length.

Using the *compareTo* method (line 34), *Green Pastures* evaluates to less than *Green Pastures II*. Although all the characters of the first *String* are found in the second *String* in the same order, the first *String* has fewer characters than the second *String*. The reason that *Green Pastures* evaluates to less than *green pastures* (line 26) is not so obvious—until we look at the Unicode character chart. The capital letters have lower numeric values than the lowercase letters, so a capital *G* is less than a lowercase *g*.

```
Enter an integer > 12
12 is even.
```

```
Enter an integer > 13
13 is odd.
```

5.10 The Conditional Operator (?:)

The conditional operator (?:), while not a statement in itself, can be used in expressions. It evaluates a condition and contributes one of two values to the expression based on the value of the condition. The conditional operator is especially useful for handling invalid input and for outputting similar messages. The syntax of the conditional operator is shown here:

```
( condition ? expression1 : expression2 )
```

Description

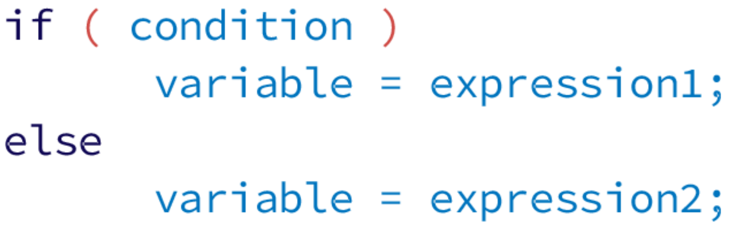
The value of an expression containing a conditional operator is determined by evaluating the condition, which is any expression that evaluates to *true* or *false*. If the condition evaluates to *true, expression1* becomes the value of the expression; if the condition evaluates to *false, expression2* becomes the value of the expression.

When assigning the result of that expression to a variable, the statement:

```
variable = ( condition ? expression1 : expression2 );
```

Description

is equivalent to

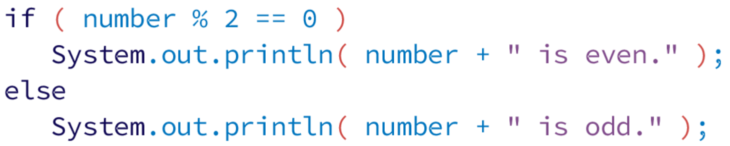


```
if ( condition )
       variable = expression1;
else
       variable = expression2;
```

Description

Some programmers like to use the conditional operator because it enables them to write compact code; other programmers feel that an *if/else* sequence is more readable.

Suppose we want to determine whether a number is even or odd. We know that if we divide a number by 2 and the remainder is 0, the number is even. If the remainder is 1, the number is odd. We could do this using the following *if/else* statement:



```
if ( number % 2 == 0 )
   System.out.println( number + " is even." );
else
   System.out.println( number + " is odd." );
```

Description

Notice that the only difference in the output is the last word.

Example 5.13 shows how we can perform the same processing using the conditional operator.

Example 5.13 Using the Conditional Operator

```
 1 /* Using the conditional operator
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6
 7 public class OddOrEven
 8 {
 9  public static void main( String [ ] args )
10  {
11   Scanner scan = new Scanner( System.in );
12
13   System.out.print( "Enter an integer > " );
14   int number = scan.nextInt( );
15
16   String outcome = ( number % 2 == 0 ? "even." : "odd." );
17
18   System.out.println( number + " is " + outcome );
19
20  }
21 }
```

Description

In lines 13 and 14, we ask the user to input an integer. In line 16, we use the conditional operator to determine whether the integer is even or odd, assigning the result to the *String outcome*. Then in line 18, we print the number, the word “ is ” and then the value of *outcome*. **Figure 5.21** shows the output from **Example 5.13** when the user enters an even number, and Figure 5.22 shows the output when the user enters an odd number.

Figure 5.21 Output of Example 5.13 When the Input Is Even

Description

Figure 5.22 Output of Example 5.13 When the Input Is Odd

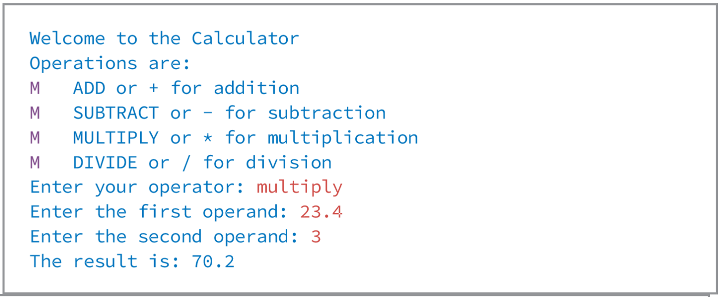
Description

Table 5.12, Operator Precedence, shows that the conditional operator is low in precedence, being just above the assignment operators.

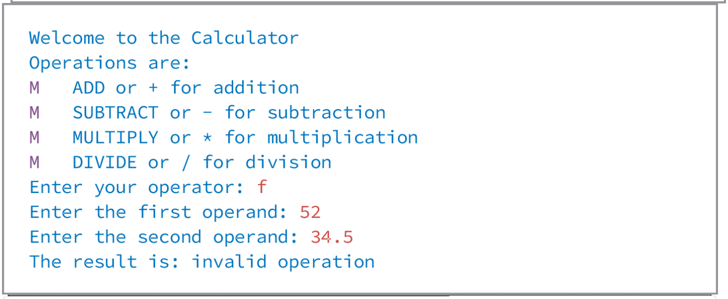
Operator Precedence

Operation Hierarchy	Order of Same-Statement Evaluation	Operation
( )	left to right	parentheses for explicit grouping
++, --	right to left	shortcut postincrement
++, --, !	right to left	shortcut preincrement, logical unary NOT
*, /, %	left to right	multiplication, division, modulus
+, -	left to right	addition or *String* concatenation, subtraction
<, <=, >, >=	left to right	relational operators: less than, less than or equal to, greater than, greater than or equal to
==, !=	left to right	equality operators: equal to and not equal to
&&	left to right	logical AND
||	left to right	logical OR
?:	left to right	conditional operator
=, +=, -=, *=, /=, %=	right to left	assignment operator and shortcut assignment operators

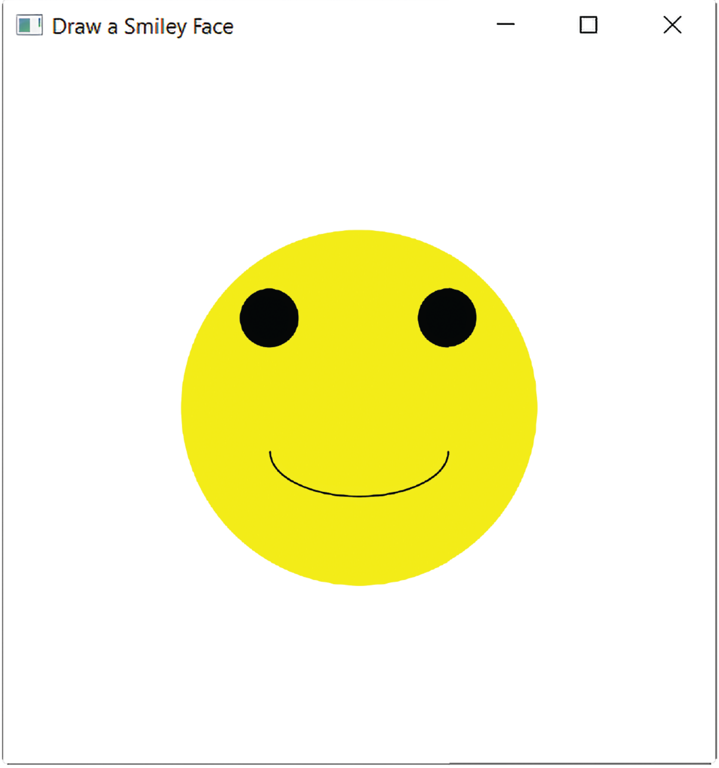
Description



```
Welcome to the Calculator
Operations are:
M   ADD or + for addition
M   SUBTRACT or - for subtraction
M   MULTIPLY or * for multiplication
M   DIVIDE or / for division
Enter your operator: multiply
Enter the first operand: 23.4
Enter the second operand: 3
The result is: 70.2
```



```
Welcome to the Calculator
Operations are:
M   ADD or + for addition
M   SUBTRACT or - for subtraction
M   MULTIPLY or * for multiplication
M   DIVIDE or / for division
Enter your operator: f
Enter the first operand: 52
Enter the second operand: 34.5
The result is: invalid operation
```



5.11 The *switch* Statement

The *switch* statement can be used instead of an *if/else if* statement for selection when the condition consists of comparing the value of an expression to constant integers (*byte, short*, or *int*), characters (*char*), or *Strings*. The latest syntax of the *switch* statement, introduced with Java 14, is as follows:

```
switch( expression )
{
   case constant1A, constant1B, … -> statement or block;
   case constant2A, constant2B, … -> statement or block;
   …
   default -> statement or block; // optional (but often needed)
}
```

Description

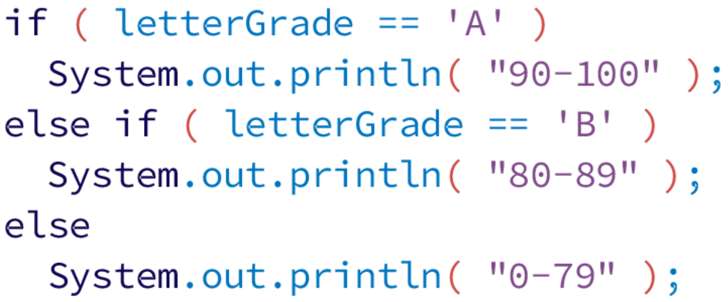
The expression is first evaluated; then its value is compared to the *case* constants in order. When a match is found, the statement or block associated with that *case* constant is executed. Then, execution jumps to the end of the *switch* statement. Cases must be exhaustive. Thus, unless the expression can match a finite list of values, a *default* label is required.

For example, the following snippet:

```
switch ( letterGrade )
{
   case 'A' -> System.out.println( "90-100" );
   case 'B' -> System.out.println( "80-89" );
   default -> System.out.println( "0-79" );
}
```

Description

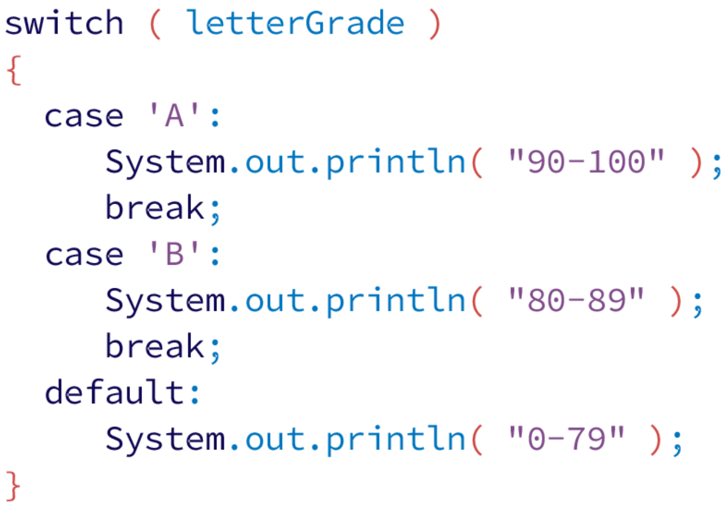
is equivalent to this snippet, using *if/else if/else*:



```
if ( letterGrade == 'A' )
  System.out.println( "90-100" );
else if ( letterGrade == 'B' )
  System.out.println( "80-89" );
else
  System.out.println( "0-79" );
```

Description

Using the old *switch* syntax (Java 13 and before, but still supported at the time of publication of this book), the equivalent of the above snippet is:



```
switch ( letterGrade )
{
  case 'A':
    System.out.println( "90-100" );
    break;
  case 'B':
    System.out.println( "80-89" );
    break;
  default:
    System.out.println( "0-79" );
}
```

Description

Furthermore, we can use a **switch expression** to assign a value to a variable depending on various scenarios. A *switch* expression uses a *switch* statement. The statement that follows a *case* label is, in this case, a value that is assigned to the variable. If the value that we want to assign to a variable requires calculations that involve several statements, we can use a block. Inside that block, the value that follows the *yield* keyword is the value that is assigned to the variable.

```
datatype identifier = switch( expression )
{
  case constant1A, constant1B, … -> expression or block with yield;
  case constant2A, constant2B, … -> expression or block with yield;
  …
  // optional default (but often needed)
  default -> expression or block with yield;
}
```

Description

Let’s look at how a *switch* expression can be used to implement a simple calculator. We first prompt the user for two numbers on which they want to perform a calculation, and then the operation they want to perform. We let them enter either the words ADD, SUBTRACT, MULTIPLY, or DIVIDE, or the symbol for the operation (1, 2, *, or /). We can use a *switch* expression to determine the outcome of the selected operation. **Example 5.14** shows the code for our simple calculator.

Example 5.14 A Simple Calculator

```java
/* A simple calculator
   Anderson, Franceschi
*/

import java.text.DecimalFormat;
import java.util.Scanner;

public class Calculator
{
  public static void main( String [ ] args )
  {
    Scanner scan = new Scanner( System.in );

    // set up the output format of the result
    DecimalFormat twoDecimals = new DecimalFormat( "#,###.##" );

    // print a welcome message
    System.out.println( "Welcome to the Calculator" );

    //  define and print a menu, then prompt for the operation
    String menu = """
      Operations are:
      \tADD or + for addition
      \tSUBTRACT or - for subtraction
      \tMULTIPLY or * for multiplication
      \tDIVIDE or / for division""";
    System.out.println( menu );
    System.out.print( "Enter your operator: " );
    String operation = scan.next( );
    operation = operation.toUpperCase( );

    // read the two operands
    System.out.print( "Enter the first operand: " );
    double fp1 = scan.nextDouble( );
    System.out.print( "Enter the second operand: " );
    double fp2 = scan.nextDouble( );

    // perform the operation
    String result = switch ( operation )
    {
      case "ADD", "+" -> twoDecimals.format( fp1 + fp2 );
      case "SUBTRACT", "-" -> twoDecimals.format( fp1 - fp2 );
      case "MULTIPLY", "*" -> twoDecimals.format( fp1 * fp2 );
      case "DIVIDE", "/" ->
      {
        if ( fp2 == 0.0 )
          yield "Dividing by 0 is not allowed";
        else
          yield twoDecimals.format( fp1 / fp2 );
      }
      default -> "invalid operation";
    };

    // output the result of the operation
    System.out.println( "The result is: " + result );
  }
}
```

Description

At lines 20–30, we define a menu using a text block, output it, ask the user to choose an operation, and convert it to upper case. At lines 32–36, we ask the user to input the two operands for the operation.

We are now ready to process the user's inputs, by using a *switch* statement with the user's selected operation as the *switch expression*. Note that because we switch on a *String*, the *default* case is required since cases must be exhaustive.

We determine which operation the user has selected by providing a *case* statement for each possible operation. We can use uppercase words as the *case* constants, because we have converted the input to uppercase. We handle the situation where the user has entered a mathematical symbol instead of a word by adding each symbol to the list of *case* constants for each operation. For example, if the user enters ADD (in any combination of uppercase and lowercase letters) or a plus sign (1), the input will match one of our *case* constants at line 41. We assign the result to the variable *result* at line 39. If we are performing a division (line 44), we need to check whether the divisor is 0 before performing division (line 46). Because we use an *if/else* statement for this with two possible outcomes, we use a block. Thus, we need to use the *yield* keyword to assign the resulting value to *result* at line 47. Although we discussed earlier in the chapter that we should compare floating-point numbers by comparing the difference between the two numbers with a threshold value, in this case we care only if the second operand is exactly 0, so we can safely compare its value to 0.0. If the second operand is not 0.0 (line 48), we perform the division at line 49 and format the result. Note that we could have used the ?: operator instead of the *if/else* statement and avoided using a block. This is left as an exercise. What if the user doesn't enter any of the valid words or mathematical symbols? This is handled by the *default* case, allowing us to assign an error message to *result* (line 51).

Figure 5.23 shows the output from Example 5.14 when the user selects multiplication, and **Figure 5.24** shows the output when the user enters an unsupported operation.

Figure 5.23 The Calculator Performing Multiplication

Description

Figure 5.24 The Calculator with an Invalid Entry for the Operation

Description

We'll create a graphical application that draws a smiley face depending on a value for a rating. In **Example 5.15**, we ask the user for a rating between 1 and 5 (lines 24–27). We define constant values that we will use to draw the smiley face at line 22. At lines 29–36, we draw the face and the eyes. Then, we use a *switch* statement (lines 38–50) to draw the mouth depending on the rating.

Example 5.15 Drawing a Smiley Face

```java
/* Drawing a smiley face
   Anderson, Franceschi
*/

import javafx.application.Application;
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;
import javafx.scene.shape.ArcType;
import javafx.stage.Stage;

import java.util.Scanner;

public class SmileyFaceDraw extends Application
{
  @Override
  public void start( Stage stage )
  {
    // set up window title and size
    GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
                  stage, "Draw a Smiley Face", 400, 400 );

    final int X = 100, Y = 100, RADIUS = 100;

    // ask the user for a rating
    Scanner scan = new Scanner( System.in );
    System.out.print( "Enter a rating (1 to 5) > " );
    int rating = scan.nextInt( );

    // Draw the face and the eyes
    gc.setFill( Color.YELLOW );
    gc.fillOval( X, Y, 2 * RADIUS, 2 * RADIUS );
    gc.setFill( Color.BLACK );
    gc.fillOval( X + RADIUS / 3, Y + RADIUS / 3,
                 RADIUS / 3, RADIUS / 3 );
    gc.fillOval( X + 4 * RADIUS / 3, Y + RADIUS / 3,
                 RADIUS / 3, RADIUS / 3 );

    // Draw the smile
    switch ( rating )
    {
      case 1, 2 ->
        gc.strokeArc( X + RADIUS / 2, Y + RADIUS,
                      RADIUS, RADIUS / 2, 0, 180, ArcType.OPEN );
      case 4, 5 ->
        gc.strokeArc( X + RADIUS / 2, Y + RADIUS,
                      RADIUS, RADIUS / 2, 0, -180, ArcType.OPEN );
      default ->
        gc.strokeLine( X + RADIUS / 2, Y + 4 * RADIUS / 3,
                       X + 3 * RADIUS / 2, Y + 4 * RADIUS / 3 );
    } // end switch
  }

  public static void main( String [ ] args )
  {
    launch( args );
  }
}
```

Description

We draw a frown at lines 42–43 if the rating is 1 or 2 (line 41). We draw a smile at lines 45–46 if the rating is 4 or 5 (line 44), and a straight line at lines 48–49 otherwise (rating of 3). Note that because we *switch* on an *int*, the *default* case is mandatory.

The output when the user input is *2* is shown in **Figure 5.25**.

5.12 Programming Activity 2: Using the *switch* Statement

In this activity, you will write a *switch* statement that selects a path depending on an input value. The framework will animate your code so that you can watch the path that the code takes in the *switch* block.

Copy to a folder on your computer all the files in this chapter's Programming Activity 2 folder in the supplied code accompanying this book.

Search for five stars (*****) in the

SelectionPractice2Controller.java source code to find where to add your code. The five stars are above the method *workWithSwitch* (the method header has already been coded for you).

You should be positioned at the code shown in **Example 5.16**.

Example 5.16 The Student Code Portion of Programming Activity 2

```
// ***** 1 student writes this method
public void workWithSwitch( int value )
{
  //
  // Student code starts here
  //

  //
  // Student code ends here
  //

}
// end of workWithSwitch
```

Description

Where indicated in the code, write a *switch* statement, as follows:

- In the method header of the method *workWithSwitch*, you see `( int value )`. The *int* variable *value* represents the input from the user; the text box that allows the user to input the score has already been coded for you. This variable, *value*, is the value entered by the user and should be used as the condition for the *switch* statement; it is available to your code as a parameter of the *workWithSwitch* method. Do not declare the variable *value* inside the method; just use it.

- Write *case* statements for the following integer constants: *0, 1, 2, 3, 4*, as well as a *default* statement.
- Within each *case* statement, you should do two things:
    - Print a message to the screen indicating which value was input. The message for the *default* case should indicate that the input value is not one of the valid values.
    - Call the *animate* method. The API for the *animate* method is

```
void animate( int caseConstant, int value )
```

Description

The first argument is the *case* constant; the second argument is the input variable, *value*. For instance, for the statement `case 2`, your *animate* method call is

```
animate( 2, value );
```

Description

For the default case, the method call should be

```
animate( -1, value );
```

Description

To test your code, compile the *SelectionPractice2Controller.java* file and run the *SelectionPractice2Application* application. When the program begins, you will see an empty graphics window with a text box as shown in **Figure 5.26.**

Figure 5.26 The Input Box of the Application

Description

To execute your *switch* statement, enter an integer in the text box and press the “Test” button. Depending on how you coded the *case* statements, the *break* statements, and the input value, the window will display (in green) the path of execution of your code. For example, **Figure 5.27** demonstrates the code path when the input value is 3. If the path is not what you expected, you will need to correct your code.

Figure 5.27 A Sample Run of the Application

Description

To test your code, enter each integer from 0 to 4, plus some other integer value into the text box, pressing the “Test” button each time. To exit the application, close the window.

DISCUSSION QUESTIONS

1. Explain the purpose of the *default* case in a *switch* statement.
2. Explain what happens when you omit the *default* case.

CHAPTER REVIEW

5.13 Chapter Summary

- Java provides equality, relational, and logical operators to evaluate a condition, and selection statements to choose which instructions to execute based on whether a condition evaluates to *true* or *false*.
- The equality operators (`==`, `!=`) are used to test whether two operands are equal. The operands are expressions that evaluate to a primitive numeric or *boolean* type or an object reference.
- The relational operators (`<`, `<=`, `>`, `>=`) compare the values of two operands that are expressions that evaluate to a primitive numeric type.
- The logical operators (`!`, `&&`, and `||`) take *boolean* expressions as operands. The logical NOT (`!`) takes one operand, and inverts its value, changing *true* to *false* and *false* to *true*. The AND operator (`&&`) takes two *boolean* expressions as operands; if both operands are *true*, then the result is *true*; otherwise, the result is *false*. The OR operator (`||`) also takes two *boolean* expressions as operands. If both operands are *false*, then the result is *false*; otherwise, the result is *true*.
- The logical NOT operator (`!`) has the highest precedence of these operators, followed by the relational operators,

then the equality operators, then the logical AND (`&&`), then the logical OR(`||`).

- DeMorgan's Laws can be used to form equivalent logical expressions to improve readability of the code.
- The *if* statement is used to perform certain operations for one set of data and to do nothing for all other data.
- Curly braces are required when the true or false block of an *if* statement consists of more than one statement.
- The *if/else* statement is used to perform certain operations for one set of data and other operations for all other data.
- The *if/else if* statement is appropriate when the data falls into more than two mutually exclusive categories and the appropriate instructions to execute are different for each category.
- *if/else* statements can be coded sequentially and can be nested inside other *if/else* statements.
- When *if* statements are nested, the compiler matches any *else* clause with the most previous *if* condition that doesn't already have an *else* clause.
- Because rounding errors can be introduced in floating-point calculations, do not use the equality operators to compare two floating-point numbers. Instead, compare the absolute value of the difference between the numbers to some threshold value.
- When we need exact precision in calculations with decimal numbers, you can use the *BigDecimal* class in the Java Class Library.
- Using the equality operator on object references compares the values of the references, not the object data. Two object references will be equal only if they point to the same object.
- Use the *equals* method to determine whether the data in two objects are equal.
- In addition to the *equals* method, two *Strings* can also be compared using the *equalsIgnoreCase* method and the *compareTo* method of the *String* class.
- The conditional operator (?:) is used in expressions where

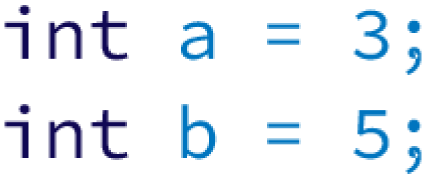
one of two values should be used depending on the evaluation of a condition. The conditional operator is useful for validating input and for outputting similar messages.

- The *switch* statement evaluates an integer or character expression or a *String*, then compares the expression's value to *case* constants. When a match is found, it executes the corresponding statement or block and exits the *switch* block.

5.14 Exercises, Problems, and Projects

5.14.1 Multiple Choice Exercises

1. Given the following code declaring and initializing two *int* variables *a* and *b* with respective values 3 and 5, indicate whether the value of each expression is *true* or *false*.



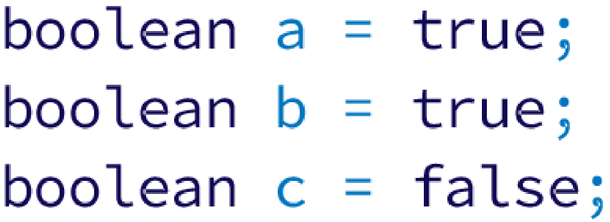
```
int a = 3;
int b = 5;
```

Description

Expression	true	false
• `a < b`	____	____
• `a != b`	____	____
• `a == 4`	____	____
• `( b - a ) <= 1`	____	____
• `Math.abs( a - b ) >= 2`	____	____
• `( b % 2 == 1 )`	____	____
• `b <= 5`	____	____

---

9. Given the following code declaring and initializing three *boolean* variables *a*, *b*, and *c*, with respective values *true*, *true*, and *false*, indicate whether the value of each expression is *true* or *false*.



```
boolean a = true;
boolean b = true;
boolean c = false;
```

Description

Expression	true	false
`!a`	____	____
`a && b`	____	____
`a && c`	____	____
`a || c`	____	____
`!( a || b )`	____	____
`!a || b`	____	____
`!( !( a && c ) )`	____	____
`a && !( b || c )`	____	____

18. Given two *boolean* variables *a* and *b*, are the following expressions equivalent?

    - `!( !a )`
    - `a`

21. Given two *boolean* variables *a* and *b*, are the following expressions equivalent?

    - `!( a && b )`
    - `!a || !b`

24. Given two *boolean* variables *a* and *b*, are the following expressions equivalent?

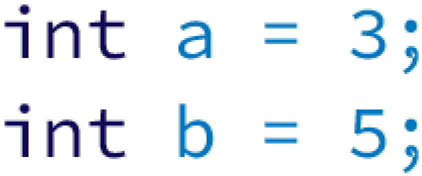
    - `!( !a && !b )`
    - `a && b`

27. Given two *boolean* variables *a* and *b*, are the following

expressions equivalent?

- `!( !a && !b )`
- `a || b`

30. Given the following code declaring and initializing two *int* variables *a* and *b* with respective values 3 and 5, indicate whether the operand (`b < 10`) will be evaluated.



```
int a = 3;
int b = 5;
```

Description

Expression	yes	no
• `a < b || b < 10`	____	____
• `a != b && b < 10`	____	____
• `a == 4 || b < 10`	____	____
• `a > b && b < 10`	____	____

---

35. Mark all the valid Java selection keywords.

- `if`
- `else if`
- `else`
- `elsif`

40. How do we compare the value of two *String* objects in Java? (Mark all that apply.)

- using the = operator
- using the == operator
- using the *equals* method

5.14.2 Reading and Understanding Code

1. What is the output of this code sequence?

   ```
   boolean a = true;
   System.out.println( a );
   ```

   Description

2. What is the output of this code sequence?

   ```
   boolean a = ( true && false );
   System.out.println( a );
   ```

   Description

3. What is the output of this code sequence?

   ```
   if ( ( true || false ) && ( false || true ) )
      System.out.println( "Inside true block" );
   System.out.println( "End of sequence" );
   ```

   Description

4. What is the output of this code sequence?

   ```
   if ( 27 % 3 == 0 )
      System.out.println( "27 is divisible by 3" );
   else
      System.out.println( "27 is not divisible by 3" );
   System.out.println( "End of sequence" );
   ```

   Description

5. What is the output of this code sequence?

   ```
   String s = "Hello";
   if ( s.equals( "hello" ) )
      System.out.println( "String is hello" );
   else
      System.out.println( "String is not hello" );
   System.out.println( "End of sequence" );
   ```

   Description

6. What is the output of this code sequence?

```
int grade = 77;
if ( grade >= 90 )
   System.out.println( "A" );
else if ( grade >= 80 )
   System.out.println( "B" );
else if ( grade >= 70 )
   System.out.println( "C" );
else
   System.out.println( "D or lower" );
System.out.println( "Done" );
```

   Description

7. What is the output of this code sequence?

```
int a = 65;
boolean b = false;

if ( a >= 70 )
{
   System.out.println( "Hello 1" );
   if ( b == true )
      System.out.println( "Hello 2" );
}
else
{
   System.out.println( "Hello 3" );
   if ( b == false )
      System.out.println( "Hello 4" );
}
System.out.println( "Done" );
```

   Description

8. Replace the block at lines 45–50 of Example 5.14 with a single line of code using the ?: operator.

9. What is the output of this code sequence?

```
int season = 3;
switch ( season )
{
   case 1->
        System.out.println( "Season is Winter" );
   case 2->
        System.out.println( "Season is Spring" );
   case 3->
        System.out.println( "Season is Summer" );
   case 4->
        System.out.println( "Season is Fall" );
   default->
        System.out.println( "Invalid season" );
}
```

Description

10. What is the output of this code sequence?

```
char c = 'e';
switch ( c )
{
   case 'H'->
        System.out.println( "letter 1" );
   case 'e'->
        System.out.println( "letter 2" );
   case 'l'->
        System.out.println( "letters 3 and 4" );
   case 'o'->
        System.out.println( "letter 5" );
   default->
        System.out.println( "letter is not in Hello" );
}
```

Description

5.14.3 Fill In the Code

For Exercises 20 through 30, assume that a *boolean* variable named *a* has been declared and assigned the value *true* or *false*. You should also assume that two *int* variables named *b* and *c* have been declared and assigned some integer values.

1. If *a* is *true*, increment *b* by 1.

```
// your code goes here
```

2. If *a* is *true*, increment *b* by 2; if *a* is *false*, decrement *b* by 1.

```
// your code goes here
```

3. If *a* is *true*, change *a* to *false*; if *a* is *false*, change *a* to *true*.

```
// your code goes here
```

4. If *b* is equal to *c*, then assign *true* to *a*.

```
// your code goes here
```

5. If *b* is less than *c*, increment *b* by 1; otherwise, leave *b* unchanged.

```
// your code goes here
```

6. If *b* is *a* multiple of *c*, set *a* to *true*; otherwise, set *a* to *false*.

```
// your code goes here
```

7. If *c* is not equal to 0, assign to *b* the value of *b* divided by *c*.

```
// your code goes here
```

8. If the product *b* times c is greater than or equal to 100, then invert *a* (if *a* is *true*, *a* becomes *false*; if *a* is *false*, *a* becomes *true*); otherwise, assign *true* to *a*.

```
// your code goes here
```

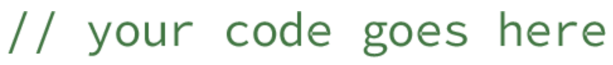
9. If *a* is *true* and *b* is greater than 10, increment *c* by 1.

```
// your code goes here
```

10. If both *b* and *c* are less than 10, then assign *true* to *a*; otherwise, assign *false* to *a*.

```
// your code goes here
```

11. If *b* or *c* is greater than 5, then assign *true* to *a*; otherwise, assign *false* to *a*.

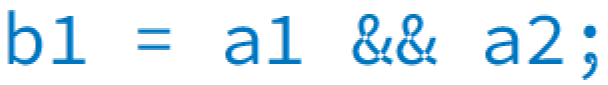


```
// your code goes here
```

5.14.4 Identifying Errors in Code

For Exercises 31 through 38, assume that two *boolean* variables named *b1* and *b2* have been declared and assigned the value *true* or *false* earlier in the program. You should also assume that two *int* variables named *a1* and *a2* have been declared and assigned some integer values earlier in the program.

1. Where is the error in this code sequence?



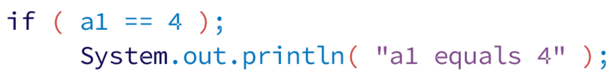
```
b1 = a1 && a2;
```

2. Where is the error in this expression?

```
( b2 == b1 ) AND ( a1 <= a2 )
```

Description

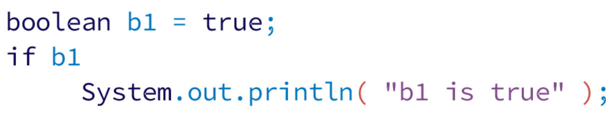
3. Where is the logical error in this code sequence?



```
if ( a1 == 4 );
      System.out.println( "a1 equals 4" );
```

Description

4. Where is the error in this code sequence?



```
boolean b1 = true;
if b1
      System.out.println( "b1 is true" );
```

Description

5. Where is the error in this code sequence?

```
if { b2 == true }
      System.out.println( "b2 is true" );
```

Description

6. Where is the error in this code sequence?

```
if ( b1 == true )
   System.out.println( "b1 is true" );
else
   System.out.println( "b1 is false" );
else if ( a1 < 100 )
   System.out.println( "a1 is <= 100" );
```

Description

7. Is there an error in this code sequence? Explain.

```
if ( b2 == b1 )
      System.out.println( "b2 and b1 have the same value" );
else if ( a1 == a2 )
      System.out.println( "a1 and a2 have the same value" );
else
      System.out.println( "All variables are different" );
```

Description

8. Is there an error in this code sequence? Explain.

```
if ( b2 )
      System.out.println( "b2 is true" );
else if ( a1 <= 10 || a2 > 50 )
{
      System.out.print( "a1 <= 10 or " );
      System.out.println( "a2 > 50" );
}
else
      System.out.println( "none of the above" );
```

Description

5.14.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

1. You coded the following in class *Test.java:*

```
boolean b = true;
if ( b )
      System.out.println( "Inside true block" );
      System.out.println( "b was true" );
else         // line 12
      System.out.println( "Inside false block" );
```

Description

At compile time, you get the following error:

```
Test.java:12: error: 'else' without 'if'
else      // line 12
^
1 error
```

Description

Explain what the problem is and how to fix it.

2. You coded the following in the class *Test.java:*

```
int a = 32;
if ( a = 31 )     // line 9
      System.out.println( "The value of a is 31" );
else
      System.out.println( "The value of a is not 31" );
```

Description

At compile time, you get the following error:

```
Test.java:9: error: incompatible types
if ( a = 31 )    // line 9
       ^
1 error
```

Description

Explain what the problem is and how to fix it.

3. You coded the following in the class *Test.java*:

```
boolean b = true;
if ( b )
{
      System.out.println( "Inside true block" );
      System.out.println( "b was true" );
else         // line 13
      System.out.println( "Inside false block" );
}
System.out.println( "Done" );
```

Description

At compile time, you get the following error:

```
Test.java:13: error: 'else' without 'if'.
else         // line 13
^
1 error
```

Description

Explain what the problem is and how to fix it.

5.14.6 Write a Short Program

1. Write a program that takes two *ints* as input from the keyboard, representing the number of hits and the number of at-bats for a batter. Then calculate the batter's hitting percentage and check if the hitting percentage is above .300. If it is, output that the player is eligible for the All Stars Game; otherwise, output that the player is not eligible.
2. Write a program that reads a *char* as an input from the keyboard and outputs whether it is a valid character to start an identifier. (Hint: look for a method in the *Character*

class.)

3. Write a program that calculates the area of the following figures:

    - a square of side 0.666666667
    - a rectangle of sides 1/9 and 4

    Test the two calculated areas for equality; discuss your result.

6. Write a program that reads a sentence from the keyboard. Depending on the last character of the sentence, print a message identifying the sentence as declarative (ends with a period), interrogative (ends with a question mark), exclamatory (ends with an exclamation point), or other.
7. An email address contains the @ character. Write a program that takes a word from the keyboard and outputs whether it is an email address based on the presence of the @ character. Do not worry about what else is in the word.

8. Write a program that takes two words as input from the keyboard, representing a password and the same password again. (Often, websites ask users to type their password twice when they register to make sure there was no typo the first time around.) Your program should do the following:

    - if both passwords match, then output "You are now registered as a new user"
    - otherwise, output "Sorry, there is a typo in your password"

11. Write a program that takes a word as input from the keyboard, representing a user ID. (Often, websites place constraints on user IDs.) Your program should do the following:

    - if the user ID contains between 6 and 10 characters inclusive, then output "Welcome, barbara" (assuming *barbara* is the user ID entered)
    - otherwise, output "Sorry, user ID invalid"

5.14.7 Programming Projects

1. Write a program that reads a web address (for instance, *www.yahoo.com*) from the keyboard and outputs whether this web address is for a government, a university, a business, an organization, or another entity.

    - If the web address ends with *gov*, it is a government web address.
    - If the web address ends with *edu*, it is a university web address.
    - If the web address ends with *com*, it is a business web address.
    - If the web address ends with *org*, it is an organization

web address.
    - Otherwise, it is a web address for another entity.

7. Write a program that reads a temperature as a whole number from the keyboard and outputs a “probable” season (winter, spring, summer, or fall) depending on the temperature.

    - If the temperature is greater than or equal to 90, it is probably summer.
    - If the temperature is greater than or equal to 70 and less than 90, it is probably spring.
    - If the temperature is greater than or equal to 50 and less than 70, it is probably fall.
    - If the temperature is less than 50, it is probably winter.
    - If the temperature is greater than 110 or less than –5, then you should output that the temperature entered is outside the valid range.

13. Write a program that takes a *String* as input from the keyboard, representing a year. Your program should do the following:

    - If the year entered has two characters, convert it to an *int*, add 2000 to it, and output it.
    - If the year entered has four characters, just convert it to an *int* and output it.
    - If the year entered has neither two nor four characters, output that the year is not valid.

17. Write a program that takes two words as input from the keyboard, representing a user ID and a password. Your program should do the following:

    - If the user ID and the password match “admin” and “open,” respectively, then output “Welcome.”
    - If the user ID matches “admin” and the password does

not match “open,” output “Wrong password.”

- If the password matches “open” and the user ID does not match “admin,” output “Wrong user ID.”
- Otherwise, output “Sorry, wrong ID and password.”

5.14.8 Technical Writing

1. When comparing two *doubles* or *floats* for equality, programmers calculate the difference between the two numbers and check if that difference is sufficiently small. Explain why and give a real-life example.
2. Look at the following code segment:

```
int b = 44;
if ( b = 23 )
      System.out.println( "Inside true block" );
```

Description

In Java, this code will generate the following compiler error:

```
Test.java:9: error: incompatible types
if ( b = 23 )
       ^
required: boolean
found: int
1 error
```

Description

In the C11 programming language, the equivalent code will compile and run and will give you the following output:

```
Inside true block
```

Discuss whether Java handles this situation better than C11 and why.

5.14.9 Group Project (for a group of 1, 2, or 3 students)

1. We want to build a simple “English language” calculator that does the following:

   - takes three inputs from the keyboard, two of them single digits (0 to 9)
   - takes a *char* from the keyboard, representing one of five operations from the keyboard: 1 (addition), – (subtraction), * (multiplication), / (division), and ^ (exponentiation)
   - outputs the description of the operation in plain English, as well as the numeric result

   For instance, if the two numbers are 5 and 3, and the operation is *, then the output should be

```
five multiplied by three is 15
```

   Note that the result is given as a number, not a word.
   If the two numbers are 2 and 9, and the operation is –, then the output should be

```
two minus nine is -7
```

   If the two numbers are 5 and 2, and the operation is ^, then the output should be

```
five to the power two is 25
```

   Hint: to perform the exponentiation, use the *pow* method of the *Math* class.
   If the two numbers are 5 and 0, and the operation is /, then the output should be

```
Division by zero is not allowed
```

   Here the operation will not be performed.
   If the two numbers are 25 and 3, and the operation is 1, then the output should be

```
Invalid number
```

because 25 has two digits.

As for the operators, they should be translated into English as follows:

+	plus
–	minus
*	multiplied by
/	divided by
^	to the power

You should use the *switch* … *case* selection statement to translate the input values into words.

You need to consider these special situations:

- For division, there is a special constraint: you cannot divide by 0, and you should therefore test whether the second number is 0. If it is 0, then you should output a message saying that you are not allowed to divide by 0.
- The “operator” is not one of the preceding five operators; in that case, output a message saying that the operator is not a valid one.
- One or two of the numbers is not a valid digit; again, you should output a message to that effect.
- Hint: You can deal with these special situations in the *default* statement of the *switch* block and possibly use some *boolean* variables to keep track of this information, as you may need it later in your program.

Introduction

Have you ever watched the cashier at the grocery store? Let's call the cashier Jane. Jane's job is to determine the total cost of a grocery purchase. To begin, Jane starts with a total cost of $0.00. She then reaches for the first item and scans it to record its price, which is added to the total. Then she reaches for the second item, scans that item to record its price, which is added to the total, and so on. Jane continues scanning each item, one at a time, until there are no more items to scan. Usually, the end of an order is signaled by a divider bar lying across the conveyor belt. When Jane sees the divider bar, she knows she is finished. At that point, she tells us the total cost of the order, collects the money, and gives us a receipt.

So we see that Jane's job consists of performing some preliminary work, processing each item one at a time, and reporting the result at the end.

In computing, we often perform tasks that follow this same pattern:

1: initialize values
2: process items one at a time
3: report results

The flow of control that programmers use to complete jobs with this pattern is called **looping**, or **repetition**.

6.1 Event-Controlled Loops Using *while*

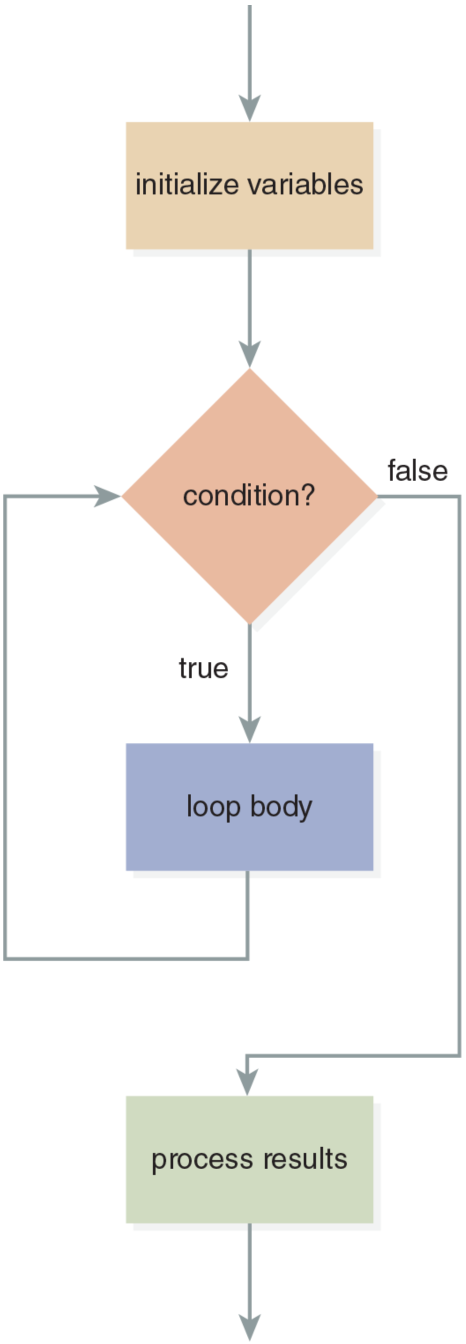
If we attempt to write pseudocode for the grocery store cashier, we may start with something like this:

```
set total to $0.00
reach for first item
if item is not the divider bar
   add price to total
reach for next item
if item is not the divider bar
   add price to total
reach for next item
if item is not the divider bar
   add price to total
… (finally)
reach for next item
item is the divider bar,
   tell the customer the total price
```

Description

We can see a pattern here. We start with an order total of $0.00. Then we repeat a set of operations for each item. We reach for the item and check whether it’s the divider bar. If the item is not the divider bar, we add the item’s price to the order total. We reach for the next item and check whether it’s the divider bar, and so on. When we reach for the item and find that it is the divider bar, we know there are no more items to process, so the total we have at that time is the total for the whole order. In other words, we don’t know the number of items that will be placed on the conveyor belt. We just process the order, item by item, until we see the divider bar, which we do not process.

In Java, the *while* loop is designed for repeating a set of instructions for each input value when we don't know at the beginning how many input values there will be. We simply process each input value, one at a time, until a signal—an event—tells us that there is no more input. This is called **event-controlled looping**. In the cashier's case, the signal for the end of input was the divider bar. In other tasks, the signal for the end of the input may be a special value that the user enters, called a **sentinel value**, or it may be that we've reached the end of an input file.



initialize variables
condition?
false
true
loop body
process results

6.2 General Form for *while* Loops

The while loop has this syntax:

```
// initialize variables
while ( condition )
{
   // process data; loop body
}
// process the results
```

Description

The condition is a *boolean* expression, that is, any expression that evaluates to *true* or *false*. When the *while* loop statement is encountered, the condition is evaluated; if the value is *true*, the statements in the **loop body** are executed. The condition is then reevaluated and, if *true*, the loop body is executed again. This repetition continues until the loop condition evaluates to *false*, at which time, the loop body is skipped and execution continues at the instruction following the loop body.

The curly braces are needed only if the loop body has more than one statement—that is, if more than one statement should be executed if the condition evaluates to *true*.

The scope of any variable defined within the *while* loop body extends from its declaration to the end of the *while* loop. Thus, any variable that is declared within a *while* loop body has block scope and cannot be referenced after the *while* loop ends.

The flow of control of a *while* loop is shown in **Figure 6.1**.

Figure 6.1 Flow of Control of a *while* Loop

Description

Each execution of the loop body is called an **iteration** of the loop. Thus, if the loop body executes five times before the condition evaluates to *false*, we say there were five iterations of the *while* loop.

What happens if the loop condition is *false* the first time it is evaluated? Because the loop condition is evaluated before executing the *while* loop body, and the loop body is executed only if the condition is *true*, it is possible that the *while* loop body is never executed. In that case, there would be **zero iterations** of the loop.

Using a *while* loop construct, the pseudocode for the cashier would look like this:

```
set total to $0.00
reach for first item
while item is not the divider bar
{
   add price to total
   reach for next item
}
// if we get here, the item is the divider bar
output the total price
```

Description

It is also possible to construct a *while* loop whose condition *never* evaluates to *false*. That results in an **endless loop**, also known as an **infinite loop**. Because the condition always evaluates to *true*, the loop body is executed repeatedly, without end. One symptom of an endless loop is that the program doesn't terminate; it appears to "hang." However, if the program writes some output in the loop body, we will see that output spewing out on the Java console. Normally, the only recourse is for the user to abort the program.

COMMON ERROR TRAP

Avoid putting a semicolon after the condition of a *while* loop. Doing so creates an empty loop body and could result in an endless loop.

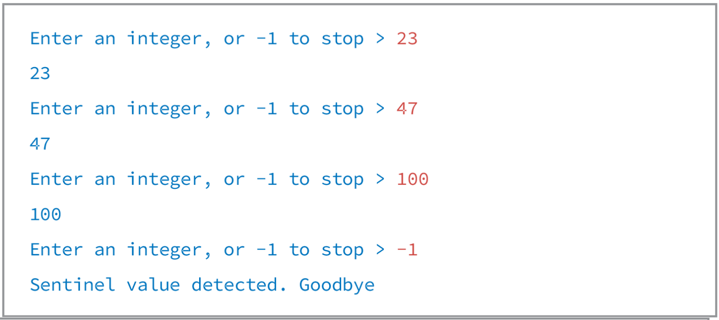
The way to ensure that the condition will eventually evaluate to *false* is to include code, called a **loop update statement**, within the loop body that appropriately changes the variable that is being tested by the loop condition. If, for example, the loop condition tests for reading a specific value, the loop update statement should read the next input value.

One common logic error that causes an endless loop is putting a semicolon after the condition, as in the following:

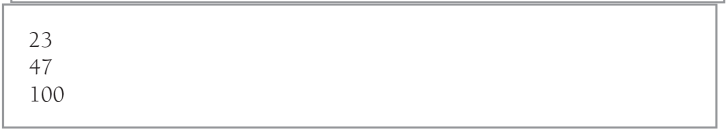
```
while ( condition ); // semicolon causes endless loop if condition is true
```

Description

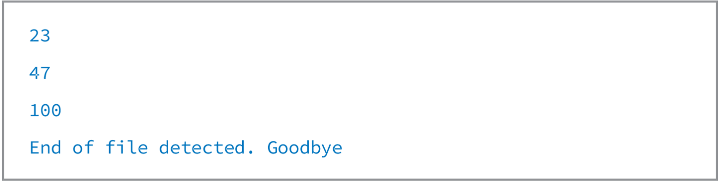
A semicolon immediately following the condition indicates an empty loop body. Although some advanced programming techniques call for the use of an empty loop body, we will not be using those techniques in this chapter.



```
Enter an integer, or -1 to stop > 23
23
Enter an integer, or -1 to stop > 47
47
Enter an integer, or -1 to stop > 100
100
Enter an integer, or -1 to stop > -1
Sentinel value detected. Goodbye
```



```
23
47
100
```



```
23
47
100
End of file detected. Goodbye
```

6.3 Event-Controlled Looping

The *while* loop is used when we don’t know how many times the loop will execute; that is, when the loop begins, we don’t know how many iterations of the loop will be required. We rely on a signal, or **event**, to tell us that we have processed all the data. For example, when the cashier begins checking out an order, she doesn’t (necessarily) know how many items are in the grocery cart; she only knows to stop when she sees the divider bar on the conveyor belt. We call this an event-controlled loop because we continue processing data until an event occurs, which signals the end of the data.

When we’re prompting the user to enter data from the console, and we don’t know at the beginning of the loop how much data the user has to be processed, we can define a special input value, called the sentinel value. The sentinel value can vary from task to task and is typically a value that is outside the normal range of data for that task.

Sometimes the data our program needs are in a text file. For example, a file could store a company’s monthly sales for the last five years. We may want to calculate average monthly sales or perform other statistical computations on that data. In this case, we need to read our data from the file, instead of asking the user to enter the data from the keyboard. Typically, we use a file when a large amount of data is involved because it would be impractical for a user to enter the data manually.

Reading from a file is also an event-controlled loop because we don't know at the beginning of the program how much data is in the file. Thus, we need some way to determine when we have finished processing all the data in the file. Java enables us to test if we have reached the end of the file. Thus, for input from a file, sensing the end-of-file indication is the event that signals that there is no more data to read.

6.3.1 Reading Data from the User

Let's look at the general form for using a *while* loop to process data entered from the user.

```
initialize variables
read the first data item // priming read
while data item is not the sentinel value
{
    process the data

    read the next data item // update read
}
report the results
```

Description

After performing any initialization, we attempt to read the first item. We call this the **priming read** because, like priming a pump, we use that value to feed the condition of the *while* loop for the first iteration. If the first item is not the sentinel value, we process it. Processing may consist of calculating a total, counting the number of data items, comparing the data to previously read values, or any number of operations. Then we read the next data item. This is called the **update read** because we update the data item in preparation for feeding its value into the condition of the *while* loop for the next iteration. This processing, followed by an update read, continues until we do read the sentinel value, at which time we do not execute the *while* loop body. Instead, we skip to the first instruction following the *while* loop. Note that the sentinel value is not meant to be processed. Like the divider bar for the cashier, it is simply a signal to stop processing.

We illustrate this pattern in **Example 6.1**, which prompts the user for integers and echoes to the console whatever the user enters. We chose the sentinel value to be –1; that is, when the user enters a –1, we stop processing.

Example 6.1 Echoing Input from the User

```java
/*  Working with a sentinel value
    Anderson, Franceschi
*/
import java.util.Scanner;

public class EchoUserInput
{
   public static void main( String [ ] args )
   {
      final int SENTINEL = -1;
      int number;

      Scanner scan = new Scanner( System.in );

      // priming read
      System.out.print( "Enter an integer, or -1 to stop > " );
      number = scan.nextInt( );

      while ( number != SENTINEL )
      {
          // processing
          System.out.println( number );

          // update read
          System.out.print( "Enter an integer, or -1 to stop > " );
          number = scan.nextInt( );
      }

      System.out.println( "Sentinel value detected. Goodbye" );
   }
}
```

Description

Figure 6.2 shows the output from this program when the user enters 23, 47, 100, and –1.

Figure 6.2 Output from Example 6.1, Using a Sentinel Value

Description

On line 10, we declare the sentinel value, −1, as a constant because the value of the sentinel will not change during the execution of the program, and it lets us clearly state via the *while* loop condition (line 19) that we want to execute the loop body only if the input is not the sentinel value.

Then on lines 16–17, we perform the priming read. The *while* loop condition on line 19 checks for the sentinel value. If the user enters the sentinel value first, we skip the *while* loop altogether and execute line 29, which prints a message that the sentinel value was entered, and we exit the program. If the user enters a number other than the sentinel value, we execute the body of the *while* loop (lines 21–26). In the *while* loop, we simply echo the user's input to the console, then perform the update read. Control then skips to the *while* loop condition, where the value the user entered in the update read is compared to the sentinel value. If this entry is the sentinel value, the loop is skipped; otherwise, the body of the loop is executed: The value is echoed, then a new value is read. This same processing continues until the user does enter the sentinel value. Note that the sentinel value (−1) is not echoed to the output.

COMMON ERROR TRAP

Omitting the update read may result in an endless loop.

A common error in constructing *while* loops is forgetting the update read. Without the update read, the *while* loop continually processes the same data item, leading to an endless loop.

Another common error is omitting the priming read and, instead, reading data inside the *while* loop before the processing, as in the following pseudocode:

```
initialize variables
while data item is not the sentinel value
{
     read the next data
     process the data
}
report the results
```

Description

This structure has several problems. The first time we evaluate the *while* loop condition, we haven't read any data, so the result of that evaluation is unpredictable. Second, when we do read the sentinel value, we will process it, leading to incorrect results.

COMMON ERROR TRAP

Omitting the priming read leads to incorrect results.

6.3.2 Reading Data from a Text File

The *Scanner* class enables us to read data easily from a text file. Java also provides a whole set of classes in the *java.io* package to enable programmers to perform user input and output with a file.

For the *Scanner* class, the general form for reading data from a text file is a little different from reading the data from the user. First, instead of reading a value and checking whether it is the sentinel value, we check whether there is more data in the file, then read a value. Second, we don't need to print a prompt because the user doesn't enter the data; we just read the next value from the file. With the *Scanner* class, the pseudocode for reading from a text file is shown here:

```
initialize variables
while we have not reached end of file
{
   read the next data item
   process the data
}
report the results
```

Description

Scanner class methods, including a constructor for reading from a text file, are shown in **Table 6.1**. Another class we will use is the *File* class, which associates a file name with a file.

The constructor for the *File* class is shown in **Table 6.2**.

Selected Methods of the *Scanner* Class

Selected Methods of the *Scanner* Class

Constructor

`Scanner( File file )`
creates a *Scanner* object and associates it with a file

Return value	Method name and argument list
`boolean`	`hasNext( )` returns *true* if there is another token in the input stream; *false*, otherwise
`byte`	`nextByte( )` returns the next input as a *byte*
`short`	`nextShort( )` returns the next input as a *short*
`int`	`nextInt( )` returns the next input as an *int*
`long`	`nextLong( )` returns the next input as a *long*
`float`	`nextFloat( )` returns the next input as a *float*
`double`	`nextDouble( )` returns the next input as a *double*
`boolean`	`nextBoolean( )` returns the next input as a *boolean*
`String`	`next( )` returns the next token in the input line as a *String*

Description

***File* Class Constructor**

A Constructor for the *File* Class

`File( String pathname )`

constructs a *File* object with the *pathname* file name so that the file name is platform independent

---

Description

The constructor shown in Table 6.1 can be used to associate a *Scanner* object with a file. The *Scanner* object will tokenize the contents of the file and return the tokens as we call the next methods. The *hasNext* method in the *Scanner* class returns *true* if the input has another token, and *false* otherwise. Thus, when the *hasNext* method returns *false*, we know we have reached the end of the file.

Example 6.2 reads integers from a file named *input.txt* and echoes the integers to the console. The contents of *input.txt* are shown in **Figure 6.3** and the output from the program is shown in **Figure 6.4**.

Example 6.2 Echoing Input from a File

```
 1 /* Reading a Text File
 2    Anderson, Franceschi
 3 */
 4 import java.util.Scanner;
 5 import java.io.File;
 6 import java.io.IOException;
 7
 8 public class EchoFileData
 9 {
10    public static void main( String [ ] args ) throws IOException
11    {
12       int number;
13
14       File inputFile = new File( "input.txt" );
15       Scanner file = new Scanner( inputFile );
16
17       while ( file.hasNext( ) )
18       {
19           // read next integer
20           number = file.nextInt( );
21           // process the value read
22           System.out.println( number );
23       }
24
25       System.out.println( "End of file detected. Goodbye" );
26    }
27 }
```

Description

Figure 6.3 Contents of *input.txt*

Description

Figure 6.4 Output from Example 6.2, Reading from a File

Description

On line 14 of Example 6.2, we use the constructor of the *File* class to convert the file name, *input.txt*, to a platform-independent file name. Because we are specifying the simple file name, the JVM will look for the file in the same folder as our source file. If the file is located in another folder, we need to specify the path as well as the file name. For example, if the file were located on a flash drive in a Windows system, we would pass the *String “e:\\input.txt”* to the constructor. Notice that we need to use an escape sequence of two backslashes in order to specify the pathname, *e:\input.txt*.

The *File* class belongs to the *java.io* package, so we include an *import* statement for that class in line 5.

In line 15, we construct a *Scanner* object associated with the *inputFile* object. If the file is not found, the constructor generates a *FileNotFoundException*. It is also possible that an *IOException* may be generated if we encounter problems reading the file. Java requires us to acknowledge that these exceptions may be generated. One way to do that is to include the phrase *throws IOException* in the header for *main* (line 10). We also import the *IOException* class on line 6.

On line 17, the first time our *while* loop condition is evaluated, we check whether there is any data in the file. If the file is empty, the *hasNext* method will return *false*, and we will skip execution of the loop body, continuing at line 25, where we print a message and exit the program.

REFERENCE POINT

You can read more about the *Scanner* class on Oracle's Java website: *www.oracle.com/technetwork/java*.

The body of the *while* loop (lines 19–22) calls the *nextInt* method to read the next integer in the file and echoes that integer to the console. We then reevaluate the *while* loop condition (line 17) to determine if more data is in the file. When no more integers remain to be read, the *hasNext* method returns *false*, and we skip to line 25, where we print a message and exit the program.

Notice that we do not use a priming read because the *hasNext* method essentially peeks ahead into the file to see if there is more data. If the *hasNext* method returns *true*, we know that there is another integer to read, so we perform the read in the first line of the *while* loop body (line 20).

```
Welcome to the addition calculator.

Enter the first number or 0 for the total > 34
Enter the next number or 0 for the total > -10
Enter the next number or 0 for the total > 2
Enter the next number or 0 for the total > 5
Enter the next number or 0 for the total > 8
Enter the next number or 0 for the total > 0
The total is 39

6.4 Looping Techniques

The *while* loop is an important tool for performing many common programming operations on a set of input values. For example, the *while* loop can be used to calculate the sum of values, count the number of values, find the average value, find the minimum and maximum values, and perform other operations.

6.4.1 Accumulation

Let's look at a common programming operation for which a *while* loop is useful: calculating the sum of a set of values. To do this, we will build a simple calculator that performs one function: addition. We will prompt the user for numbers one at a time. We'll make the sentinel value a 0; that is, when the user wants to stop, the user will enter a 0. At that point, we will print the total.

The calculator can be developed using an event-controlled *while* loop and a standard computing technique: **accumulation.** In the accumulation operation, we initialize a *total* variable to 0. Each time we input a new value, we add that value to the *total*. When we reach the end of the input, the current value of *total* is the total for all the input.

Here is the pseudocode for the addition calculator:

```
set total to 0
read a number // priming read
while the number is not the sentinel value
{
    add the number to total
    read the next number // update read
}
output the total
```

Description

Notice that this operation is almost identical to the grocery cashier's job in that we perform a priming read before the *while* loop. Inside the *while* loop, we process each number one at a time—adding each number to the total, then we read the next value, until we see the sentinel value, which is the signal to stop.

Example 6.3 provides the code for the addition calculator, and **Figure 6.5** shows the output for a sample execution of the calculator.

Example 6.3 An Addition Calculator

```
 1 /*  Addition Calculator
 2     Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6
 7 public class Calculator
 8 {
 9    public static void main( String [ ] args )
10    {
11       final int SENTINEL = 0;
12       int number;
13       int total = 0;
14
15       Scanner scan = new Scanner( System.in );
16
17       System.out.println( "Welcome to the addition calculator.\n" );
18
19       System.out.print( "Enter the first number"
20                         + " or 0 for the total > " );
21       number = scan.nextInt( );
22
23       while ( number != SENTINEL )
24       {
25           total += number;
26
27           System.out.print( "Enter the next number"
28                             + " or 0 for the total > " );
29           number = scan.nextInt( );
30       }
31
32       System.out.println( "The total is " + total );
33    }
34 }
```

Description

Figure 6.5 Output from a Sample Run of the Addition Calculator

Description

Line 13 declares and initializes the *total* to 0. This is an important step because the loop body will add each input value to the total. If the total is not set to 0 before the first input, we will get incorrect results. Furthermore, if *total* is declared but not initialized, our program will not compile.

COMMON ERROR TRAP

Forgetting to initialize the total to 0 will produce incorrect results.

Lines 19–21 read the first input value (the priming read). The *while* loop begins at line 23, and its condition checks for the sentinel value. The first time the *while* loop is encountered, this condition will check the value of the input from the priming read.

The loop body processes the input (line 25), which consists of adding the input value to the *total*. The final step in the loop body (lines 27–29) is to read the next input (the update read).

SOFTWARE ENGINEERING TIP

Indent the body of a *while* loop to clearly illustrate the logic of the program.

When the end of the loop body is reached, control is transferred back to line 23, where the loop condition is again tested with the input value read on line 29. If the condition is *true*, that is, if the input just read is not the sentinel value, then the loop body is reexecuted and the condition is retested, continuing until the input is the sentinel value, which causes the condition to evaluate to *false*. At that time, the loop body is skipped and line 32 is executed, which reports the results by printing the *total*.

COMMON ERROR TRAP

Choosing the wrong sentinel value may result in logic errors.

Notice that the body of the *while* loop is indented and that the opening and closing curly braces are aligned in the same column as the *w* in the *while*. This style lets us easily see which statements belong to the *while* loop body.

It is important to choose the sentinel value carefully. Obviously, the sentinel value cannot be a value that the user might want to be processed. In the addition calculator, we want to allow the user to enter positive or negative integers. We chose 0 as the sentinel value for two reasons. First, adding 0 to a total has no effect, so it is unlikely that the user will want to enter that value to be processed. Second, to the user, it is logical to enter a 0 to signal that there are no more integers to be added.

CODE IN ACTION

To see a step-by-step illustration of a *while* loop with a

sentinel value, look for the movie within the online resources. Click on the link to start the movie.

6.4.2 Counting Items

Counting is used when we need to know how many items are input or how many input values fit some criterion, for example, how many items are positive numbers or how many items are odd numbers. Counting is similar to accumulation in that we start with a count of 0 and increment (add 1 to) the count every time we read a value that meets the criterion. When there are no more values to read, the count variable contains the number of items that meet our criterion.

For example, let's count the number of students who passed a test. The pseudocode for this operation is as follows:

```
set countPassed to 0
read a test score
while the test score is not the sentinel value
{
   if the test score >= 60
   {
      add 1 to countPassed
   }
   read the next test score
}
output countPassed
```

Description

The application in **Example 6.4** counts the number of students that passed a test. We also calculate the percentage of the class that passed the test. To do this, we maintain a second count: the number of scores entered. This value will be incremented each time we read a score, whereas the *countPassed* value will be incremented only if the score is greater than or equal to 60. The sentinel value is –1. A sample run of this program is shown in Figure 6.6.

Example 6.4 Counting Passing Test Scores

```
 1 /* Counting passing test scores
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6 import java.text.DecimalFormat;
 7
 8 public class CountTestScores
 9 {
10    public static void main( String [ ] args )
11    {
12      int countPassed = 0;
13      int countScores = 0;
14      int score;
15      final int SENTINEL = -1;
16
17      Scanner scan = new Scanner( System.in );
18
19      System.out.println( "This program counts "
20                  + "the number of passing test scores." );
21      System.out.println( "Enter a -1 to stop." );
22
23      System.out.print( "Enter the first score > " );
24      score = scan.nextInt( );
25
26      while ( score != SENTINEL )
27      {
28          if ( score >= 60 )
29          {
30                countPassed++;
31          }
32
33          countScores++;
34
35          System.out.print( "Enter the next score > " );
36          score = scan.nextInt( );
37      }
38
39      System.out.println( "You entered " + countScores + " scores" );
40      System.out.println( "The number of passing test scores is "
41                               + countPassed );
42      if ( countScores != 0 )
43      {
44         DecimalFormat percent = new DecimalFormat( "0.0%" );
45         System.out.println(
46           percent.format( (double)  countPassed  / countScores )
47           + " of the class passed the test" );
48      }
49    }
50 }
```

Description

Figure 6.6 Counting Passing Test Scores

Description

Lines 12 and 13 declare the variables *countPassed* and *countScores* and initialize both to 0. Initializing these values to 0 is critical; otherwise, we will get the wrong results or a compiler error. We initialize these values to 0 because at that point, we have not yet processed any test scores.

Our *while* loop framework follows the familiar pattern. We perform the priming read for the first input (lines 23–24); our *while* loop condition checks for the sentinel value (line 26); and the last statements of the *while* loop (lines 35–36) read the next value.

COMMON ERROR TRAP

Forgetting to initialize the count variables will produce a compiler error.

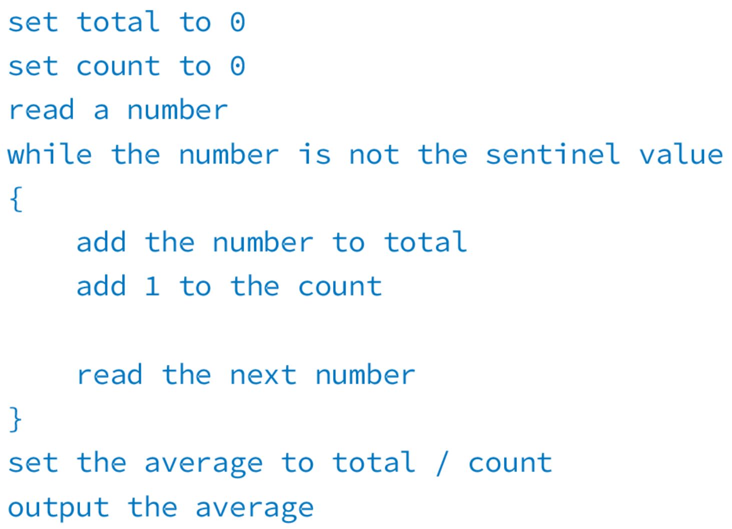
In the processing portion of the *while* loop, line 28 checks if the score just read is a passing score, and if so, line 30 adds 1 to *countPassed*. For each score entered, regardless of whether the student passed, we increment *countScores* (line 33).

When the sentinel value is entered, the *while* loop condition evaluates to *false* and control skips to line 39, where we output the number of scores entered and the number of passing scores. So that we avoid dividing by 0, note that line 42 checks whether no scores were entered. Note also that in line 46 we type cast *countPassed* to a *double* to force floating-point division, rather than integer division, so that the fractional part of the quotient will be maintained.

6.4.3 Calculating an Average

Calculating an average is a combination of accumulation and counting. We use accumulation to calculate the total and we use counting to count the number of items to average.

Here’s the pseudocode for calculating an average:



```
set total to 0
set count to 0
read a number
while the number is not the sentinel value
{
    add the number to total
    add 1 to the count

    read the next number
}
set the average to total / count
output the average
```

Description

Thus, to calculate an average test score for the class, we need to calculate the total of all the test scores, then divide by the number of students who took the test.

```
average = total / count;
```

It’s important to remember that if we declare *total* and *count* as integers, then the *average* will be calculated using integer division, which truncates the remainder. To get a floating-point average, we need to type cast one of the variables (either *total* or *count*) to a *double* or a *float* to force the division to be performed as floating-point.

```
double average = (double) total / count;
```

Description

The application in **Example 6.5** calculates an average test score for a class of students. The output is shown in **Figure 6.7**.

Example 6.5 Calculating an Average Test Score

```
 1 /* Calculate the average test score
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6 import java.text.DecimalFormat;
 7
 8 public class AverageTestScore
 9 {
10   public static void main( String [ ] args )
11   {
12     int count = 0;
13     int total = 0;
14     final int SENTINEL = -1;
15     int score;
16
17     Scanner scan = new Scanner( System.in );
18
19     System.out.println( "To calculate a class average," );
20     System.out.println( "enter each test score." );
21     System.out.println( "When you are finished, enter a -1" );
22
23     System.out.print( "Enter the first test score > " );
24     score = scan.nextInt( );
25
26     while ( score != SENTINEL )
27     {
28        total += score;   // add score to total
29        count++;          // add 1 to count of test scores
30
31        System.out.print( "Enter the next test score > " );
32        score = scan.nextInt( );
33     }
34
35     if ( count != 0 )
36     {
37         DecimalFormat oneDecimalPlace = new DecimalFormat( "0.0" );
38         System.out.println( "\nThe class average is "
39           + oneDecimalPlace.format( (double) total / count ) );
40     }
41     else
42         System.out.println( "\nNo grades were entered" );
43   }
44 }
```

Description

Figure 6.7 Calculating the Average Test Score

Description

In Example 6.5, lines 12 and 13 declare both *count* and *total* variables as *ints* and initialize each to 0. Again, our *while* loop structure follows the same pattern. Lines 23–24 read the first input value; the *while* loop condition (line 26) checks for the sentinel value; and the last statements in the *while* loop (lines 31–32) read the next score. For the processing portion of the *while* loop, we add the score to the total and increment the count of scores (lines 28–29). When the sentinel value is entered, we stop executing the *while* loop and skip to line 35.

In line 35, we avoid dividing by 0 by checking whether *count* is 0 (that is, if no scores were entered) before performing the division. If *count* is 0, we simply print a message saying that no grades were entered. If *count* is not 0, we calculate and print the average. We first instantiate a *DecimalFormat* object (line 37) so that we can output the average to one decimal place. Remember that we need to type cast the total to a *double* (lines 38–39) to force floating-point division, rather than integer division.

COMMON ERROR TRAP

Forgetting to check whether the denominator is 0 before performing division is a logic error.

6.4.4 Finding Maximum or Minimum Values

In previous examples, we calculated a total for a group of numbers by keeping a running total. We started with a total of 0, then added each new input value to the running total. Similarly, we counted the number of input items by keeping a running count. We started with a count of 0 and incremented the count each time we read a new value. We can apply that same logic to calculating a maximum or minimum. For example, to find the maximum of a group of values, we can keep a “running,” or current, maximum. We start by assuming that the first value we read is the maximum. In fact, it is the largest value we have seen so far. Then as we read each new value, we compare it to our current maximum. If the new value is greater, we make the new value our current maximum. When we come to the end of the input values, the current maximum is the maximum for all the input values.

Finding the minimum value, of course, uses the same approach, except that we replace the current minimum only if the new value is less than the current minimum.

Here’s the pseudocode for finding a maximum value in a file:

```
read a first number and make it the maximum
while there is another number to read
{
    read the next number
    if number > maximum
    {
       set maximum to number
    }
}
output the maximum
```

Description

Example 6.6 shows the code to find a maximum test grade in a file. As shown in **Figure 6.8**, the grades are stored as integers, one per line, in the file *grades.txt*. When this program runs, its output is shown in **Figure 6.9**.

Example 6.6 Finding the Maximum Value

```
 1 /* Find the maximum test grade
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6 import java.io.*;
 7
 8 public class FindMaximumGrade
 9 {
10    public static void main( String [ ] args ) throws IOException
11    {
12      int maxGrade;
13      int grade;
14
15      Scanner file = new Scanner( new File( "grades.txt" ) );
16
17      System.out.println( "This program finds the maximum grade "
18                          + "for a class" );
19
20      if ( ! file.hasNext( ) )
21      {
22           System.out.println( "No test grades are in the file" );
23      }
24      else
25      {
26          maxGrade = file.nextInt( ); // make first grade the max
27
28          while ( file.hasNext( ) )
29          {
30             grade = file.nextInt( ); // read next grade
31
32             if ( grade > maxGrade )
33               maxGrade = grade; // save as current max
34          }
35
36          System.out.println( "The maximum grade is " + maxGrade );
37      }
38   }
39 }
```

Description

Figure 6.8 The Contents of *grades.txt*

Description

Figure 6.9 Finding the Maximum Value

Description

In line 20, we call the *hasNext* method to test whether the file is empty. If so, we print a message (line 22) and the program ends. If, however, the file is not empty, we read the first value and automatically make it our maximum by storing the grade in *maxGrade* (line 26). In line 28, our *while* loop condition tests whether we have reached the end of the file. If not, we execute the body of the *while* loop (lines 30–33). We read the next grade and check whether that grade is greater than the current maximum. If so, we assign that grade to *maxGrade*; otherwise, we leave *maxGrade* unchanged. Then control is transferred to line 28 to retest the *while* loop condition.

When we do reach the end of the file, the *while* loop condition becomes *false*; control is transferred to line 36, and we output *maxGrade* as the maximum value.

COMMON ERROR TRAP

Initializing a maximum or a minimum to an arbitrary value, such as 0 or 100, is a logic error and could result in incorrect results.

A common error is to initialize the maximum or minimum to an arbitrary value, such as 0 or 100. This will not work for all conditions, however. For example, let's say we are finding the maximum number and we initialize the maximum to 0. If the user enters all negative numbers, then when the end of data is encountered, the maximum will still be 0, which is clearly an error. The same principle is true when finding a minimum value. If we initialize the minimum to 0, and the user enters all positive numbers greater than 0, then at the end of our loop, our minimum value will still be 0, which is also incorrect.

```

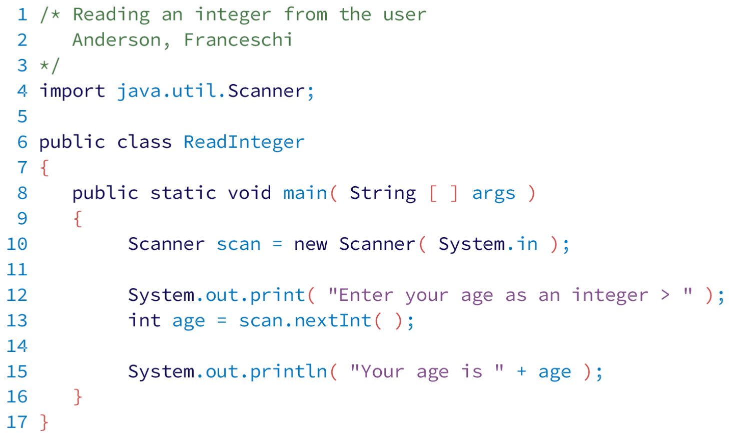
6.5 Type-Safe Input Using *Scanner*

One problem with reading input using *Scanner* is that if the next token does not match the data type we expect, an *InputMismatchException* is generated, which stops execution of the program. This could be caused by a simple typo on the user's part; for example, the user may type a letter or other nonnumeric character when our program prompts for an integer. To illustrate this problem, **Example 6.7** shows a small program that prompts the user for an integer and calls the *nextInt* method of the *Scanner* class to read the integer, and **Figure 6.10** shows the *InputMismatchException* generated when the user enters an *a* instead of an integer. Notice that the program ends when the exception is generated; we never execute line 15, which would echo the age to the console.

Example 6.7 Reading an Integer



```java
/* Reading an integer from the user
   Anderson, Franceschi
*/
import java.util.Scanner;

public class ReadInteger
{
   public static void main( String [ ] args )
   {
        Scanner scan = new Scanner( System.in );

        System.out.print( "Enter your age as an integer > " );
        int age = scan.nextInt( );

        System.out.println( "Your age is " + age );
   }
}
```

Description

Figure 6.10 Input Failure

Description

We can make our program more robust by checking, before we read, that the next token matches our expected input. The *Scanner* class provides *hasNext* methods for doing this, which are shown in **Table 6.3**. The *hasNext* methods return *true* if the next token can be read as the data type requested. For example, if we expect an integer, we can test whether the user has typed characters that can be interpreted as an integer by calling the *hasNextInt* method. If that method returns *true*, it is safe to read the value using the *nextInt* method. If the next token is not what we need, that is, if the *hasNextInt* method returns *false*, then reading that value as an *int* will generate the *InputMismatchException*. In that case, we need to notify the user that the value typed is not valid and reprompt for new input. But first we need to clear the invalid input. We can flush the invalid input by calling the *nextLine* method of the *Scanner* class, which returns any remaining tokens on the input line as a *String*. Then we just ignore that *String*. **Example 6.8** shows a revised version of Example 6.7 that is type-safe, meaning we guarantee we have an integer to read before reading it.

Scanner Methods for Testing Tokens

Selected Input Stream Testing Methods of the *Scanner* Class

Return value	Method name and argument list
`boolean`	`hasNext( )` returns *true* if there is another token in the input stream; *false*, otherwise
`boolean`	`hasNextByte( )` returns *true* if the token in the input stream can be read as a *byte*; *false*, otherwise
`boolean`	`hasNextShort( )` returns *true* if the token in the input stream can be read as a *short*; *false*, otherwise
`boolean`	`hasNextInt( )` returns *true* if the token in the input stream can be read as an *int*; *false*, otherwise
`boolean`	`hasNextLong( )` returns *true* if the token in the input stream can be read as a *long*; *false*, otherwise
`boolean`	`hasNextFloat( )` returns *true* if the token in the input stream can be read as a *float*; *false*, otherwise
`boolean`	`hasNextDouble( )` returns *true* if the token in the input stream can be read as a *double*; *false*, otherwise
`boolean`	`hasNextBoolean( )` returns *true* if the token in the input stream can be read as a *boolean*; *false*, otherwise
`String`	`nextLine( )` returns the remainder of the input line as a *String*

Description

Example 6.8 Type-Safe Input

```
 1 /* Type-Safe Input Using Scanner

 5 import java.util.Scanner;
 6
 7 public class TypeSafeReadInteger
 8 {
 9    public static void main( String [ ] args )
10    {
11       Scanner scan = new Scanner( System.in );
12       String garbage;
13
14       System.out.print( "Enter your age as an integer > " );
15       while ( ! scan.hasNextInt( ) )
16       {
17             garbage = scan.nextLine( );
18             System.out.print( "\nPlease enter an integer > " );
19       }
20       int age = scan.nextInt( );
21       System.out.println( "Your age is " + age );
22    }
23 }
```

Description

On line 14 of Example 6.8, we prompt for the integer. Then on line 15, the *while* loop condition checks whether the user has, indeed, typed an integer value. If not, we ignore whatever the user did type by calling the *nextLine* method (line 17). On line 18, we reprompt the user. The *while* loop continues executing until the user does enter an integer and the *hasNextInt* method returns *true*. At that point, we execute line 20, which reads the integer into the *age* variable. Note that we need to use a *while* loop rather than an *if* statement because an *if* statement will test only the first invalid input value. Using a *while* loop allows us to keep prompting the user as many times as needed until a valid value is entered. **Figure 6.11** shows the output of this program when the user enters data other than integers, then finally enters an integer.

Figure 6.11 Reprompting Until the User Enters an Integer

Description

```
Welcome to Bonnie's Burgers. Select from our menu:
        C  Cheeseburger: $7.49
        H  Hot dog: $6.99
        L  Lemonade: $2.50
        T  Iced tea: $2.75
Order an item, or "S" to stop > h
Hot dog ordered. Subtotal: $6.99

Order another item, or "S" to stop > T
Iced tea ordered. Subtotal: $9.74

Order another item, or "S" to stop > s

Total order cost is $9.74
```

6.6 Constructing Loop Conditions

Constructing the correct loop condition may seem a little counterintuitive. The loop executes as long as the loop condition evaluates to *true*. Thus, if we want our loop to terminate when we read the sentinel value, then the loop condition should check that the input value is *not* the sentinel value. In other words, the loop continuation condition is the inverse of the loop termination condition. For a simple sentinel-controlled loop, the condition normally follows this pattern:

```
while ( inputValue != sentinel )
```

In fact, we can see that the loop conditions in many of the examples in this chapter use this form of *while* loop condition.

For some applications, there may be multiple sentinel values. For example, suppose we provide a menu for a user with each menu option being a single character. The user can repeatedly select options from the menu, with the sentinel value being *S* for stop. To allow case-insensitive input, we want to recognize the sentinel value as either *S* or *s*. To do this, we need a compound loop condition, that is, a loop condition that uses a logical AND (`&&`) or logical OR (`||`) operator.

Our first inclination might be to form the condition this way, which is **incorrect:**

```
while ( option != 'S' || option != 's' ) // INCORRECT
```

Description

With this condition, the loop will execute forever. Regardless of what the user enters, the loop condition will be *true*. If the user types *S*, the first expression (`option != 'S'`) is *false*, but the second expression (`option != 's'`) is *true*. Thus, the loop condition evaluates to true and the *while* loop body is executed. Similarly, if the user types *s*, the first expression (`option != 'S'`) is *true*, so the loop condition evaluates to *true* and the *while* loop body is executed.

An easy method for constructing a correct *while* loop condition consists of three steps:

1. Define the loop termination condition; that is, define the condition that will make the loop stop executing.
2. Create the loop continuation condition—the condition that will keep the loop executing—by applying the logical NOT operator (!) to the loop termination condition.
3. Simplify the loop continuation condition by applying DeMorgan's Laws, where possible.
   DeMorgan's Laws are the following:
   NOT(A AND B) = (NOT A) OR (NOT B)
   and
   NOT(A OR B) = (NOT A) AND (NOT B)

Let's use these three steps to construct the correct loop condition for the menu program.

1. Define the loop termination condition:
   The loop will stop executing when the user enters an *S* or the user enters an *s*. Translating that into Java, we get

   
   ```
   ( option == 'S' || option == 's' )
   ```

   Description
2. Create the loop continuation condition by applying the ! operator:

```
! ( option == 'S' || option == 'S' )
```

Description

3. Simplify by applying DeMorgan’s Laws:

   To apply DeMorgan’s Laws, we change the == equality operators to != and change the logical OR operator (`||`) to the logical AND operator (`&&`), producing an equivalent, but simpler expression:

```
( option != 'S' && option != 's' )
```

Description

We now have our loop condition.

To illustrate, let’s write an application that calculates the cost of an order at Bonnie’s Burgers. We provide a menu with prices, and the user selects items from the menu one at a time until the user enters *S* or *s* to stop. This is an accumulation operation because we are accumulating the cost of the user’s order. **Example 6.9** shows the code for this application, and **Figure 6.12** shows the output of a sample run.

Example 6.9 A Compound Loop Condition

```java
/* Order from a menu
   Anderson, Franceschi
*/

import java.util.Scanner;
import java.text.DecimalFormat;

public class BonniesBurgers
{
   public static void main( String [ ] args )
   {
      String menu = "\tC Cheeseburger: $7.49";
             menu += "\n\tH Hot dog: $6.99";
             menu += "\n\tL Lemonade: $2.50";
             menu += "\n\tT Iced tea: $2.75";

      DecimalFormat money = new DecimalFormat( "$#.00" );
      Scanner scan = new Scanner( System.in );

      System.out.println( "Welcome to Bonnie's Burgers. "
                           + "Select from our menu: " );

      System.out.println( menu ); // print the menu
      System.out.print( "Order an item, "
                         + "or \"S\" to stop > " );
      char option = scan.next( ).charAt( 0 );
      double orderCost = 0.0;

      while ( option != 'S' && option != 's' )
      {
        switch ( option )
        {
          case 'c', 'C' ->
          {
            System.out.print( "Cheeseburger ordered. " );
            orderCost += 7.49;
          }
          case 'h', 'H' ->
          {
            System.out.print( "Hot dog ordered. " );
            orderCost += 6.99;
          }
          case 'l', 'L' ->
          {
            System.out.print( "Lemonade ordered. " );
            orderCost += 2.50;
          }
          case 't', 'T' ->
          {
            System.out.print( "Iced tea ordered. " );
            orderCost += 2.75;
          }
          default ->
             System.out.println( "Unrecognized menu item." );
        }

        System.out.println( "Subtotal: "
                             + money.format( orderCost ) );

        System.out.print( "\nOrder another item, "
                           + "or \"S\" to stop > " );
        option = scan.next( ).charAt( 0 );
      }

      System.out.println( "\nTotal order cost is "
                            + money.format( orderCost ) );
  }
}
```

Description

Figure 6.12 Ordering from a Menu

Description

We use the compound condition in the *while* loop (line 29). Then within the *while* loop, we use a *switch* statement (lines 31–55) to determine which menu item the user has chosen. We handle case-insensitive input by including *case* constants for both the lowercase and uppercase versions of each letter option. After the *switch* statement, we include the update read (lines 60–62) to input the user’s next item.

Note that we don’t provide *case* statements for the sentinel values. Instead, we use the *while* loop condition to detect when the user enters the sentinel values.

6.7 Testing Techniques for *while* Loops

It's a good feeling when our code compiles without errors. Getting a clean compile, however, is only part of the job for the programmer. The other part of the job is verifying that the code is correct; that is, that the program produces accurate results.

It usually isn't feasible to test a program with all possible input values, but we can get a reasonable level of confidence in the accuracy of the program by concentrating our testing in three areas:

1. Does the program produce correct results with a set of known inputs?
2. Does the program produce correct results if the sentinel value is the first and only input?
3. Does the program deal appropriately with invalid input?

Let's take a look at these three areas in more detail:

1. Does the program produce correct results with known input?

To test the program with known input, we select valid input values and determine what the results should be by performing the program's operation either by hand or by using a calculator. For example, to test whether a total or average is computed correctly, enter some values and compare the program's output to a total or average we calculate by entering those same values into a calculator.

It's especially important to select input values that represent boundary conditions, that is, values that are the lowest or highest expected values. For example, to test a program that determines whether a person is old enough to vote in a presidential election (that is, the person is 18 or older), we should select test values of 17, 18, and 19. These values are the boundary conditions for `age >= 18`; the test values are one integer less, the same value, and one integer greater than the legal voting age. We then run the program with the three input values and verify that the program correctly identifies 17 as an illegal voting age and 18 and 19 as legal voting ages.

1. Does the program produce correct results if the sentinel value is the first and only input?

In our *while* loops, when we find the sentinel value, the flow of control skips the *while* loop body and picks up at the statement following the *while* loop. When the sentinel value is the first input value, our *while* loop body does not execute at all. We simply skip to the statement following the *while* loop. In cases like this, the highly respected computer scientist Donald Knuth recommends that we “do exactly nothing, gracefully.”

In many programs that calculate a total or an average for the input values, when no value is input, our program should either report the total or average as 0 or output a message that no values were entered. It’s important to write our program so that it tolerates the only input being the sentinel value; therefore, we need to test our programs by entering the sentinel value first.

Let’s revisit the earlier examples in this chapter to see how they handle the case when only the sentinel value is entered.

In the addition calculator (Example 6.3), we set the total to 0 before the *while* loop and simply report the value of total after the *while* loop. So we get the correct result (0) with only the sentinel value.

In Example 6.4 where we count the percentage of passing test scores, we handle the sole sentinel value by performing some additional checking after the *while* loop. If only the sentinel value is entered, the count will be 0. We check for this case and if we find a count of 0, we skip reporting the percentage so that we avoid dividing by 0. We use similar code in Example 6.5, where we calculate the average test score. If we detect a count of 0, we also skip the calculation of the average to avoid dividing by 0 and simply report the class average as 0.

1. Does the program deal appropriately with invalid input?

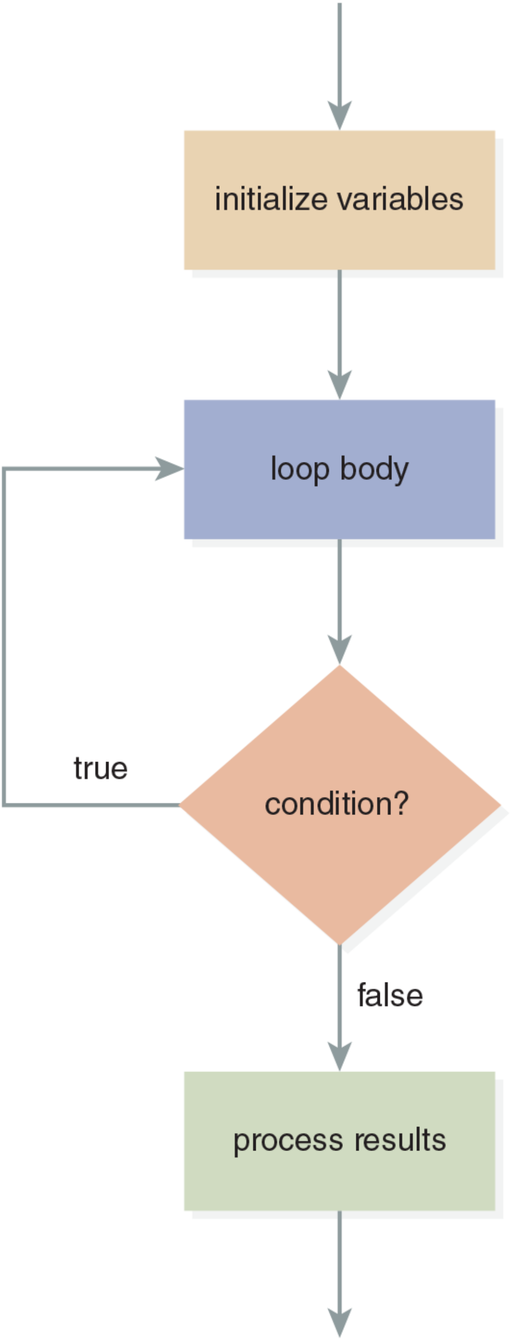
If the program expects a range of values or certain discrete values, then it should notify the user when the input doesn't fit the expected values.

In Example 6.9, we implemented a menu for ordering food items. The user could enter *c, h, l, or t* (or the corresponding capital letters) representing their desired options. If the user entered a letter other than those expected values, we used the *default* clause of the *switch* statement to issue an error message, "*Unrecognized menu item*."

In the next section, we explain how to validate that user input is within a range of values using a *do/while* loop.

SOFTWARE ENGINEERING TIP

Expect that the user might enter the sentinel value first. The program needs to handle this special case.



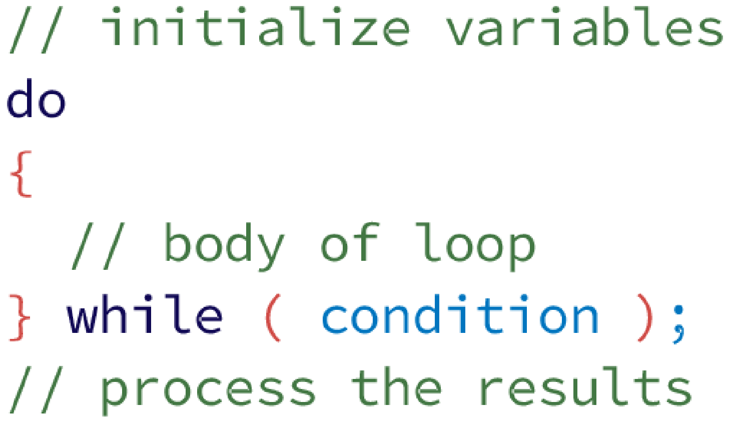
initialize variables
loop body
true
condition?
false
process results

```
Enter a number between 1 and 10 > 20
Enter a number between 1 and 10 > -1
Enter a number between 1 and 10 > 0
Enter a number between 1 and 10 > 11
Enter a number between 1 and 10 > 5
Thank you!
```

6.8 Event-Controlled Loops Using *do/while*

Another form of loop that is especially useful for validating user input is the *do/while* loop. In the *do/while* loop, the loop condition is tested at the end of the loop (instead of at the beginning, as in the *while* loop). Thus the body of the *do/while* loop is executed at least once.

The syntax of the *do/while* loop is the following:



```
// initialize variables
do
{
  // body of loop
} while ( condition );
// process the results
```

Description

Figure 6.13 shows the flow of control of a *do/while* loop.

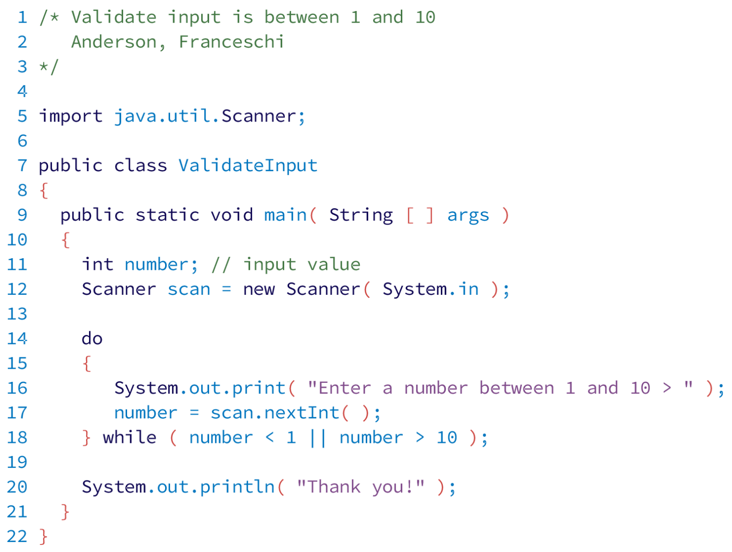
Figure 6.13 The Flow of Control of a *do/while* Statement

Description

To use the *do/while* loop to validate user input, we insert the prompt for the input inside the body of the loop, then use the loop condition to test the value of the input. Like the *while* loop, the body of the loop will be reexecuted if the condition is *true*. Thus, we need to form the condition so that it’s *true* when the user enters invalid values. Be aware that because of scope, any variable that will be referenced in the *while* condition must be defined before the *do/while* loop begins.

Example 6.10 implements a *do/while* loop (lines 14–18) that prompts the user for an integer between 1 and 10. **Figure 6.14** shows the output of the program. If the user enters a number outside the valid range, we reprompt the user until the input is between 1 and 10. Thus, the condition for the *do/while* loop (line 18) checks whether the number is less than 1 or greater than 10. Note also that because we will be referencing *number* in the *while* condition, we must define *number* before the *do/while* loop begins (line 11).

Example 6.10 Validating User Input



```java
/* Validate input is between 1 and 10
   Anderson, Franceschi
*/

import java.util.Scanner;

public class ValidateInput
{
  public static void main( String [ ] args )
  {
    int number; // input value
    Scanner scan = new Scanner( System.in );

    do
    {
       System.out.print( "Enter a number between 1 and 10 > " );
       number = scan.nextInt( );
    } while ( number < 1 || number > 10 );

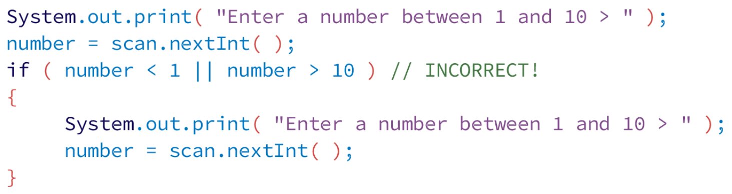
    System.out.println( "Thank you!" );
  }
}
```

Description

Figure 6.14 Validating Input

Description

For validating input, we may be tempted to use an *if* statement rather than a *do/while* loop. For example, to perform the same validation as Example 6.10 we may try this **incorrect** code:



```java
System.out.print( "Enter a number between 1 and 10 > " );
number = scan.nextInt( );
if ( number < 1 || number > 10 ) // INCORRECT!
{
     System.out.print( "Enter a number between 1 and 10 > " );
     number = scan.nextInt( );
}
```

Description

The problem with this approach is that the *if* statement will reprompt the user only once. If the user enters an invalid value a second time, the program will not catch it. A *do/while* loop, however, will continue to reprompt the user as many times as needed until the user enters a valid value.

COMMON ERROR TRAP

Do not use an *if* statement to validate input because it will catch invalid values entered the first time only. Use a *do/while* loop to reprompt the user until the user enters a valid value.

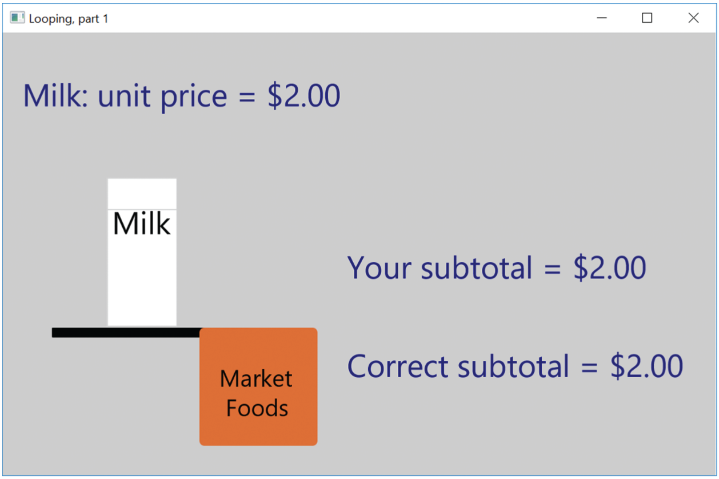
© Hemera Technologies/Photos.com/Thinkstock



Milk: unit price = $2.00

Your subtotal = $2.00

Correct subtotal = $2.00

6.9 Programming Activity 1: Using *while* Loops

In this activity, you will work with a sentinel-controlled *while* loop, performing this activity:

> Write a *while* loop to process the contents of a grocery cart and calculate the total price of the items. It is important to understand that, in this example, we do not know how many items are in the cart.

The framework will animate your code and display the current subtotal so that you can check the correctness of your code. The window will display the various *Item* objects moving down a conveyor belt toward a grocery bag. It will also display the unit price of the item and your current subtotal, as well as the correct subtotal.

For example, **Figure 6.15** demonstrates the animation: We are currently scanning the first item, a milk carton, with a unit price of $2.00; thus, the correct subtotal is $2.00.

Figure 6.15 Animation of the *Cashier* Application

Description

As the animation will show, *Item* objects could be milk, cereal, orange juice, or the divider bar. The number of *Item* objects in the cart is determined randomly; as you watch the animation, sometimes you will find that there are two items in the cart, sometimes six, sometimes three, sometimes only the divider bar, and so forth. Scanning the divider bar signals the end of the items in the cart.

Task Instructions

Copy the files in this chapter’s Programming Activity 1 folder in the source code provided with this text to a folder on your computer. Searching for five stars (*****) in the *CashierDrawing.java* source code will show you where to add your code. You will add your code inside the *checkout* method of the *CashierDrawing* class (the method header for the *checkout* method has already been coded for you). **Example 6.11** shows a fragment of the *CashierDrawing* class, where you will add your code:

Example 6.11 The *checkout* Method in *CashierDrawing.java*

```
public void checkout( )
{
 /* ***** Student writes the body of this method ***** */
 //
 //  Using a while loop, calculate the total price
 //  of the groceries.
 //
 // The getNext method (in this CashierDrawing class) returns the
 // next item on the conveyor belt, which is an Item object
 // (we do not know which item and we do not know how many items
 // are in the cart - this is randomly generated).
 // getNext does not take any arguments. Its API is:
 //       Item getNext( )
 //
 // Right after you update the current subtotal,
 // you should call the animate method.
 // The animate method takes one argument: a double,
 // which is your current subtotal.
 // For example, if the name of your variable representing
 // the current subtotal is total, your call to the animate
 // method should be:
 //    animate( total );
 //
 // The instance method getPrice of the Item class
 // returns the price of the Item object.
 // The method getPrice does not take any arguments.
 // Its API is:
 //        double getPrice( )
 //
 // The cart is empty when the getNext method returns
 // the divider Item.
 // You detect the divider Item because its price
 // is -0.99. So an Item with a price of -0.99
 // is the sentinel value for the loop.
 //
 // After you scan the divider, print the total to the console.

 // End of student code
}
```

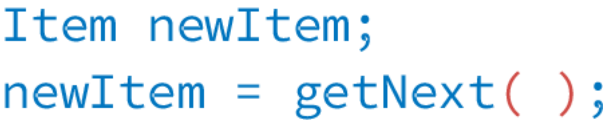
Description

- You can access items in the cart by calling the *getNext* method of the *CashierDrawing* class, which has the following API:

```
Item getNext( )
```

Description

The *getNext* method returns an *Item* object, which represents an *Item* in the cart. As you can see, the *getNext* method does not take any arguments. Since we call the method *getNext* from inside the *CashierDrawing* class, we call the method without an object reference. For example, a call to *getNext* could look like the following:

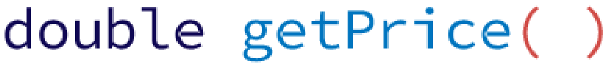


```
Item newItem;
newItem = getNext( );
```

Description

The *getNext* method is already written and contains code to randomly generate *Items*. It is written in such a way that the first *Item* object on the conveyor belt may or may not be the divider. (If the first *Item* is the divider, the cart is empty.)

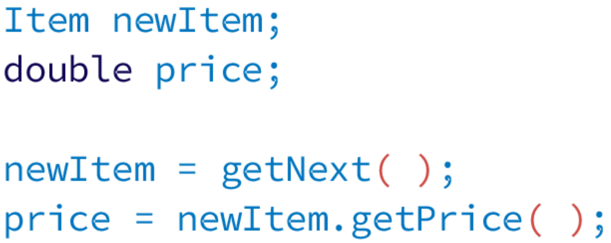
- After you get a new *Item*, you can “scan” the item to get its price by calling the *getPrice* method of the *Item* class. The *getPrice* method has this API:



```
double getPrice( )
```

Description

Thus, you would get an item, then get its price using code like the following:



```
Item newItem;
double price;

newItem = getNext( );
price = newItem.getPrice( );
```

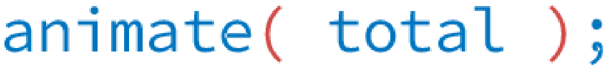
Description

- After adding the price of an item to your subtotal, call the *animate* method of the *CashierDrawing* class. This method will display both your subtotal and the correct subtotal so that you can verify that your code is correct.
  The animate method has the following API:

```
void animate( double subtotal )
```

Description

Thus, if your variable representing the current total is *total*, you would call the animate method using the following code:



```
animate( total );
```

- You want to exit the loop when the next *Item* is the divider. You will know that the *Item* is the divider because its price will be –0.99 (negative 0.99); thus, scanning an *Item* whose price is –0.99 should be your condition to exit the *while* loop.
- When your loop ends, verify that your total matches the correct subtotal displayed.
- To test your code, compile *CashierDrawing.java* and run the application from the *CashierApplication* class.

Troubleshooting

If your method implementation does not animate or animates incorrectly, check these items:

- Verify that you have correctly coded the priming read.
- Verify that you have correctly coded the condition for exiting the loop.
- Verify that you have correctly coded the body of the loop.

DISCUSSION QUESTIONS

1. What is the sentinel value of your *while* loop?
2. Explain the purpose of the priming read.

The sentence backwards is
```

6.10 Count-Controlled Loops Using *for*

Before the loop begins, if we know the number of times the loop body should execute, we can use a **count-controlled loop**. The *for* loop is designed for count-controlled loops, that is, when the number of iterations is determined before the loop begins.

6.10.1 Basic Structure of *for* Loops

The *for* loop has this syntax:

```
for ( initialization; loop condition; loop update )
{
        // loop body
}
```

Description

COMMON ERROR TRAP

Be sure to use semicolons, rather than commas, to separate the statements in a *for* loop header.

Notice that the initialization, loop condition, and loop update in the *for* loop header are separated by semicolons (not commas). Notice also that there is no semicolon after the closing parenthesis in the *for* loop header. A semicolon here would indicate an empty *for* loop body. Although some advanced programs might correctly write a *for* loop with an empty loop body, the programs we write in this text will have at least one statement in the *for* loop body.

The scope of any variable declared within the *for* loop header or body extends from the point of declaration to the end of the *for* loop body.

COMMON ERROR TRAP

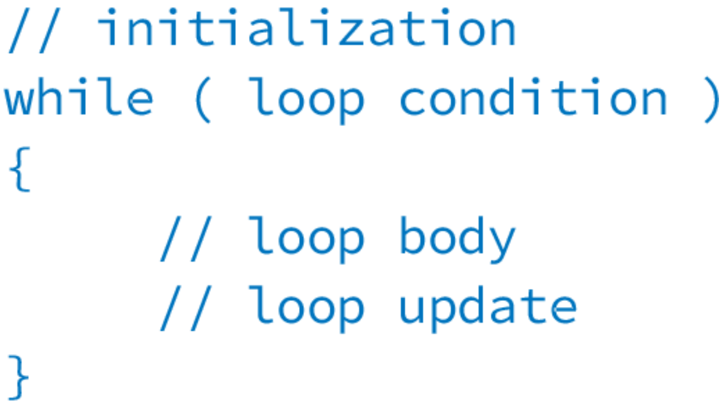
Adding a semicolon after the closing parenthesis in the *for* loop header indicates an empty loop body and will likely cause a logic error.

The flow of control of the *for* loop is shown in **Figure 6.16**. When the *for* loop is encountered, the initialization statement is executed. Then the loop condition is evaluated. If the condition is true, the loop body is executed, then the loop update statement is executed, and the loop condition is reevaluated. Again, if the condition is true, the loop body is executed, followed by the loop update, then the reevaluation of the condition, and so on, until the condition is false.

Figure 6.16 Flow of Control of the *for* Loop

Description

The *for* loop is equivalent to the following *while* loop:



```
// initialization
while ( loop condition )
{
      // loop body
      // loop update
}
```

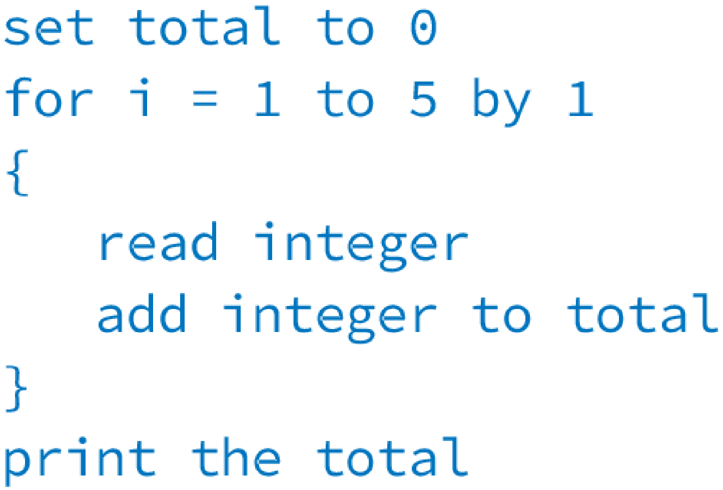
Description

As we can see, *while* loops can be used for either event-driven or count-controlled loops. A *for* loop is especially useful for count-controlled loops, however. Because all the loop control is contained in the *for* loop header, we can easily see what condition will stop the loop and how the condition will be updated after each iteration.

6.10.2 Constructing *for* Loops

Typically, we use a **loop control variable** in a *for* loop; that control variable is usually used for counting. We set its initial value in the initialization statement, increment or decrement its value in the loop update statement, and check its value in the loop condition.

For example, if we want to find the sum of five integers, we know the loop body should execute five times—once for each integer. We set our loop control variable to 1 in the initialization statement, increment the loop control variable by 1 in the loop update statement, and check if its value is less than or equal to 5 in the loop condition. The pseudocode for this program is the following:



```
set total to 0
for i = 1 to 5 by 1
{
   read integer
   add integer to total
}
print the total
```

Description

With a *for* loop, we do not need to perform a priming read because the condition for exiting the loop is controlled by a counter, not by an input value.

Example 6.12 shows the *for* loop for calculating the sum of five integers.

Example 6.12 Finding the Sum of Five Numbers

```
 1 /* Find the total of 5 numbers
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6
 7 public class Sum5Numbers
 8 {
 9   public static void main( String [ ] args )
10   {
11     int total = 0;    // stores the sum of the 5 numbers
12     int number;       // stores the current input
13
14     Scanner scan = new Scanner( System.in );
15
16     for ( int i = 1; i <= 5; i++ )
17     {
18       System.out.print( "Enter an integer > " );
19       number = scan.nextInt( );
20
21       total += number;  // add input to total
22     }
23
24     // process results by printing the total
25     System.out.println( "The total is " + total );
26   }
27 }
```

Description

In this example, which is a standard accumulation operation, the *for* loop initialization statement declares *i*, which will be our loop control variable. We start *i* at 1, and after each execution of the loop body, we increment *i* by 1 in the loop update statement. The loop condition checks if the value of *i* is less than or equal to 5; when *i* reaches 6, we have executed the loop body five times. **Figure 6.17** shows the execution of this *for* loop.

Figure 6.17 Finding the Sum of Five Integers

Description

Note that because we declare our loop counter variable *i* in the *for* loop header, we cannot reference *i* after the *for* loop ends. Thus, this code would generate a compiler error, because *i* is out of scope on line 24:

```
16    for ( int i = 1; i <= 5; i++ )
17    {
18      System.out.print( "Enter an integer > " );
19      number = scan.nextInt( );
20
21      total += number;  // add input to total
22    }
23
24    System.out.println( "The total for the " + ( i - 1 )
25                        + " numbers is " + total ); // i is out of scope
```

Description

Defining a new variable using the same name as a variable already in scope is invalid and generates a compiler error. However, a variable name can be reused when a previously defined variable with the same name is no longer in scope. In the code above, the scope of the variable *i* defined in line 16 is limited to the *for* loop on lines 16–22. We cannot define another variable named *i* in that *for* loop; however, as shown below, we could reuse the name *i* in a subsequent *for* loop (lines 24–29), because the first *i* is no longer in scope. In fact, programmers often reuse the variable name *i* for the counter variable in their *for* loops.

```
16    for ( int i = 1; i <= 5; i++ )
17    {
18      System.out.print( "Enter an integer > " );
19      number = scan.nextInt( );
20
21      total += number; // add input to total
22    }
23
24    for ( int i = 1; i <= 10; i++ )
25    {
26      System.out.print( "Enter integer " + i + " > " );
27      number = scan.nextInt( );
28    }
```

Description

If we do want to refer to the loop variable after the loop ends, we can define the variable before the *for* loop, as shown in the following code:

```
    int i;
    for ( i = 1; i <= 5; i++ )
    {
      System.out.print( "Enter an integer > " );
      number = scan.nextInt( );

      total += number; // add input to total
    }

    System.out.println( "The total for " + ( i - 1 ) // i is 6
                         + " numbers is " + total );
```

Description

We can also increment the loop control variable by values other than 1. **Example 6.13** shows a *for* loop that increments the control variable by 2 to print the even numbers from 0 to 20.

The pseudocode for this program is the following:

```
set output to an empty String
for i = 0 to 20 by 2
{
    append i and a space to the output String
}
print the output String
```

Description

Example 6.13 Printing Even Numbers

```
/* Print the even numbers from zero to twenty
   Anderson, Franceschi
*/

public class PrintEven
{
  public static void main( String [ ] args )
  {
    String toPrint = ""; // initialize output String

    for ( int i = 0; i <= 20; i += 2 )
    {
       toPrint += i + " "; // append current number and a space
    }

    System.out.println( toPrint ); // print results
  }
}
```

Description

We start with an empty *String* variable, *toPrint*, and with each iteration of the loop we append the next even number and a space. When the loop completes, we output *toPrint*, which prints all numbers on one line, as shown in **Figure 6.18**.

Figure 6.18 Printing Even Numbers from 0 to 20

Description

In this example, we initialize the loop control variable to 0, then increment *i* by 2 in the loop update statement (`i += 2`) to skip the odd numbers. Notice that we used the value of the loop control variable *i* inside the loop, illustrating that the loop control variable can perform double duty such as being the counter and the data.

The loop control variable also can be used in our prompt to the user. For example, in Example 6.12 we could have prompted the user for each integer using this statement:

```
System.out.print( "Enter integer " + i + " > " );
```

Then the user’s prompt would look like that shown in **Figure 6.19**.

Figure 6.19 Adding the Loop Control Variable to the Prompt

Description

CODE IN ACTION

To see a step-by-step illustration of a *for* loop, look for the movie within the online resources. Click on the link to start the movie.

© Hemera Technologies/Photos.com/Thinkstock

A *for* loop can be especially useful for processing a *String* character by character. We define the loop control variable so that it corresponds to the index of each character in the *String.* We initialize the loop control variable to 0 (the index of the first character in a *String*), increment the loop control variable by 1 in the loop update, and set the condition of the *for* loop to be that the loop control variable is less than the length of the *String*. In each iteration of the loop, we process one character of the *String* by extracting the character at the loop control variable using the *charAt* method of the *String* class.

Example 6.14 demonstrates this technique. In this example, we prompt the user for a sentence and count the number of tokens in the sentence. A token is defined as a sequence of non-white space characters delimited by one or more white space characters; that is, spaces or tabs.

Example 6.14 Counting Tokens

```java
/* Count tokens in a sentence
*  Anderson, Franceschi
*/

import java.util.Scanner;
public class CountTokens
{
  public static void main( String [ ] args )
  {
     Scanner scan = new Scanner( System.in );

     System.out.println( "Enter a sentence:" );
     String sentence = scan.nextLine( );
     sentence = sentence.trim( ); // remove leading/trailing white space

     if ( sentence.length( ) == 0 )
     {
        System.out.println( "The sentence is empty." );
     }
     else
     {
         boolean inWhiteSpace = false;
         int countTokens = 1;

         for ( int i = 0; i < sentence.length( ); i++ )
         {
            char c = sentence.charAt( i );
            if ( c == ' ' || c == '\t' )
            {
              if ( ! inWhiteSpace )
              {
                  countTokens++;
                  inWhiteSpace = true;
              }
            }
            else // not a white space character
            {
              inWhiteSpace = false;
            }

         }
         System.out.println( "The sentence contains " + countTokens
                      + ( countTokens == 1 ? " token." : " tokens." ) );
     }
  }
}
```

Description

To count the tokens, we look at each character in the sentence, one at a time. If a character is not a white space character, then it is part of a token. When we find a white space character, however, it is a signal that the token is complete. At that time, we increment our token count.

Tokens may be separated by more than one white space character, however, so we need to detect when we find multiple consecutive white space characters and ignore all but the first white space character. To do this, we define a *boolean* variable, called a **flag**. We set the flag to true when we see a white space character and to false when we see a non-white space character. If we find a white space character when the flag is false, it must be the first white space character. If the flag is set to true, however, we have found an extra white space character, which we should ignore.

The pseudocode for this example is

```
read a sentence
remove leading and trailing white space
if sentence is empty
       print message no tokens found
else
     set countTokens = 1
    initialize flag variable to false to indicate that the current character is not
    white space
    for i = 0 to (sentence length -1) by 1
   {
        get character at position i in sentence
        if ( character is a space or tab )
             if flag variable is false
                   we have found the end of a token, so increment countTokens
                  set flag variable to true to indicate that current character is
                  white space
        else
            set flag variable to false to indicate that current character is not
            white space
   }
   print the number of tokens found
```

Description

Example 6.14 shows our code. We prompt the user for a sentence using *Scanner*'s *nextLine* method, which reads all characters on the line including leading and trailing white space. We want to remove those extraneous white space characters, so we call the *trim* method of the *String* class (line 14), shown in **Table 6.4**, which will remove any leading and trailing white space for us.

The *trim* Method of the *String* Class

The *trim* Method of the *String* Class

Return value	Method name and argument list
`String`	`trim( )` returns a *String* with leading and trailing white space characters removed

Description

It is possible that the user pressed the *Enter* key without entering any characters (or only white space characters). In that case, the trimmed sentence will be empty. We check for an empty *String* on line 16, and if true, we output a message and do nothing more.

If, however, the user has entered some characters, we initialize our flag variable, *inWhiteSpace,* to *false* (line 22), because we have indeed not processed any characters and thus have not found white space.

We detect tokens by finding the white space following the token, but when we finish processing the sentence, the last character will not be white space because we trimmed the sentence. Thus we will have one more token than the number of times we found white space. To account for that last token, we initialize our *tokenCount* variable to 1 (line 23).

Now we are ready for our *for* loop (lines 25–41), which processes each character in the sentence looking for white space and counting tokens. As mentioned, the loop control variable*, i*, corresponds to the index of the current character being processed. We initialize *i* to 0, the first index of the *String*; increment *i* by 1 in the loop update; and check that *i* is less than *sentence.length( )* in the loop condition (line 25). We extract the character at *i* using the *charAt* method (line 27).

In line 28, we check whether the current character is a space or a tab. If so, we have detected white space. If the flag is not set to *true* (line 30), then this is the first white space character in a possible sequence of white space characters, and we count the token, then set the flag to *true* so that we ignore any succeeding white space characters (lines 32–33). If the current character is not white space, we set the flag to *false* to indicate that we are inside a token (line 38).

When the loop ends, we print a message with the token count (lines 42–43). **Figure 6.20** shows the output when the user enters a sentence with six tokens separated by spaces and a tab character.

Figure 6.20 Output from Example 6.14

Description

We can also decrement the loop control variable. **Example 6.15** shows an application that reads a sentence entered by the user and prints the sentence backward.

Example 6.15 Printing a Sentence Backwards

```java
/* Print a sentence backwards
   Anderson, Franceschi
*/
import java.util.Scanner;

public class Backwards
{
  public static void main( String [ ] args )
  {
    Scanner scan = new Scanner( System.in );

    String backwards = "";

    System.out.println( "Enter a sentence:" );
    String original = scan.nextLine( );

    for ( int i = original.length( ) - 1; i >= 0; i-- )
    {
        backwards += original.charAt( i );
    }

    System.out.println( "The sentence backwards is: \n" + backwards );
  }
}
```

Description

The pseudocode for this program is the following:

```
set backwards to an empty String
read a sentence

for i = ( length of sentence - 1 ) to 0 by -1
{
   get character at position i in sentence
   append character to backwards
}
print backwards
```

Description

To print a sentence backward, we treat the sentence, a *String*, like a stream of characters; each iteration of the loop extracts and processes one character from the *String*, using the *charAt* method of the *String* class. Line 12 declares a *String*, *backwards* (initialized as an empty *String*), to hold the reverse of the user's sentence. Lines 14–15 prompt the user for a sentence. Lines 17 through 20 make up the *for* loop, whose purpose is to copy the original sentence into the *String* *backwards* with its characters in reverse order. We do this by starting the copying at the last character in the *original String* and moving backward one character at a time until we have copied the first character. Thus, we initialize our loop variable to the position of the last character in *original* (`original.length( ) – 1`) and extract one character at a time, appending it to *backwards*. The loop update statement (`i––`) moves the loop variable backward by one position, and our loop condition (`i >= 0`) checks whether we have reached the beginning of the *String original*. **Figure 6.21** shows the execution of the program with the user entering the sentence, "*Programming is not a spectator sport!*"

Figure 6.21 Printing a Sentence Backward

Description

We can display some interesting graphics using *for* loops. The graphical application in **Example 6.16** draws the bull's-eye target shown in **Figure 6.22**. To make the bull's-eye target, we draw 12 concentric circles (circles that have the same center point), beginning with the largest circle and successively drawing a smaller circle on top of the circles already drawn. Thus, the bull's-eye target circles have the same center point, but different diameters. The pseudocode for this program is

```
for diameter = 300 to 25 by -25
{
    draw the circle with current diameter
    if color is black
         set color to red
    else
         set color to black
}
```

Description

Translating the pseudocode into Java, we get the code shown in Example 6.16.

Example 6.16 Drawing a Bull's Eye

```
 1 /* Bull's-eye Target
 2    Anderson, Franceschi
 3 */
 4
 5 import javafx.application.Application;
 6 import javafx.scene.canvas.Canvas;
 7 import javafx.scene.canvas.GraphicsContext;
 8 import javafx.scene.paint.Color;
 9 import javafx.stage.Stage;
10
11 public class BullsEye extends Application
12 {
13
14     @Override
15     public void start( Stage stage )
16     {
17         // set up window title and size
18         GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
19                   stage, "Bull's Eye", 700, 400 );
20
21        // center of the bull's eye
22        final int CENTER_X = 350, CENTER_Y = 200;
23
24        // start and end diameter, amount to decrease diameter
25        final int START_DIAMETER = 300, END_DIAMETER = 25,
26                  DECREMENT = 25;
27
28        // color of first circle
29        Color toggleColor = Color.BLACK;
30        gc.setFill( toggleColor );
31
32        for ( int diameter = START_DIAMETER; diameter >= END_DIAMETER;
33                  diameter -= DECREMENT )
34        {
35           // draw circle with current diameter value
36           gc.fillOval( CENTER_X - diameter / 2, CENTER_Y - diameter / 2,
37                        diameter, diameter );
38           // switch color
39           if ( toggleColor.equals( Color.BLACK ) )
40                toggleColor = Color.RED;
41           else
42                toggleColor = Color.BLACK;
43
44           gc.setFill( toggleColor );
45
46        }
47     }
48
49     public static void main( String [ ] args )
50     {
51         launch( args );
52     }
53 }
```

Description

Figure 6.22 Drawing a Bull's-Eye

Description

Our *for* loop initialization statement in lines 32–33 sets up the diameter of the largest circle as 300 pixels and the loop update statement decreases the diameter of each circle by 25 pixels. The smallest circle we want to draw should have a diameter of 25 pixels, so we set the loop condition to check that the diameter is greater than or equal to 25. We need to start with the largest circle rather than the smallest circle so that new circles we draw don't hide the previously drawn circles.

Drawing the bull's-eye target circles illustrates two common programming techniques: conversion between units and a toggle variable.

We need to convert between units because the *fillOval* method of the *GraphicsContext* class takes as its arguments the upper-left (*x, y*) coordinate and the width and height of the circle's bounding rectangle. However, all our circles have the same center point, but not the same upper-left *x* and *y* coordinates. Given the diameter and the center point of the circle, however, we can calculate the (*x, y*) coordinate of the upper-left corner. **Figure 6.23** shows how we make the conversion.

Figure 6.23 Drawing a Bull's-Eye

Description

The difference between the center point and the upper-left corner of the bounding rectangle is the radius of the circle, which is half of the diameter (`diameter / 2`). So, the upper-left *x* value is the *x* value of the center point minus half the diameter (`centerX – diameter / 2`). Similarly, the upper-left *y* value is the *y* value of the center point minus half the diameter (`centerY – diameter / 2`).

Thus, we draw each circle using the following statement:

```
gc.fillOval ( centerX - diameter / 2,
              centerY - diameter / 2,
              diameter, diameter );
```

Description

To alternate between red and black circles, we use a **toggle**

variable, which is a variable whose value alternates between two values. We use a *Color* object for our toggle variable, *toggleColor*, and initialize it to *Color.BLACK*. After drawing each circle, we switch the color (lines 38–42). If the current color is black, we set it to red; otherwise, the color must be red, so we set the color to black.

SOFTWARE ENGINEERING TIP

Use a toggle variable when you need to alternate between two values.

6.10.3 Testing Techniques for *for* Loops

One of the most important tests for *for* loops is that the starting and ending values of the loop variable are set correctly. For example, to execute a *for* loop five times, we could set the initial value of the loop variable to 0 and use the condition (`i < 5`), or we could set the initial value of the loop variable to 1 and use the condition (`i <= 5`). Either of these *for* loop headers will cause the loop to execute five times.

```
for ( int i = 0; i < 5; i++ ) // executes 5 times
```

Description

or

```
for ( int i = 1; i <= 5; i++ ) // executes 5 times
```

Description

However, the following *for* loop header is incorrect; the loop will execute only four times.

```
for ( int i = 1; i < 5; i++ ) // INCORRECT! executes only 4 times
```

Description

Thus, to test the *for* loop in Example 6.12 that prompts for five integers, we need to verify that the program outputs exactly five prompts. To test that we are prompting the user five times, we can enter the integers 1, 2, 3, 4, and 5 at the prompts. Another option, shown in **Figure 6.24**, is to append a number to the prompt, which does double duty. Besides keeping the user informed of the number of integers entered so far, it also helps to verify that we have the correct number of prompts.

Figure 6.24 Counting Five Prompts

Description

Like *while* loops, the body of a *for* loop may not be executed at all. If the loop condition is *false* the first time it is tested, the body of the *for* loop is skipped. Thus, when testing, we want to simulate input that would cause the loop condition to be *false* when the *for* loop statement is first encountered. For example, in the *Backwards* class in Example 6.15, we need to test the *for* loop with an empty sentence. In other words, when the prompt appears to enter a sentence, we simply press the *Enter* key. If we try this, we will find that the application still works, as **Figure 6.25** shows.

Figure 6.25 The *Backwards* Class with an Empty Sentence

Description

The program works correctly with an empty sentence because the *for* loop initialization statement is

```
int i = original.length( ) - 1;
```

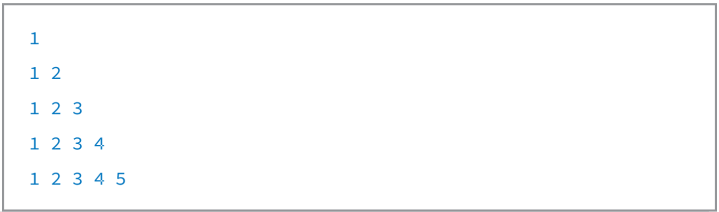
Description

Because the length of an empty *String* is 0, this statement sets *i* to –1. The loop condition (`i >= 0`) is immediately *false*, so the loop body is never executed. The flow of control skips to the statement following the loop,

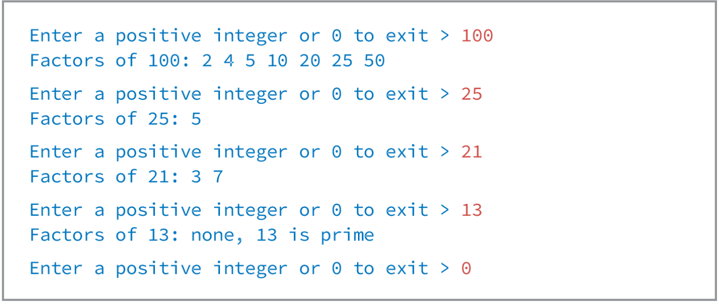
```
System.out.println( "The sentence backwards is: \n" + backwards );
```

Description

which prints an empty *String*. Although it would be more user friendly to check whether the sentence is empty and print a message to that effect, the program does indeed “do exactly nothing, gracefully.”



```
1
1 2
1 2 3
1 2 3 4
1 2 3 4 5
```



```
Enter a positive integer or 0 to exit > 100
Factors of 100: 2 4 5 10 20 25 50
Enter a positive integer or 0 to exit > 25
Factors of 25: 5
Enter a positive integer or 0 to exit > 21
Factors of 21: 3 7
Enter a positive integer or 0 to exit > 13
Factors of 13: none, 13 is prime
Enter a positive integer or 0 to exit > 0
```

6.11 Nested Loops

Loops can be nested inside other loops; that is, the body of one loop can contain another loop. For example, a *while* loop can be nested inside another *while loop* or a *for* loop can be nested inside another *for* loop. In fact, the nested loops do not need to be the same loop type; that is, a *for* loop can be nested inside a *while* loop, and a *while* loop can be nested inside a *for* loop.

Nested loops may be useful if we are performing multiple operations, each of which has its own count or sentinel value. Going back to Jane, our grocery cashier, her workday can be modeled using nested loops. In Programming Activity 1, we wrote the code for our cashier to calculate the total cost of the contents of one customer's grocery cart. But cashiers check out multiple customers, one after another. While the line of people in front of the cashier is not empty, she will help the next customer. For each customer, she will set the total order to $0.00 and start scanning items and add the prices to the total. While the current customer still has items in the cart, Jane will scan the next item. When Jane finishes processing a customer's cart, she will check to see if there is a customer waiting in line. If there is one, she will set the total to $0.00 and start scanning the next customer's items.

Thus, the cashier's job can be described using a *while* loop nested inside another *while* loop. The pseudocode for these nested loops is shown here:

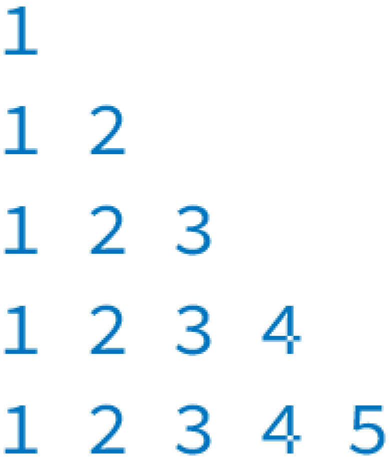
```
look for a customer
while there is a customer in line
{
  set total to $0.00
  reach for first item
while item is not the divider bar
{
      add price to total
      reach for next item
}
// if we get here, the item is the divider bar
output the total price

look for another customer
```

Description

The important point to understand with nested loops is that the inner (or nested) loop executes completely (executes all its iterations) for each single iteration of the outer loop.

Let's look at a simple example that uses nested *for* loops. Suppose we want to print five rows of numbers as shown here:



```
1

1 2

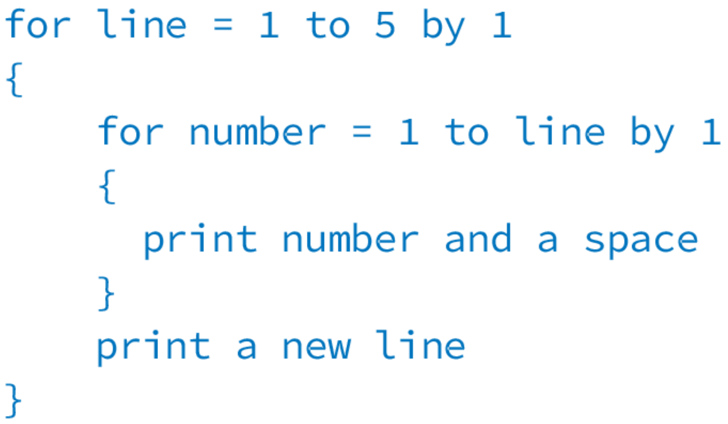
1 2 3

1 2 3 4

1 2 3 4 5
```

Description

We can see a pattern here. In the first line, we print one number; in the second line, we print two numbers, and so on. In other words, the quantity of numbers we print and the line number are the same. The pseudocode for this pattern is the following:



```
for line = 1 to 5 by 1
{
    for number = 1 to line by 1
    {
      print number and a space
    }
    print a new line
}
```

Description

Translating this pseudocode into nested *for* loops, we get the code shown in **Example 6.17**.

Example 6.17 Nested *for* Loops

```
 1 /*  Printing numbers using nested for loops
 2     Anderson, Franceschi
 3 */
 4
 5 public class NestedForLoops
 6 {
 7   public static void main( String [ ] args )
 8   {
 9      // outer for loop prints 5 lines
10      for ( int line = 1; line <= 5; line++ )
11      {
12        // inner for loop prints one line
13        for ( int number = 1; number <= line; number++ )
14        {
15          // print the number and a space
16          System.out.print( number + " " );
17        }
18
19        System.out.println( ); // print a newline
20      }
21   }
22 }
```

Description

Notice that the inner *for* loop (lines 12–17) uses the value of *line*, which is set by the outer *for* loop (lines 9–20). Thus, for the first iteration of the outer loop, *line* equals 1, so the inner loop executes once, printing the number 1 and a space. Then we print a newline character because line 19 is part of the outer *for* loop. The outer loop then sets the value of *line* to 2, and the inner loop starts again at 1 and executes two times (until *number* equals the line number in the outer loop). Then we again print a newline. This operation continues until the *line* exceeds 5, when the outer loop terminates. The output from Example 6.17 is shown in **Figure 6.26**.

Figure 6.26 Output from Example 6.17

Description

Note that we needed to use different names for our *for* loop control variables. The loop control variable *line* is in scope from lines 10 to 20, which includes the inner *for* loop.

Let’s look at another example of a nested loop. We’ll let the user enter positive integers, with a 0 being the sentinel value. For each number, we'll find all its factors; that is, we will find all the integers that are evenly divisible into the number, except 1 and the number itself.

If a number is evenly divisible by another, the remainder after division will be 0. The modulus operator (`%`) will be useful here, because it calculates the remainder after integer division. Thus, to find all the factors of a number, we can test all integers from 1 up to the number to see if the remainder after division is 0. But let's think about whether that's a good approach. The number 1 will be a factor for every number, because every number is evenly divisible by 1. So we can test integers beginning at 2. Then, because 2 is the smallest factor, there's no need to test integers higher than *number* / 2. Thus, our range of integers to test will be from 2 to *number* / 2.

For this example, we'll use a *for* loop nested inside a *while* loop. The pseudocode for this example is

```
read first number // priming read
while number is not 0
{
     print "The factors for number are "
     for factor = 2 to ( number / 2 ) by 1
     {
       if number % factor is 0
            print factor and a space
     }
     print a new line

     read next number // update read
}
```

Description

But what happens if we don't find any factors for a number? In that case, the number is a prime number. We can detect this condition by using a *boolean* flag variable. We set the flag to *false* before starting the *for* loop that checks for factors. Inside the *for* loop, we set the flag to *true* when we find a factor. In other words, we signal (or flag) the fact that we found a factor. Then, after the *for* loop terminates, we check the value of the flag. If it is still *false*, we did not find any factors and the number is prime. Our pseudocode for this program now becomes

```
read first number // priming read
while number is not 0
{
   print "The factors for number are "
   set flag to false
   for factor = 2 to ( number / 2 ) by 1
   {
       if number % factor is 0
       {
          print factor and a space
          set flag to true
       }
   }
   if flag is false
      print "number is prime"

   print a new line

   read next number // update read
}
```

Description

Since we want to read positive numbers only, the lines “read first number” and “read next number” in the preceding pseudocode will actually be more complex than a simple statement. Indeed, we will prompt the user to enter a positive number until the user does so. In order to do that, we will use a *do/while* loop to validate the input from the user. Therefore, inside the *while* loop, we nest not only a *for* loop, but also a *do/while* loop. In the interest of keeping the pseudocode simple, we did not show that *do/while* loop. However, it is included in the code in **Example 6.18** at lines 17–23 and 45–51.

Example 6.18 Finding Factors

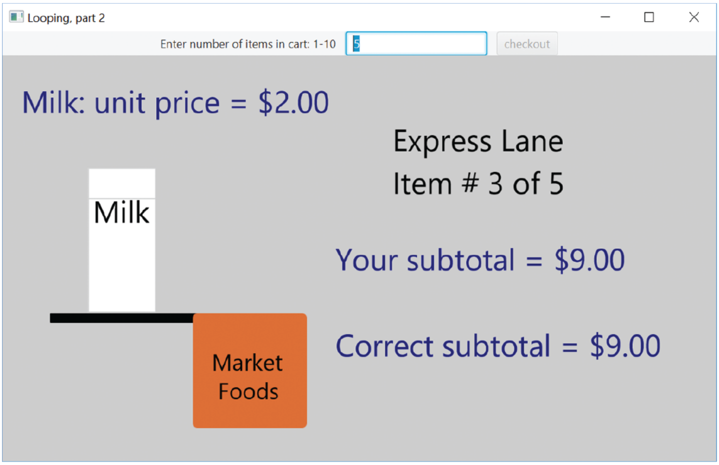
```
 1 /* Factors of integers
 2    with checks for primes
 3    Anderson, Franceschi
 4 */
 5 import java.util.Scanner;
 6
 7 public class Factors
 8 {
 9   public static void main( String [ ] args )
10   {
11     int number; // positive integer entered by user
12     final int SENTINEL = 0;
13     boolean factorsFound; // flag signals whether factors are foun
14
15     Scanner scan = new Scanner( System.in );
16
17     // priming read
18     do
19     {
20       System.out.print( "Enter a positive integer "
21                          + "or 0 to exit > " );
22       number = scan.nextInt( );
23     } while ( number < 0 );
24
25     while ( number != SENTINEL )
26     {
27       System.out.print( "Factors of " + number + ": " );
28       factorsFound = false; // reset flag to no factors
29
30       for ( int factor = 2; factor <= number / 2; factor++ )
31       {
32         if ( number % factor == 0 )
33         {
34            System.out.print( factor + " " );
35            factorsFound = true;
36         }
37       } // end of for loop
38
39       if ( ! factorsFound )
40           System.out.print( "none, " + number + " is prime" );
41
42       System.out.println( ); // print a newline
43       System.out.println( ); // skip a line
44
45       // read next number
46       do
47       {
48          System.out.print( "Enter a positive integer "
49                             + "or 0 to exit > " );
50          number = scan.nextInt( );
51       } while ( number < 0 );
52     } // end of while loop
53   }
54 }
```

Description

Translating this pseudocode into Java, we get the code shown in Example 6.18; the output of a sample run of the program is shown in **Figure 6.27**.

Figure 6.27 Output of Finding Factors

Description



```
Milk: unit price = $2.00

Express Lane
Item # 3 of 5

Your subtotal = $9.00

Correct subtotal = $9.00
```

6.12 Programming Activity 2: Using *for* Loops

In this activity, you will write a *for* loop:

> For this Programming Activity, you will again calculate the total cost of the items in a grocery cart. This time, however, you will write the program for the Express Lane. In this lane, the customer is allowed up to 10 items. The user will be asked for the number of items in the grocery cart. Your job is to write a *for* loop to calculate the total cost of the items in the cart.

Like Programming Activity 1, the framework will animate your *for* loop, displaying the items in the cart moving down a conveyor belt toward a cashier station (a grocery bag). It will also display the unit price of the item, the correct subtotal, and your current subtotal. By comparing the correct subtotal to your subtotal, you will be able to check whether your code is calculating the correct value.

Figure 6.28 demonstrates the animation. The cart contains five items. The third item, a carton of milk, is being scanned at a unit price of $2.00, bringing the correct subtotal for the cart to $9.00.

Figure 6.28 Sample Animation

Description

Instructions

Copy the files in this chapter’s Programming Activity 2 folder in the source code provided with this text to a folder on your computer. Searching for five stars (*****) in the *CashierDrawing.java* code will show you where to add your code. You will add your code inside the *checkout* method of the *CashierDrawing* class (the method header for the *checkout* method has already been coded for you). **Example 6.19** shows a fragment of the *CashierDrawing* class, where you will add your code:

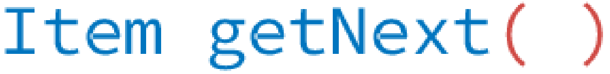
Example 6.19 The *checkout* Method in the *CashierDrawing* Class

```
public void checkout( int numberOfItems )
{
   /* ***** Student writes the body of this method ***** */
   //
   //  The parameter of this method, numberOfItems,
   //  represents the number of items in the cart. The
   //  user will be prompted for this number.
   //
   //  Using a for loop, calculate the total price
   //  of the groceries in the cart.
   //
   //  The getNext method (in this CashierDrawing class) returns the next
   //  item in the cart, which is an Item object (we do not
   //  know which item will be returned; this is randomly generated).
   //  getNext does not take any arguments. Its API is
   //      Item getNext( )
   //
   // As the last statement of the body of your for loop,
   // you should call the animate method.
   // The animate method takes one argument a double,
   // which is your current subtotal.
   // For example, if the name of your variable representing
   // the current subtotal is total, your call to the animate
   // method should be:
   //     animate( total );
   //
   // The getPrice method of the Item class
   // returns the price of the Item object as a double.
   // The getPrice method does not take any arguments. Its API is
   // double getPrice( )
   //
   //  End of student code
   //
   //
}
```

Description

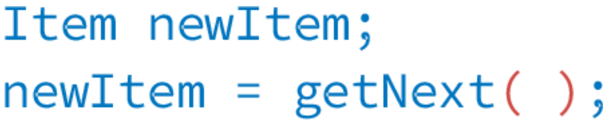
To write the body of your *for* loop, you can use the following methods:

- You can access items in the cart using the *getNext* method of the *CashierDrawing* class, which has the following API:



```
Item getNext( )
```

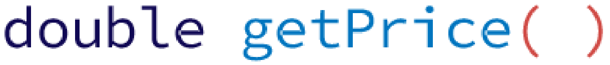
The *getNext* method returns an *Item* object, which represents an *Item* in the cart. As you can see, the *getNext* method does not take any arguments. Since we call the method *getNext* from inside the *CashierDrawing* class, we can simply call the method without an object reference. For example, a call to *getNext* could look like the following:



```
Item newItem;
newItem = getNext( );
```

Description

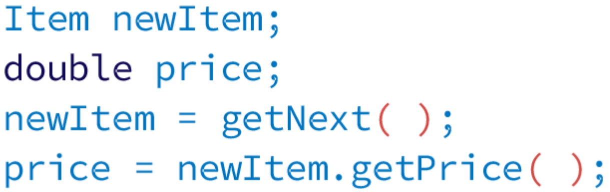
- After you get a new *Item*, you can “scan” the item to get its price by calling the *getPrice* method of the *Item* class. The *getPrice* method has this API:



```
double getPrice( )
```

Description

Thus, you would get the next item, then get its price using code like the following:



```
Item newItem;
double price;
newItem = getNext( );
price = newItem.getPrice( );
```

Description

When you have finished writing the code for the *checkout* method, compile *CashierDrawing.java* and run the application from the *CashierApplication* class. When the application finishes executing, verify that your code is correct by:

- checking that your subtotal matches the correct subtotal displayed
- checking that you have processed all the items in the cart by verifying that the current item number matches the total number of items. For example, if the cart has five items, check that the message in the top right of the screen displays: `Item # 5 of 5`.

Troubleshooting

If your method implementation does not animate or animates incorrectly, check these items:

- Verify that you have correctly coded the header of your *for* loop.
- Verify that you have correctly coded the body of the loop.

DISCUSSION QUESTIONS

1. Explain why a *for* loop is appropriate for this activity.
2. Explain how you set up your *for* loop; that is, what initialization statement did you use, what was your condition, and what was the loop update statement?

© Lois GoBe/Shutterstock.

CHAPTER REVIEW

6.13 Chapter Summary

- Looping repeats a set of operations for each input item while a condition is *true*.
- The *while* loop is especially useful for event-controlled looping. The *while* loop executes a set of operations in the loop body as long as the loop condition is *true*. Each execution of the loop body is an iteration of the loop.
- If the loop condition evaluates to *false* the first time it is evaluated, the body of the *while* loop is never executed.
- If the loop condition never evaluates to *false*, the result is an infinite loop.
- In event-controlled looping, processing of items continues until the end of input is signaled either by a sentinel value or by reaching the end of the file.
- A sentinel value is a special input value that signals the end of the items to be processed. With a sentinel value, we perform a priming read before the *while* loop. The body of the loop processes the input, then performs an update read of the next data item.
- When reading data from an input file, we can test whether we have reached the end of the file by calling a *hasNext* method of the *Scanner* class.
- In the accumulation programming technique, we initialize a

total variable to 0 before starting the loop. In the loop body, we add each input value to the total. When the loop completes, the current total is the total for all processed input values.

- In the counting programming technique, we initialize a count variable to 0 before starting the loop. In the loop body, we increment the count variable for each input value that meets our criteria. When the loop completes, the count variable contains the number of items that met our criteria.
- To find an average, we combine accumulation and counting. We add input values to the total and increment the count. When the loop completes, we calculate the average by dividing the total by the count. Before computing the average, however, we should verify that the divisor (that is, the count) is not 0.
- To find the maximum or minimum values in a set of input, we assign the first input to a running maximum or minimum. In the loop body, we compare each input value to our running maximum or minimum. If the input value is less than the running minimum, we assign the input value to the running minimum. Similarly, if the input value is greater than the running maximum, we assign the input value to the running maximum. When the loop completes, the running value is the maximum or minimum value of all the input values.
- To avoid generating exceptions when the user types characters other than the data type expected, use the *hasNext* methods of the *Scanner* class.
- To construct a loop condition, construct the inverse of the loop termination condition.
- When testing a program that contains a loop, test that the program produces correct results by inputting values and comparing the results with manual calculations. Also test that the results are correct if the loop body never executes. Finally, test the results with input that is invalid.
- The *do/while* loop checks the loop condition after executing the loop body. Thus, the body of a *do/while* loop always executes at least once. This type of loop is useful for

validating input.

- The *for* loop is useful for count-controlled loops, that is, loops for which the number of iterations is known when the loop begins.
- When the *for* loop is encountered, the initialization statement is executed. Then the loop condition is evaluated. If the condition is *true*, the loop body is executed. The loop update statement is then executed and the loop condition is reevaluated. Again, if the condition is *true*, the loop body is executed, followed by the loop update, then the reevaluation of the condition, and so on, until the condition evaluates to *false*.
- Typically, we use a loop control variable in a *for* loop. We set its initial value in the initialization statement, increment or decrement its value in the loop update statement, and check its value in the loop condition.
- The loop update statement can increment or decrement the loop variable by any value.
- In a *for* loop, it is important to test that the starting and ending values of the loop variable are correct. Also test with input for which the *for* loop body does not execute at all.

6.14 Exercises, Problems, and Projects

6.14.1 Multiple Choice Exercises

1. How do you discover that you have an infinite loop in your code?

    - The code does not compile.
    - The code compiles and runs but gives the wrong result.
    - The code runs forever.
    - The code compiles, but there is a run-time error.

6. If you want to execute a loop body at least once, what type of loop would you use?

    - *for* loop
    - *while* loop
    - *do/while* loop
    - none of the above

11. What best describes a *for* loop?

    - It is a count-controlled loop.
    - It is an event-controlled loop.
    - It is a sentinel-controlled loop.

15. You can simulate a *for* loop with a *while* loop.

    - true
    - false

6.14.2 Reading and Understanding Code

1. What is the output of this code sequence? (The user successively enters 3, 5, and –1.)

```
System.out.print( "Enter an int > " );
int i = scan.nextInt( );
while ( i != -1 )
{
   System.out.println( "Hello" );

   System.out.print( "Enter an int > " );
   i = scan.nextInt( );
}
```

   Description

2. What is the output of this code sequence? (The user successively enters 3, 5, and –1.)

```
int i = 0;
while ( i != -1 )
{
   System.out.println( "Hello" );
   System.out.print( "Enter an int > " );
   i = scan.nextInt( );
}
```

   Description

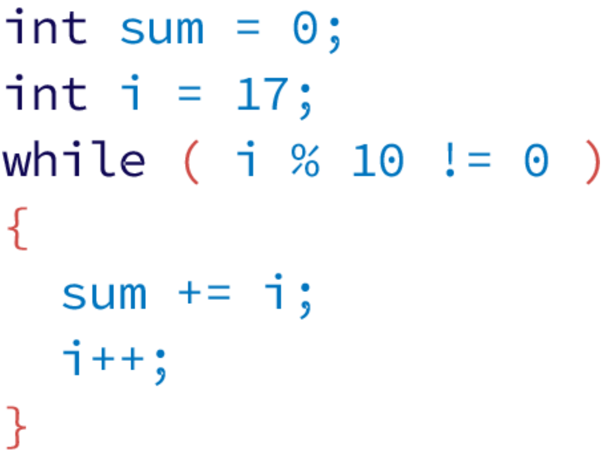
3. What is the output of this code sequence? (The user successively enters 3, 5, and –1.)

```
System.out.print( "Enter an int > " );
int i = scan.nextInt( );
while ( i != -1 )
{
   System.out.print( "Enter an int > " );
   i = scan.nextInt( );

   System.out.println( "Hello" );
}
```

   Description

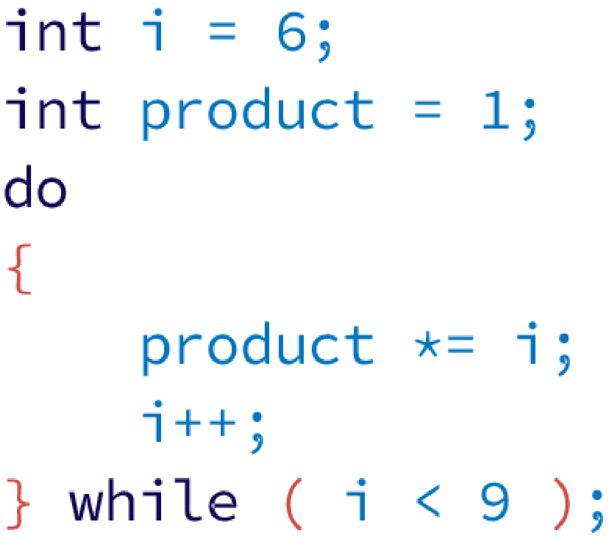
4. What are the values of *i* and *sum* after this code sequence is executed?



```
int sum = 0;
int i = 17;
while ( i % 10 != 0 )
{
   sum += i;
   i++;
}
```

Description

5. What are the values of *i* and *product* after this code sequence is executed?

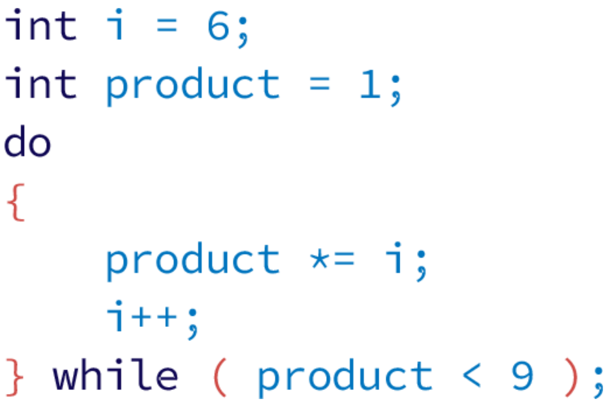


```
int i = 6;
int product = 1;
do
{
     product *= i;
     i++;
} while ( i < 9 );
```

Description

6. What are the values of *i* and *product* after this code

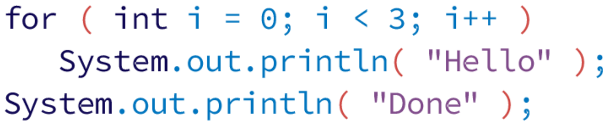
sequence is executed?



```
int i = 6;
int product = 1;
do
{
     product *= i;
     i++;
} while ( product < 9 );
```

Description

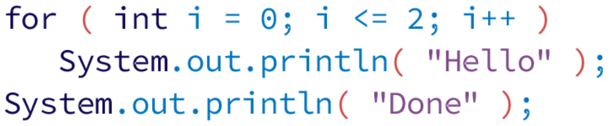
7. What is the output of this code sequence?



```
for ( int i = 0; i < 3; i++ )
   System.out.println( "Hello" );
System.out.println( "Done" );
```

Description

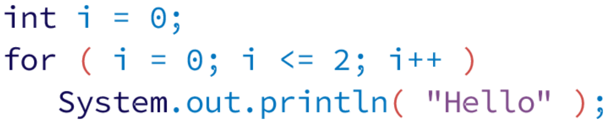
8. What is the output of this code sequence?



```
for ( int i = 0; i <= 2; i++ )
   System.out.println( "Hello" );
System.out.println( "Done" );
```

Description

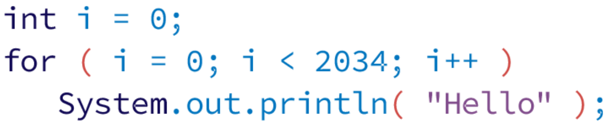
9. What is the value of *i* after this code sequence is executed?



```
int i = 0;
for ( i = 0; i <= 2; i++ )
   System.out.println( "Hello" );
```

Description

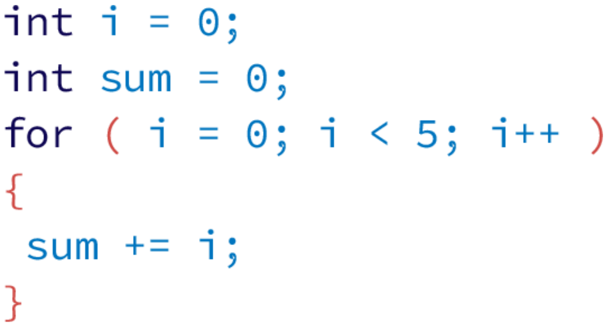
10. What is the value of *i* after this code sequence is executed?



```
int i = 0;
for ( i = 0; i < 2034; i++ )
   System.out.println( "Hello" );
```

Description

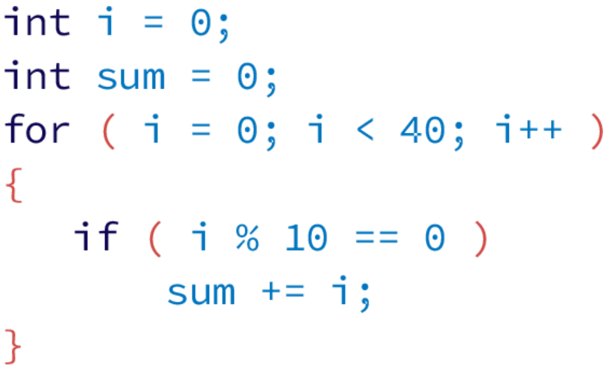
11. What are the values of *i* and *sum* after this code sequence is executed?



```
int i = 0;
int sum = 0;
for ( i = 0; i < 5; i++ )
{
 sum += i;
}
```

Description

12. What are the values of *i* and *sum* after this code sequence is executed?



```
int i = 0;
int sum = 0;
for ( i = 0; i < 40; i++ )
{
    if ( i % 10 == 0 )
          sum += i;
}
```

Description

13. What is the value of *sum* after this code sequence is executed?

```
int sum = 0;
for ( int i = 1; i < 10; i++ )
{
     i++;
     sum += i;
}
```

Description

14. What is the value of *sum* after this code sequence is executed?

```
int sum = 0;
for ( int i = 10; i > 5; i-- )
{
     sum += i;
}
```

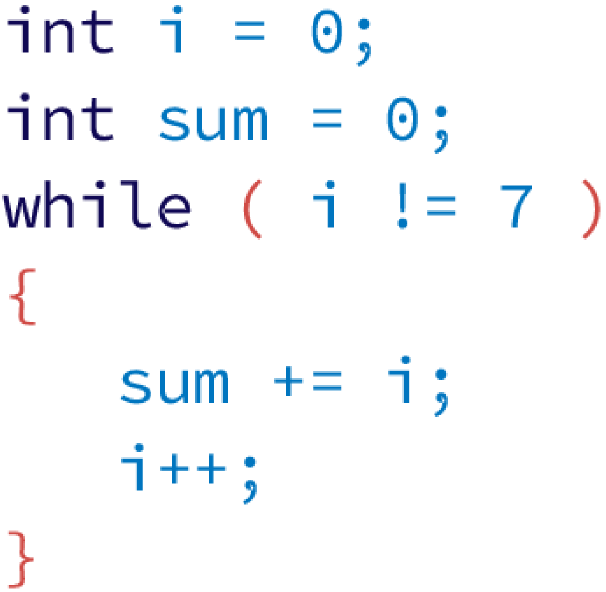
Description

15. What is printed when this code sequence is executed?

```
for ( int i = 0; i < 5; i++ )
{
   System.out.println( Math.max( i, 3 ) );
}
```

Description

16. What are the values of *i* and *sum* after this code sequence is executed?



```
int i = 0;
int sum = 0;
while ( i != 7 )
{
     sum += i;
     i++;
}
```

Description

6.14.3 Fill In the Code

1. This *while* loop generates random integers between 3 and 7 until a 5 is generated and prints all the random integers, excluding 5.

   
   ```
   Random random = new Random( );
   int i = random.nextInt( 5 ) + 3;
   // your code goes here
   ```

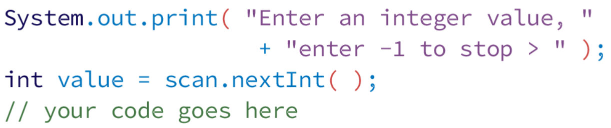
   Description

2. This *while* loop takes an integer input from the user, then prompts for additional integers and prints all integers that are greater than or equal to the original input until the user enters 20, which is not printed.

   
   ```
   System.out.print( "Enter a starting integer > " );
   int start = scan.nextInt( );
   // your code goes here
   ```

Description

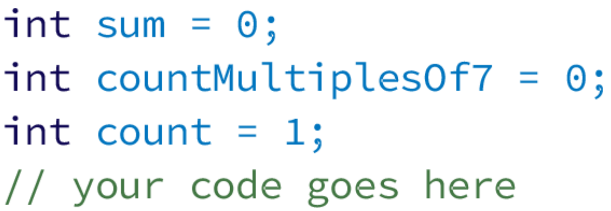
3. This *while* loop takes integer values as input from the user and finds the sum of those integers until the user types in the value –1 (which is not added).



```
System.out.print( "Enter an integer value, "
                   + "enter -1 to stop > " );
int value = scan.nextInt( );
// your code goes here
```

Description

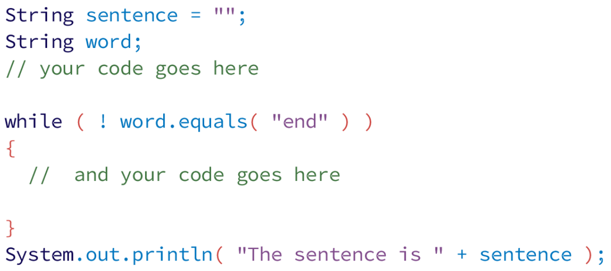
4. This loop calculates the sum of the first four positive multiples of 7 using a *while* loop (the sum will be equal to 7 + 14 + 21 + 28 = 70).



```
int sum = 0;
int countMultiplesOf7 = 0;
int count = 1;
// your code goes here
```

Description

5. This loop takes words as input from the user and concatenates them until the user types in the word “end” (which is not concatenated). The code then outputs the concatenated *String*.



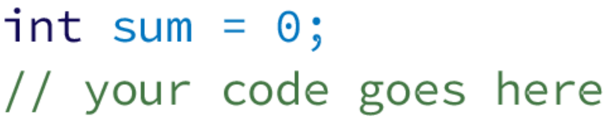
```
String sentence = "";
String word;
// your code goes here

while ( ! word.equals( "end" ) )
{
  //  and your code goes here

}
System.out.println( "The sentence is " + sentence );
```

Description

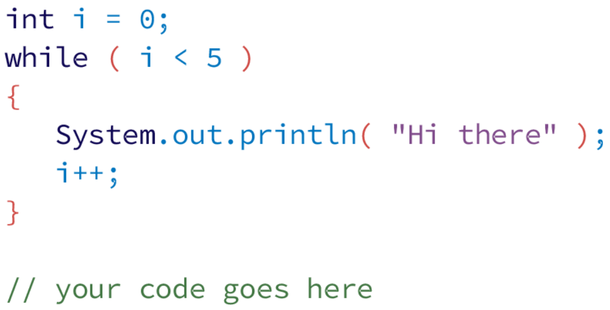
6. This loop reads integers from a file (already associated with the *Scanner* object reference *file*) and computes the sum. We don’t know how many integers are in the file.



```
int sum = 0;
// your code goes here
```

Description

7. Here is a *while* loop; write the equivalent *for* loop.



```
int i = 0;
while ( i < 5 )
{
   System.out.println( "Hi there" );
   i++;
}

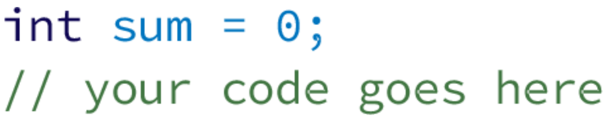
// your code goes here
```

Description

8. This loop reads integers from the user until the user enters either 0 or 100. Then it prints the sum of the numbers entered (excluding the 0 or 100).

```
// your code goes here
```

9. This loop calculates the sum of the integers from 1 to 5 using a *for* loop.



```
int sum = 0;
// your code goes here
```

Description

6.14.4 Identifying Errors in Code

1. Where is the problem with this code sequence (although this code sequence does compile)?

   ```
   int i = 0;
   while ( i < 3 )
      System.out.println( "Hello" );
   ```

   Description

2. Where is the error in this code sequence that is supposed to read and echo integers until the user enters –1?

   ```
   int num;
   Scanner scan = new Scanner( System.in );
   while ( num != -1 )
   {
      System.out.print( "Enter an integer > " );
      num = scan.nextInt( );
      System.out.println( num );
   }
   ```

   Description

3. The following code sequence intends to print *Hello* three times; however, it prints *Hello* only once. Where is the problem in this code sequence?

   ```
   for ( int i = 0; i < 3; i++ );
      System.out.println( "Hello" );
   ```

   Description

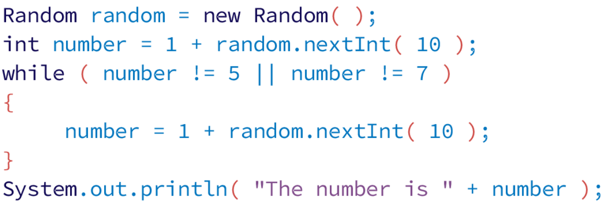
4. Where is the error in this code sequence, which is intended to print *Hello* 10 times?

   ```
   for ( int i = 10; i > 0; i++ )
      System.out.println( "Hello" );
   ```

   Description

5. Where is the problem with this code sequence? The code is intended to generate random numbers between 1 and 10

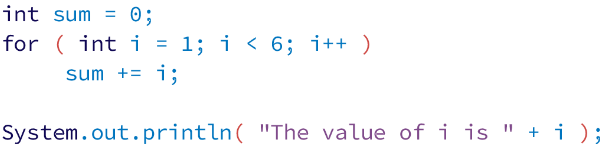
until the number is either a 7 or a 5.



```
Random random = new Random( );
int number = 1 + random.nextInt( 10 );
while ( number != 5 || number != 7 )
{
     number = 1 + random.nextInt( 10 );
}
System.out.println( "The number is " + number );
```

Description

6. Where is the error with this code sequence?



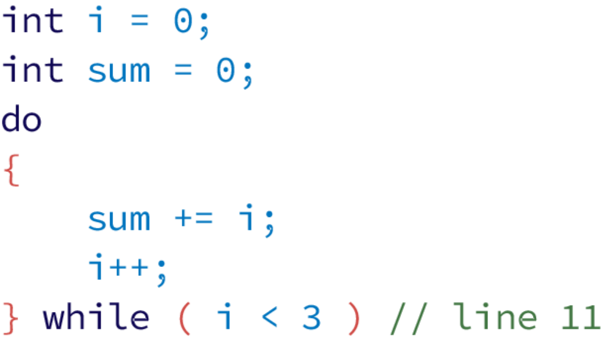
```
int sum = 0;
for ( int i = 1; i < 6; i++ )
     sum += i;

System.out.println( "The value of i is " + i );
```

Description

6.14.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

1. You coded the following in the class *Test.java*:



```
int i = 0;
int sum = 0;
do
{
     sum += i;
     i++;
} while ( i < 3 ) // line 11
```

Description
At compile time, you get the following error:

```
Test.java:11: error: ';' expected
while( i < 3 ) // line 11
              ^
1 error
```

Description

Explain what the problem is and how to fix it.

2. You coded the following in the class *Test.java*:

```
int i = 0;
while ( i < 3 )
{
   System.out.println( "Hello" );
   i--;
}
```

Description

The code compiles but never terminates.
Explain what the problem is and how to fix it.

3. You coded the following in the class *Test.java*:

```
for ( int i = 0; i++; i < 3 ) // line 5
   System.out.println( "Hello" );
```

Description

At compile time, you get the following error:

```
Test.java:5: error: not a statement
for ( int i = 0; i++; i < 3 ) // line 5
                        ^
1 error
```

Description

Explain what the problem is and how to fix it.

4. You coded the following in the class *Test.java*:

```
for ( int i = 1; i < 3; i++ ) // line 5
   System.out.println( "Hello" );
```

Description

The code compiles and runs, but prints *Hello* only twice, whereas we expected to print *Hello* three times.

Explain what the problem is and how to fix it.

5. You coded the following in the class *Test.java*:

```
int product = 1;
for ( int i = 1, i < 5, i++ ) // line 8
   product *= i;
System.out.println( "Product is " + product );    // line 10
```

Description

At compile time, you get the following errors:

```
Test.java:8: error: ';' expected
    for ( int i = 1, i < 5, i++ ) // line 8
                      ^
Test.java:8: error: illegal start of type
    for ( int i = 1, i < 5, i++ )       // line 8
                         ^
2 errors
```

Description

Explain what the problem is and how to fix it.

6. You coded the following in the class *Test.java*:

```
for ( int i = 0; i < 3; i++ )
   System.out.println( "Hello" );
System.out.println( "i = " + i ); // line 8
```

Description

At compile time, you get the following error:

```
Test.java:8: error: cannot find symbol
       System.out.println( "i = " + i ); // line 8
                                    ^
symbol : variable i
location: class Test
1 error
```

Description

Explain what the problem is and how to fix it.

7. You coded the following in the class *Test.java*:

```
int i = 0;
for ( int i = 0; i < 3; i++ ) // line 6
   System.out.println( "Hello" );
```

Description

At compile time, you get the following error:

```
Test.java:6: error: variable i is already defined in method main( String[] )
for( int i = 0; i < 3; i++ )      // line 6
         ^
1 error
```

Description

Explain what the problem is and how to fix it.

6.14.6 Write a Short Program

1. Write a program that prompts the user for a value greater than 10 as an input (you should loop until the user enters a valid value) and finds the square root of that number and the square root of the result, and continues to find the square root of the result until you reach a number that is smaller than 1.01. The program should output how many times the square root operation was performed.
2. Write a program that expects a word containing the @ character as an input. If the word does not contain an @ character, then your program should keep prompting the user for a word. When the user types in a word containing an @ character, the program should simply print the word and terminate.
3. Write a program that reads *double* values from a file named *input.txt* and outputs the average.
4. Write a program that uses a *for* loop to output the sum of all the integers between 10 and 20, inclusive, that is, 10 + 11 + 12 + ... + 19 + 20.
5. Write a program that uses a *for* loop to output the product

of all the integers between 3 and 7, inclusive, that is, 3 * 4 * 5 * 6 * 7.

6. Write a program that uses a *for* loop to count how many multiples of 7 are between 33 and 97, inclusive.
7. Write a program that reads a value (say *n*) from the user and outputs *Hello World n* times. Verify that the user has entered an integer. If the input is 3, the output will be *Hello World* printed three times.
8. Write a program that takes a word as an input from the keyboard and outputs each character in the word, separated by a space.
9. Write a program that takes a value as an input from the keyboard and outputs the factorial of that number; the factorial of an integer *n* is *n* * (*n* – 1) * (*n* – 2) * … * 3 * 2 * 1. For instance, the factorial of 4 is 4 * 3 * 2 * 1, or 24.
10. Using a loop, write a program that takes 10 integer values from the keyboard and outputs the minimum value of all the values entered.
11. Alter Example 6.14 that counts the tokens in a sentence so that it prints each token and counts the number of tokens.

6.14.7 Programming Projects

1. Write a program that inputs a word representing a binary number (0s and 1s). First, your program should verify that it is indeed a binary number, that is, the number contains only 0s and 1s. If that is not the case, your program should print a message that the number is not a valid binary number. Then, your program should count how many 1s are in that word and output the count.

2. Perform the same operations as Question 54, with the following modification: If the word does not represent a valid binary number, the program should keep prompting the user for a new word until a word representing a valid binary number is input by the user.
3. Write a program that inputs a word representing a binary number (0s and 1s). First, your program should check that it is indeed a binary number, that is, the number contains only 0s and 1s. If that is not the case, your program should output that the number is not a valid binary number. If that word contains exactly two 1s, your program should output that that word is “accepted,” otherwise that it is “rejected.”
4. Perform the same operations as Question 56, with the following modification: If the word does not represent a valid binary number, the program should keep prompting the user for a new word until a word representing a valid binary number is input by the user.
5. Write a program that inputs a word representing a binary number (0s and 1s). First, your program should check that it is indeed a binary number, that is, that it contains only 0s and 1s. If that is not the case, your program should output that the number is not a valid binary number. If that word contains at least three consecutive 1s, your program should output that that word is “accepted,” otherwise that it is “rejected.”
6. Write a program that inputs 7 double values from a file *dja.txt* that represent the Dow Jones Average for 7 days. Your program should output the lowest value for those 7 days and the number of the day on which the lowest value occurred. For this program, instead of setting the initial minimum value to the first value in the file, use the

maximum value for a *double*. The Java Class Library provides this value as a constant in the *Double* wrapper class. Be sure to handle the case of the file being empty.

7. Write a program that takes website names as keyboard input until the user types the word *stop* and counts how many of the website names are commercial website names (i.e., end with *.com*), then outputs that count.
8. Using a loop, write a program that takes 10 values representing exam grades (between 0 and 100) from the keyboard and outputs the minimum value, maximum value, and average value of all the values entered. Your program should not accept values less than 0 or greater than 100.
9. Write a program that takes an email address as an input from the keyboard and, using a loop, steps through every character looking for an @ sign. If the email address has exactly one @ character, then print a message that the email address is valid; otherwise, print a message that it is

invalid.

10. Write a program that takes a user ID as an input from the keyboard and steps through every character, counting how many digits are in the user ID; if there are exactly two digits, output that the user ID is valid, otherwise that it is invalid.
11. Write a program that takes an integer value as an input and converts that value to its binary representation; for instance, if the user inputs 17, then the output will be 10001.
12. Write a program that takes a word representing a binary number (0s and 1s) as an input and converts it to its decimal representation; for instance, if the user inputs 101, then the output will be 5; you can assume that the *String* is guaranteed to contain only 0s and 1s.
13. Write a program that simulates an XOR operation. The input should be a word representing a binary number (0s and 1s). Your program should XOR all the digits from left to right and output the results as "True" or "False." In an XOR operation, *a* XOR *b* is true if *a* or *b* is *true* but not both; otherwise, it is *false*.

    In this program, we will consider the character "1" to represent true and a "0" to represent false. For instance, if the input is 1011, then the output will be 1 (1 XOR 0 is 1, then 1 XOR 1 is 0, then 0 XOR 1 is 1, which causes the output to be "True"). You can assume that the input word is guaranteed to contain only 0s and 1s.
14. Write a program that takes a sentence as an input and checks whether that sentence is a palindrome. A palindrome is a word, phrase, or sentence that is symmetrical; that is, it is spelled the same forward and backward. Examples are "otto," "mom," and "Able was I ere

I saw Elba.” Your program should be case insensitive; that is, “Otto” should also be counted as a palindrome.

15. Write a program that takes an HTML-like sequence as an input and checks whether that sequence has the same number of opening brackets (<) and closing brackets (>).

6.14.8 Technical Writing

1. In programming, a programmer can make syntax errors that lead to a compiler error; these errors can then be corrected. Other errors can lead to a run-time error; these errors can also be corrected. Logic errors, however, can lead to an incorrect result or no result at all. Discuss examples of logic errors that can be made when coding loops and the consequences of these logic errors.
2. Discuss how you would detect whether you have an infinite loop in your code.

6.14.9 Group Project (for a group of 1, 2, or 3 students)

1. Often on a webpage, the user is asked to supply personal information, such as a telephone number. Your program should take an input from the keyboard representing a telephone number. We will consider that the input is a valid telephone number if it contains exactly 10 digits and any number of dash (-) and whitespace characters. Keep prompting the user for a telephone number until the user gives you a valid one. Once you have a valid telephone number, you should assume that the digits (only the digits, not the hyphen[s] nor the white space) in the telephone number may have been encrypted by shifting each number by a constant value. For instance, if the shift is 2, a 0

becomes a 2, a 1 becomes a 3, a 2 becomes a 4, …, an 8 becomes a 0, and a 9 becomes a 1. However, we know that the user is from New York where the decrypted area code (after the shift is applied), represented by the first three digits of the input, is 212. Your program needs to decrypt the telephone number and output the decrypted telephone number with the format 212-xxx-xxxx, as well as the shift value of the encryption. If there was an error in the input and the area code cannot be decrypted to 212, you should output that information.

Introduction

When you see the title of this chapter, you might say, “Finally, we get to write our own classes.” Actually, we’ve been writing classes all along. All Java source code belongs to a class. The classes we’ve been writing are application classes. Now it’s time to write some service classes—classes that encapsulate data and methods for use by applications or service classes. These are called **user-defined classes** because we, rather than the Java authors, create them.

First, let’s take a moment to examine why we want to create user-defined classes.

We have written a lot of programs using Java’s primitive data types (*boolean, char, int, double*, etc.), but the real world requires manipulation of more complex data than just individual *booleans* or *ints*. For example, if you are the programmer for an online bookstore, you will need to manipulate data associated with books. Books typically have an ISBN, a title, an author, a price, an in-stock quantity, and perhaps other pieces of data. We can create a *Book* class so that each object will hold the data for one book. For example, the ISBN, the title, and the author can be represented by *Strings*, the price by a *double*, and the in-stock quantity by an *int*. If we create this *Book* class, our program will be able to store and manipulate all the data of a book as a whole. This is one of the concepts of object-oriented programming.

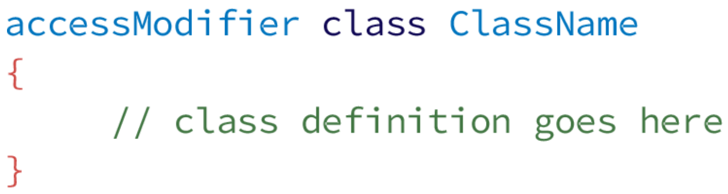
By incorporating into the class the methods that work with the book data, we also are able to hide the details involved with handling that data. An application can simply call the methods as needed. Thus, creating your own classes can simplify your program.

Finally, a well-written class can be reused in other programs. Thus, user-defined classes speed up development.

7.1 Defining a Class

Classes encapsulate the data and functionality for a person, place, or thing, or more generally, an object. For example, a class might be defined to represent a student, a college, or a course.

To define a class, we use the following syntax:



```
accessModifier class ClassName
{
     // class definition goes here
}
```

Description

SOFTWARE ENGINEERING TIP

Use a noun for the class name, and start the class name with a capital letter.

This syntax should look familiar as the first line in our programs. You may also notice that the class names in the Java Class Library are nouns and start with a capital letter: *Scanner, String, Math*, for example. The Java developers encourage programmers to use these conventions to name their user-defined classes.

Inside the curly braces we define the data of the class, called its **fields**, and the methods. An important function performed by the class methods is maintaining the values of the class data for the **client programs**, which are the users of the class, in that the clients create objects and call the methods of the class. Our programs have been clients of many Java classes, such as *String, DecimalFormat*, and *Math*. The fields and methods of a class are called the **members** of the class.

For each class and for each member of a class, we need to provide an **access modifier** that specifies where the class or member can be used (see **Table 7.1**). The possible access modifiers are *public, private*, and *protected*, or no modifier at all, which results in package access. The *public* access modifier allows the class or member to be used, or **referenced**, by methods of the same or other classes. The *private* access modifier specifies that the class or member can be referenced only by methods of the same class. Package access specifies that the class or member can be accessed by methods in classes that are in the same package or in the same folder. Later in the chapter, we will learn how to create our own package.

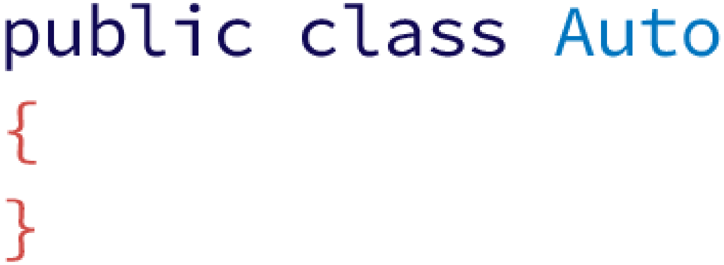
Access Modifiers

Access Modifier	Class or Member Can Be Referenced By ...
public	methods of the same class, as well as methods of other classes
private	methods of the same class only
protected	methods in the same class, as well as methods of subclasses and methods in classes in the same package
no modifier (package access)	methods in the same package or same folder only

Description

Typically, the *accessModifier* for a class will be *public*, and we know that a *public* class must be stored in a file named *ClassName.java* where *ClassName* is the name of the class.

Let's start to define a class that represents an automobile, which we can use to calculate miles per gallon. We'll name the class *Auto*, and we'll use the *public* access modifier so that any application can use this class. The class header will look like the following:



```
public class Auto
{
}
```

Description

When we write a class, we will make known the *public* method names and their APIs so that a client program will know how to instantiate objects and call the methods of the class. We will not publish the implementation (or code) of the class, however. In other words, we will publish the APIs of the methods, but not the method bodies. This is called **data hiding.** A client program can use the class without knowing how the class is implemented, and we, as class authors, can change the implementation of the methods as long as we don't change the interface, or APIs.

7.2 Defining Instance Variables

The instance variables of a class hold the data for each object of that class. Thus, we also say that the instance variables represent the properties of the object. Each object, or instance of a class, gets its own copy of the instance variables, each of which can be given a value appropriate to that object. The values of the instance variables, therefore, can represent the state of the object.

Instance variables are defined using the following syntax:

```
accessModifier dataType identifierList;
```

Description

The *private* modifier is typically used for the nonconstant instance variables of the class. This permits only methods of the same class to set or change the values of the instance variables. In this way, we achieve encapsulation; the class provides a protective shell around the data.

SOFTWARE ENGINEERING TIP

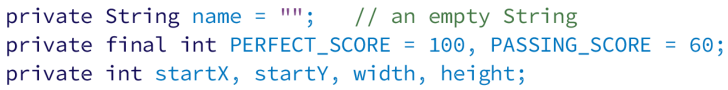
Define instance variables of a class as *private* so that only methods of the class will be able to set or change their values.

The data type of an instance variable can be any of Java's primitive types or a class type.

The *identifierList* consists of one or more names for instance variables of the same data type and can optionally assign initial values to the instance variables. If more than one instance variable name is given, a comma is used as a separator. By convention, identifier names for instance variables are nouns and begin with a lowercase letter; internal words begin with a capital letter. Each instance variable and class variable must be given a name that is unique to the class. It is legal to use the same names for instance variables in different classes, but within a class, the same name cannot be used for more than one instance variable or class variable. Thus, we say that the fields of a class have **class scope**.

Optionally, you can declare an instance variable to be a constant (*final*).

The following statements are examples of instance variable definitions:



```
private String name = "";    // an empty String
private final int PERFECT_SCORE = 100, PASSING_SCORE = 60;
private int startX, startY, width, height;
```

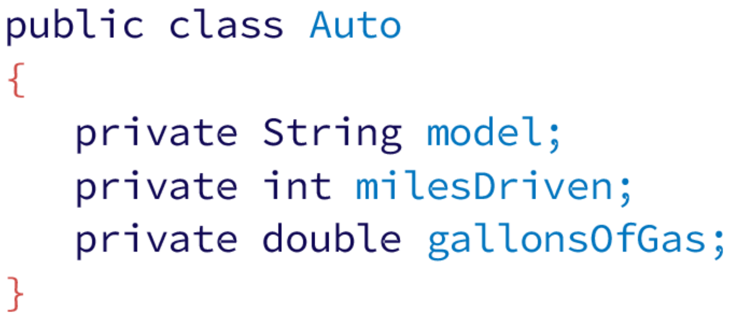
Description

What criteria should you use to select the instance variables of the class? The answer is to select the data that all objects will have in common. For example, for a *Student* class, you might select the student name, grade point average, and projected graduation date. For a *Calculator* class, you might select two operands, an operator, and a result.

SOFTWARE ENGINEERING TIP

Use nouns for identifier names for instance variables. Begin the identifier with a lowercase letter and capitalize internal words.

Thus, for our *Auto* class, we will define instance variables to hold the model of the automobile, the number of miles the auto has been driven, and the gallons of gas used. As a result, our *Auto* class definition now becomes the following:



```
public class Auto
{
   private String model;
   private int milesDriven;
   private double gallonsOfGas;
}
```

Description

SOFTWARE ENGINEERING TIP

Define instance variables for the data that all objects will have in common.

7.3 Writing Class Methods

We declared the instance variables of the *Auto* class as *private* so that only the methods of the *Auto* class will be able to access or change the values of the instance variables directly. Clients of the *Auto* class will need to use the methods of the class to access or change any of the instance variables. We will therefore need to write some methods.

SOFTWARE ENGINEERING TIP

Use verbs for method names. Begin the method name with a lowercase letter and begin internal words with a capital letter.

Methods have this syntax:

```
accessModifier returnType methodName( parameter list ) // method header
{
      // method body
}
```

Description

where *parameter list* is a comma-separated list of data types and variable names.

The method header syntax should be familiar because we've seen the API for many class methods. One difference is just a matter of semantics. The method caller sends **arguments**, or **actual parameters**, to the method; the method refers to these arguments as its **formal parameters**.

Because methods provide a function for the class, typically method names are verbs. Like instance variables, the method name should begin with a lowercase letter, with internal words beginning with a capital letter.

The access modifier for methods that provide services to the client will be *public*. Methods that provide services only to other methods of the class are typically declared to be *private*.

SOFTWARE ENGINEERING TIP

Declare methods that provide services to clients as *public*. Methods that will be called only by other methods of the class should be declared *private.*

The return type of a method is the data type of the value that the method returns to the caller. The return type can be any of Java's primitive data types, any class type, or *void*. Methods with a return type of *void* do not return a value to the caller.

The body of each method, which consists of the code that performs the method's function, is written between the beginning and ending curly braces. Unlike *if* statements and loops, however, these curly braces are not optional; the curly braces are required, regardless of the number of statements in the method body.

COMMON ERROR TRAP

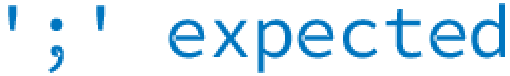
Forgetting to enclose the body of a method in curly braces generates one or more compiler errors.

Several compiler errors can result from forgetting one or both of the curly braces. You might receive either of these messages:

```
illegal start of expression
```

Description

or



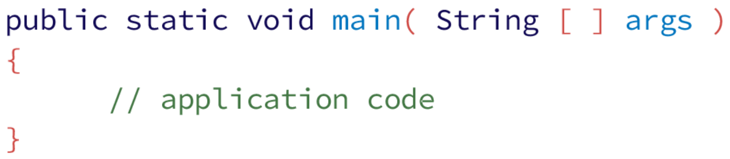
```
';' expected
```

Description

In the method body, a method can declare variables, call other methods, and use any of the program structures we've discussed: *if/else* statements, *while* loops, *for* loops, *switch* statements, and *do/while* loops.

All objects of a class share one copy of the class methods.

We have actually written methods already. For example, we've written the method *main*. Its definition looks like this:

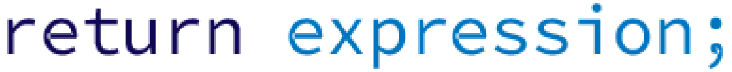


```
public static void main( String [ ] args )
{
      // application code
}
```

Description

We know that the *static* keyword means that the Java Virtual Machine (JVM) can call *main* to start the application running without first instantiating an object. The return type is *void* because *main* does not return a value. The parameter list expects one argument, a *String* array.

We have not previously written a value-returning method. A value-returning method sends back its results to the caller using a *return* statement in the method body. The syntax for the *return* statement is

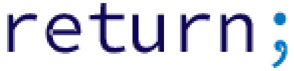


```
return expression;
```

Description

As you would expect, the data type of the expression must match the return type of the method. Recall that a value-returning method is called from an expression, and when the method completes its operation, its return value replaces the method call in the expression.

If the data type of the method is *void*, as in *main*, we have a choice of using the *return* statement without an expression, as in this statement:



```
return;
```

Description

or omitting the *return* statement altogether. Given that control automatically returns to the caller when the end of the method is reached, most programmers omit the *return* statement in *void* methods. Optionally, a *return* statement can be used if needed to exit a method before reaching the end of the method's code.

```
Instantiate sedan
Instantiate suv
Instantiate mini
```

7.4 Writing Constructors

A constructor is a special method that is called when an object is instantiated using the *new* keyword. A class can have several constructors. The job of the class constructors is to initialize the fields of the new object.

The syntax for a constructor follows:

```
accessModifier ClassName( parameter list )
{
    // constructor body
}
```

Description

Notice that a constructor has the same name as the class and has no return type—not even *void*.

It's import ant to use the *public* access modifier for the constructors so that applications can instantiate objects of the class.

SOFTWARE ENGINEERING TIP

Define constructors to be *public* so that clients can instantiate objects of the class.

The constructor can either assign default values to the instance variables or the constructor can accept initial values from the client through parameters.

Providing a constructor for a class is optional. If you don't write a constructor, the compiler provides a **default constructor**, which is a constructor that takes no arguments. This default constructor assigns default initial values to all instance variables; this is called **autoinitialization**. Numeric variables are given the value of 0, characters are given the Unicode null character, *boolean* variables are given the value *false*, and object references are given the value *null*. **Table 7.2** shows the values the default constructor assigns to instance variables.

Default Initial Values of Instance Variables

Data Type	**Initial Value**
byte	0
short	0
int	0
long	0
float	0.0
double	0.0
char	null character ('\u0000')
boolean	*false*
object reference	*null*

Description

If we do provide a constructor, any instance variables our constructor does not initialize will still be given the predefined default value. Also, if we do provide a constructor, the compiler no longer generates a default constructor for us.

Example 7.1 shows Version 1 of our *Auto* class with two constructors.

Example 7.1 The *Auto* Class, Version 1

```
 1 /* Auto class, Version 1
 2    Anderson, Franceschi
 3 */
 4
 5 public class Auto
 6 {
 7    // instance variables
 8    private String model;          //  model of auto
 9    private int milesDriven;       //  number of miles driven
10    private double gallonsOfGas;   //  number of gallons of gas
11
12    // Default constructor:
13    //  initializes model to "unknown";
14    //  milesDriven is autoinitialized to 0
15    //        and gallonsOfGas to 0.0
16    public Auto( )
17    {
18       model = "unknown";
19    }
20
21    // Overloaded constructor:
22    // allows client to set beginning values for
23    //   model, milesDriven, and gallonsOfGas.
24    public Auto( String startModel,
25                 int startMilesDriven,
26                 double startGallonsOfGas )
27    {
28       model = startModel;
29
30       // validate startMilesDriven parameter
31       if ( startMilesDriven >= 0 )
32           milesDriven = startMilesDriven;
33
34       // validate startGallonsOfGas parameter
35       if ( startGallonsOfGas >= 0.0 )
36           gallonsOfGas = startGallonsOfGas;
37    }
38 }
```

Description

Our default constructor (lines 12–19) does not set values for the *milesDriven* and *gallonsOfGas* instance variables. Because *ints* and *doubles* are autoinitialized to 0 and 0.0, respectively, we just accept those default values.

However, it is necessary for our constructor to set the *model* instance variable to a valid *String* value. Because *Strings* are object references, they are autoinitialized to *null*. Any attempt to call a method using the *model* instance variable with a *null* value would generate a *NullPointerException*.

As mentioned earlier, we can provide multiple constructors for a class. We provide a second constructor (lines 21–37) that lets the client set initial values for all the instance variables. Because the class is the caretaker of its fields, it is the class's responsibility to ensure that the data for each object is valid. Thus, when the constructor sets initial values for the instance variables, it should first check whether its parameters are, indeed, valid values. What constitutes a valid value for any instance variable depends in part on the data type of the variable and in part on the class and is a design decision. For our *Auto* class, we have decided that *milesDriven* and *gallonsOfGas* cannot be negative. If the constructor finds that the *startMilesDriven* or *startGallonsOfGas* parameters are negative, it lets the instance variables be assigned default values of 0 and 0.0, respectively. Some methods in the Java Class Library generate an exception when a parameter value is invalid; others substitute a default value for the invalid parameter. Again, how your classes handle invalid argument values is a design decision.

When we provide multiple constructors, we are **overloading** a method. To overload a method, we provide a method with the same name but with a different number of parameters, or with the same number of parameters but with at least one parameter having a different data type. The name of the method, along with the number, data types, and order of its parameters, is called the method's **signature**. Thus, to overload a method, the new method must have a different signature. Notice that the return type is not part of the signature.

When a client calls a method that is overloaded, Java determines which version of the method to execute by looking at the number, data types, and order of the arguments in the method call. **Example 7.2** shows a client program that instantiates three *Auto* objects.

Example 7.2 The *Auto* Client, Version 1

```
 1 /* Auto Client, Version 1
 2    Anderson, Franceschi
 3 */
 4
 5 public class AutoClient
 6 {
 7   public static void main( String [ ] args )
 8   {
 9      System.out.println( "Instantiate sedan" );
10      Auto sedan = new Auto( );
11
12      System.out.println( "\nInstantiate suv" );
13      Auto suv = new Auto( "Trailblazer", 7000, 437.5 );
14
15      System.out.println( "\nInstantiate mini" );
16      // attempt to set invalid value for gallons of gas
17      Auto mini = new Auto( "Mini Cooper", 200, -1.0 );
18   }
19 }
```

Description

SOFTWARE ENGINEERING TIP

Provide, at the minimum, a default constructor and a constructor that accepts initial values for all instance variables.

Line 10 causes the default constructor to be called because no arguments are passed to the constructor. Line 13 causes the overloaded constructor to be called because it passes three arguments to the constructor. If the client attempted to instantiate a new object with a number of parameters other than 0 or 3, the compiler would generate an error because there is no constructor that matches those arguments. In general, the arguments sent to an overloaded method must match the formal parameters of some version of that method.

The number of constructors we provide is a design decision and depends on the class. Providing multiple constructors gives the client a choice of ways to create an object. It is good practice to provide, at minimum, a default constructor. The reason for this will become clear as we explore classes in more depth. It is also good practice to provide another constructor that accepts values for all the instance variables.

On line 17, we instantiate an *Auto* object with an invalid argument for gallons of gas. The object is still created, but the value of its *gallonsOfGas* instance variable is autoinitialized to 0.0. The output of Example 7.2 is shown in **Figure 7.1**.

Figure 7.1 Output from *Auto* Client, Version 1

Description

Beware of this common error: declaring a *void* return type for a constructor. Remember that constructors have no return type at all. For example, the following invalid constructor definition declares a return type of *void*:

```
// Error! void return value specified
public void Auto( String model,
                  int startMilesDriven,
                  double startGallonsOfGas )
{
     // body of constructor
}
```

Description

This is a difficult error to find. The class file will compile without an error because the compiler doesn’t recognize this method as a constructor. Instead, the client program will get a compiler error when it attempts to instantiate an *Auto* object. For example, this statement in a client program

```
Auto gm = new Auto( "Prius", 350, 15.5 );
```

Description

would generate this compiler error:

```
AutoClient.java:13: error: constructor Auto in class Auto cannot be applied to given types;
      Auto gm = new Auto( "Prius", 350, 15.5 );
                ^
  required: no arguments
  found: String,int,double
  reason: actual and formal argument lists differ in length
1 error
```

Description

Notice that both constructors access the instance variables directly. Remember that instance variables have class scope, which means that they can be accessed anywhere in the class. Thus, any method of the class can access any of the instance variables directly. In our *Auto* class, any method can access the instance variables *model, milesDriven*, and *gallonsOfGas*.

COMMON ERROR TRAP

Specifying a return value for a constructor will cause a compiler error in the client program when the client attempts to instantiate an object of that class.

Methods have class scope as well. Any method can call any of the methods in the class, regardless of whether the methods have been declared *private, public*, or *protected*.

In addition to accessing the instance variables, a method can also access its own parameters. When a method begins executing, its parameters have been declared and have been given the values of the arguments sent by the caller of the method.

The parameters have **local scope** in that a method can access its parameters directly. We call this local scope because the parameters can be accessed only in that method; that is, a method can access its own parameters, but attempting to access another method's parameters generates a compiler error.

Similarly, the method can define variables to be used within the method. These variables also have local scope and are accessible from the point of definition until the end of the method or the end of the block in which the variable was defined, whichever comes first.

Table 7.3 summarizes the rules of scope.

Rules of Scope

A method in a class can access

- the instance variables of its class
- any parameters sent to the method
- any variable the method declares within its body from the point of declaration until the end of the method or until the end of the block in which the variable was declared, whichever comes first

- any methods in the class

Description

Attempting to use an identifier that is not in scope will generate the following compiler error:

```
cannot find symbol
```

Description

When the client in Example 7.2 runs, it instantiates three objects, but there is nothing more our application can do with them. To allow our client to manipulate the *Auto* objects further, we need to provide more methods.

```
sedan: model is unknown
 miles driven is 0
 gallons of gas is 0.0
suv: model is Trailblazer
 miles driven is 7000
 gallons of gas is 437.5
```

7.5 Writing Accessor Methods

Because clients cannot directly access *private* instance variables of a class, classes usually provide *public* accessor methods for the instance variables. These methods have a simple, almost trivial, standard form:

```
public returnType getInstanceVariable( )
{
   return instanceVariable;
}
```

The standard name of the method is *get*, followed by the instance variable's name with an initial capital letter. Because the method names usually start with "get," accessor methods are often called **getters**. The method takes no arguments and simply returns the current value of the instance variable. Thus, the return type is the same data type as the instance variable.

You can see this simple pattern in the accessor methods for Version 2 of our *Auto* class, shown in **Example 7.3** (lines 39–58).

Example 7.3 *Auto* Class, Version 2

```java
/* Auto class, Version 2
   Anderson, Franceschi
*/

public class Auto
{
    // instance variables
    private String model;          //  model of auto
    private int milesDriven;       //  number of miles driven
    private double gallonsOfGas;   //  number of gallons of gas

    // Default constructor:
    //  initializes model to "unknown";
    //  milesDriven is autoinitialized to 0
    //      and gallonsOfGas to 0.0
    public Auto( )
    {
       model = "unknown";
    }

    // Overloaded constructor:
    // allows client to set beginning values for
    //   model, milesDriven, and gallonsOfGas.
    public Auto( String startModel,
                 int startMilesDriven,
                 double startGallonsOfGas )
    {
       model = startModel;

       // validate startMilesDriven parameter
       if ( startMilesDriven >= 0 )
          milesDriven = startMilesDriven;

       // validate startGallonsOfGas parameter
       if ( startGallonsOfGas >= 0.0 )
          gallonsOfGas = startGallonsOfGas;
    }

    // Accessor method:
    // returns current value of model
    public String getModel( )
    {
       return model;
    }

    // Accessor method:
    // returns current value of milesDriven
    public int getMilesDriven( )
    {
       return milesDriven;
    }

    // Accessor method:
    //  returns current value of gallonsOfGas
    public double getGallonsOfGas( )
    {
       return gallonsOfGas;
    }
}
```

Description

In the client code in **Example 7.4**, we’ve added a few statements to call the accessor methods for the two *Auto* objects we’ve instantiated. Then we print the values, as shown in **Figure 7.2**.

Example 7.4 *Auto* Client, Version 2

```java
/* Auto Client, Version 2
   Anderson, Franceschi
*/

public class AutoClient
{
    public static void main( String [ ] args )
    {
        Auto sedan = new Auto( );
       String sedanModel = sedan.getModel( );
       int sedanMiles = sedan.getMilesDriven( );
       double sedanGallons = sedan.getGallonsOfGas( );
       System.out.println( "sedan: model is " + sedanModel
                  + "\n miles driven is " + sedanMiles
                  + "\n gallons of gas is " + sedanGallons );

       Auto suv = new Auto( "Trailblazer", 7000, 437.5 );
       String suvModel = suv.getModel( );
       int suvMiles = suv.getMilesDriven( );
       double suvGallons = suv.getGallonsOfGas( );
       System.out.println( "suv: model is " + suvModel
                  + "\n miles driven is " + suvMiles
                  + "\n gallons of gas is " + suvGallons );
   }
}
```

Description

Figure 7.2 Output from *Auto* Client, Version 2

Description

Because the *sedan* object was instantiated by calling the default constructor, its model is *unknown* and the miles driven and gallons of gas are set to default values. On the other hand, the *suv* object data reflects the values sent to the overloaded constructor when the *suv* object was instantiated.

SOFTWARE ENGINEERING TIP

Provide *public* accessor methods for any instance variable for which the client should be able to retrieve the value. Each accessor method returns the current value of the corresponding instance variable.

Thus, Version 2 of our *Auto* class lets our clients instantiate objects and get the values of the instance variables. But we still need to give the client a way to change the instance variables. In order to do this, we provide mutator methods.

```
suv: model is Trailblazer
 miles driven is 7000
 gallons of gas is 437.5

suv: model is Sportage
 miles driven is 200
 gallons of gas is 10.5

suv: model is Sportage
 miles driven is 200
 gallons of gas is 10.5
```

7.6 Writing Mutator Methods

As we have discussed, we declare the instance variables as *private* to encapsulate the data of the class. We allow only the class methods to directly set the values of the instance variables. Thus, it is customary to provide a *public* **mutator** method for any instance variable that the client will be able to change. Because the method names usually start with “set,” mutator methods are often called **setters**.

The general form of a mutator method is the following:

```
public void setInstanceVariable( dataType newValue )
{
    // validate newValue, then assign to the instance variable
}
```

Description

SOFTWARE ENGINEERING TIP

Provide a mutator method for any instance variable that you want to allow the client to change.

We declare mutator methods as *public* so that client programs can use the methods to change the values of the instance variables. We do not return a value, so we declare the return type as *void*. By convention, the name of each mutator method starts with the lowercase word *set* followed by the instance variable name with an initial capital letter. For obvious reasons, the data type of the method’s parameter should match the data type of the instance variable being set.

Whenever possible, the body of your mutator method should validate the parameter value passed by the client. If the parameter value is valid, the mutator assigns that value to the instance variable.

Example 7.5 shows Version 3 of our *Auto* class.

Example 7.5 *Auto* Class, Version 3

```java
/* Auto class, Version 3
   Anderson, Franceschi
*/

public class Auto
{
    // instance variables
    private String model;          //  model of auto
    private int milesDriven;       //  number of miles driven
    private double gallonsOfGas;   //  number of gallons of gas

    // Default constructor:
    //  initializes model to "unknown";
    //  milesDriven is autoinitialized to 0
    //       and gallonsOfGas to 0.0
    public Auto( )
    {
       model = "unknown";
    }

    // Overloaded constructor:
    // allows client to set beginning values for
    //   model, milesDriven, and gallonsOfGas.
    public Auto( String startModel,
                 int startMilesDriven,
                 double startGallonsOfGas )
    {
       model = startModel;
       setMilesDriven( startMilesDriven );
       setGallonsOfGas( startGallonsOfGas );
    }

    // Accessor method:
    // returns current value of model
    public String getModel( )
    {
      return model;
    }

    // Accessor method:
    // returns current value of milesDriven
    public int getMilesDriven( )
    {
      return milesDriven;
    }

    // Accessor method:
    //  returns current value of gallonsOfGas
    public double getGallonsOfGas( )
    {
      return gallonsOfGas;
    }

    // Mutator method:
    // allows client to set model
    public void setModel( String newModel )
    {
      model = newModel;
    }

    // Mutator method:
    // allows client to set value of milesDriven;
    // if new value is not less than 0
    public void setMilesDriven( int newMilesDriven )
    {
      if ( newMilesDriven >= 0 )
       milesDriven = newMilesDriven;
    }

    // Mutator method:
    // allows client to set value of gallonsOfGas;
    // if new value is not less than 0.0
    public void setGallonsOfGas( double newGallonsOfGas )
    {
      if ( newGallonsOfGas >= 0.0 )
        gallonsOfGas = newGallonsOfGas;
    }
}
```

Description

The mutator methods for the *milesDriven* (lines 61–68) and *gallonsOfGas* (lines 70–77) instance variables validate that the parameter value is greater than or equal to 0. If the parameter value is less than 0, the methods do not change the value of the instance variable. In previous versions of our *Auto* class, the constructor performed the same validation. Now that the mutator methods perform this validation, the constructor can call the mutator methods (lines 29–30) passing its parameters through to the mutator methods. In this way, we eliminate duplicate code; the validation of each parameter's value is performed in one place. If later we decide to impose other restrictions on any instance variable's value, we will need to change the code in only one place. In this way, a client cannot set invalid values for *milesDriven* or *gallonsOfGas*, either when the object is instantiated or by calling a mutator method.

In **Example 7.6**, our client instantiates one *Auto* object, *suv* (line 9), and prints the values of its instance variables (lines 11–14). Then we call each mutator method, setting new values for each instance variable (lines 16–19). We again print the values of the instance variables (lines 21–24) to show that the values have been changed. Then, in line 27, we attempt to set an invalid value for *milesDriven*. As **Figure 7.3** shows, the mutator method does not change the value, which we verify by again printing the values of the instance variables (lines 28–31).

Example 7.6 *Auto* Client, Version 3

```
 1 /* Auto Client, Version 3
 2    Anderson, Franceschi
 3 */
 4
 5 public class AutoClient
 6 {
 7   public static void main( String [ ] args )
 8   {
 9      Auto suv = new Auto( "Trailblazer", 7000, 437.5 );
10
11      // print initial values of instance variables
12      System.out.println( "suv: model is " + suv.getModel( )
13             + "\n miles driven is " + suv.getMilesDriven( )
14             + "\n gallons of gas is " + suv.getGallonsOfGas( ) );
15
16      // call mutator method for each instance variable
17      suv.setModel( "Sportage" );
18      suv.setMilesDriven( 200 );
19      suv.setGallonsOfGas( 10.5 );
20
21      // print new values of instance variables
22      System.out.println( "\nsuv: model is " + suv.getModel( )
23             + "\n miles driven is " + suv.getMilesDriven( )
24             + "\n gallons of gas is " + suv.getGallonsOfGas( ) );
25
26      // attempt to set invalid value for milesDriven
27      suv.setMilesDriven( -1 );
28      // print current values of instance variables
29      System.out.println( "\nsuv: model is " + suv.getModel( )
30             + "\n miles driven is " + suv.getMilesDriven( )
31             + "\n gallons of gas is " + suv.getGallonsOfGas( ) );
32   }
33 }
```

Description

Figure 7.3 Output from *Auto* Client, Version 3

Description

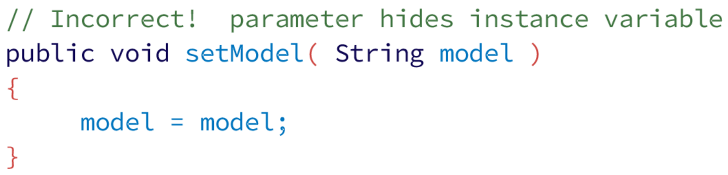
SOFTWARE ENGINEERING TIP

Write the validation code for instance variables in mutator methods and have the constructor call the mutator methods to set initial values.

When a method begins executing, the parameters have been defined and have been assigned the values sent by the client. When the client calls the *setModel* method at line 17, the *newModel* parameter has the value *Sportage* when the method starts executing.

A common error in writing mutator methods is using the instance variable name for the parameter name. When a method parameter has the same name as an instance variable, the parameter hides the instance variable. In other words, the parameter has **name precedence**, so any reference to that name refers to the parameter, not to the instance variable.

For example, the intention in this incorrectly coded method is to set a new value for the *model* instance variable:

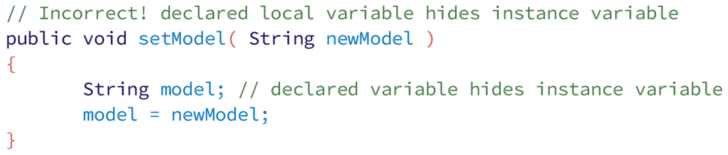


```
// Incorrect!  parameter hides instance variable
public void setModel( String model )
{
      model = model;
}
```

Description

Because the parameter, *model*, has the same identifier as the *model* instance variable, the result of this method is to assign the value of the parameter to the parameter! This is called a ***No-op***, which stands for “No operation,” because the statement has no effect. To avoid this logic error, we can choose a different name for the parameter. To avoid name conflicts, we name each parameter using the pattern *newInstanceVariable*.

A similar common error is to declare a local variable with the same name as the instance variable, as shown in the following incorrectly coded method:



```
// Incorrect! declared local variable hides instance variable
public void setModel( String newModel )
{
       String model; // declared variable hides instance variable
       model = newModel;
}
```

Description

COMMON ERROR TRAP

Be aware that a method parameter or local variable that has the same name as an instance variable hides the instance variable.

Any variable that a method declares is a local variable because its scope is local to the method. Thus, the declared variable, *model*, is a local variable to the *setModel* method.

With the preceding code, the *model* local variable hides the instance variable with the same name, so the method assigns the parameter value to the local variable, not to the instance variable. The result is that the value of the *model* instance variable is unchanged.

COMMON ERROR TRAP

Do not declare the parameters of a method inside the method body. When the method begins executing, the parameters exist and have been assigned the values set by the client in the method call.

The instance variable, *model*, is defined already in the class. Thus, the method should simply assign the parameter value to the instance variable without attempting to declare the instance variable (again) in the method.

Finally, another common error is declaring the parameter, as shown below:

```
// Incorrect! Declaring the parameter; parameters are declared already
public void setModel( String newModel )
{
       String newModel; // local variable has same name as parameter
       model = newModel;
}
```

Description

This code generates this compiler error:

```
variable newModel is already defined in method setModel(String)
```

Description

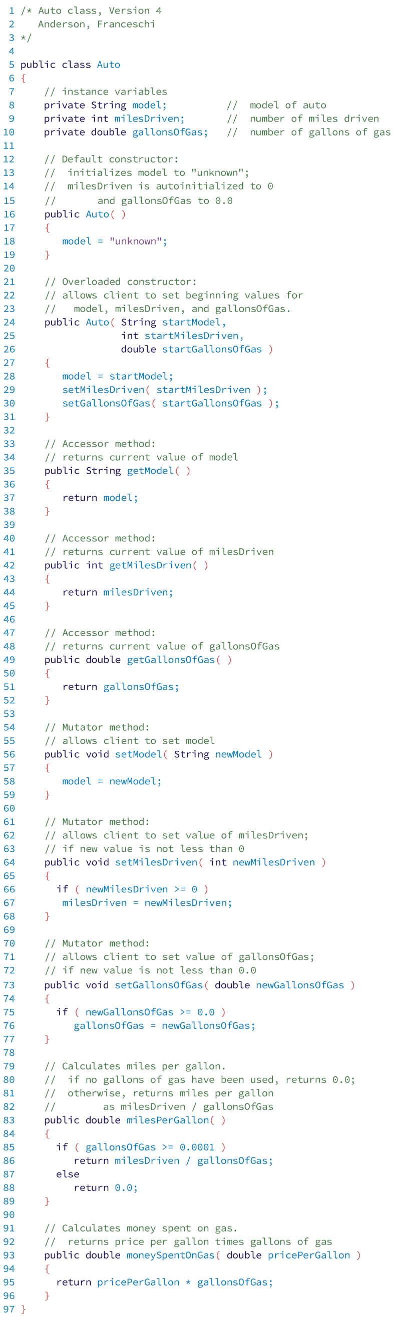
```
Mileage for suv is 16.0
Gas cost for suv is $1,220.62
```

7.7 Writing Data Manipulation Methods

Now we finally get down to the business of the class. Usually you will define a class not only to encapsulate the data, but also to provide some service. Thus, you would provide one or more methods that perform the functionality of the class. These methods might calculate a value based on the instance variables and/or parameters, or manipulate the instance variables in some way. The API of these methods depends on the function being performed. If a method merely manipulates the instance variables, it requires no parameters because instance variables are accessible from any method and, therefore, are in scope.

For example, in our *Auto* class, part of the functionality of our class is to calculate miles per gallon and the gas cost, so we provide the *milesPerGallon* and *moneySpentOnGas* methods in our *Auto* class, Version 4, shown in Example 7.7.

Example 7.7 *Auto* Class, Version 4



```java
/* Auto class, Version 4
   Anderson, Franceschi
*/

public class Auto
{
    // instance variables
    private String model;          //  model of auto
    private int milesDriven;       //  number of miles driven
    private double gallonsOfGas;   //  number of gallons of gas

    // Default constructor:
    //  initializes model to "unknown";
    //  milesDriven is autoinitialized to 0
    //       and gallonsOfGas to 0.0
    public Auto( )
    {
       model = "unknown";
    }

    // Overloaded constructor:
    // allows client to set beginning values for
    //   model, milesDriven, and gallonsOfGas.
    public Auto( String startModel,
                 int startMilesDriven,
                 double startGallonsOfGas )
    {
       model = startModel;
       setMilesDriven( startMilesDriven );
       setGallonsOfGas( startGallonsOfGas );
    }

    // Accessor method:
    // returns current value of model
    public String getModel( )
    {
       return model;
    }

    // Accessor method:
    // returns current value of milesDriven
    public int getMilesDriven( )
    {
       return milesDriven;
    }

    // Accessor method:
    // returns current value of gallonsOfGas
    public double getGallonsOfGas( )
    {
       return gallonsOfGas;
    }

    // Mutator method:
    // allows client to set model
    public void setModel( String newModel )
    {
       model = newModel;
    }

    // Mutator method:
    // allows client to set value of milesDriven;
    // if new value is not less than 0
    public void setMilesDriven( int newMilesDriven )
    {
      if ( newMilesDriven >= 0 )
       milesDriven = newMilesDriven;
    }

    // Mutator method:
    // allows client to set value of gallonsOfGas;
    // if new value is not less than 0.0
    public void setGallonsOfGas( double newGallonsOfGas )
    {
      if ( newGallonsOfGas >= 0.0 )
         gallonsOfGas = newGallonsOfGas;
    }

    // Calculates miles per gallon.
    //  if no gallons of gas have been used, returns 0.0;
    //  otherwise, returns miles per gallon
    //        as milesDriven / gallonsOfGas
    public double milesPerGallon( )
    {
      if ( gallonsOfGas >= 0.0001 )
         return milesDriven / gallonsOfGas;
      else
         return 0.0;
    }

    // Calculates money spent on gas.
    //  returns price per gallon times gallons of gas
    public double moneySpentOnGas( double pricePerGallon )
    {
      return pricePerGallon * gallonsOfGas;
    }
}
```

Description

Our class now provides the method to calculate mileage and estimate gas cost for an *Auto* object. The *milesPerGallon* method (lines 79–89) needs no parameters since it accesses only instance variables of the class, which are in scope. As you can see from the code, we guard against dividing by 0 by checking the value of *gallonsOfGas* before using it as the divisor. If *gallonsOfGas* is not equal to zero, we divide *milesDriven* by *gallonsOfGas* and return the result as a *double*. Otherwise, we return 0.0.

The *moneySpentOnGas* method (lines 91–96) accepts one parameter that represents the average price of a gallon of gas. It returns the amount of money spent on gas, calculated by multiplying that parameter by the *gallonsOfGas* instance variable.

Notice that we do not format the returned values from *milesPerGallon* or *moneySpentOnGas*. Returning a *double* allows the client to use those values in further calculations. If the client wants to display the values to the user, the client can format the values at that time.

Example 7.8 shows a client program that instantiates an *Auto* object, calls the *milesPerGallon* and *moneySpentOnGas* methods, and prints their return value, as shown in **Figure 7.4**.

Example 7.8 *Auto* Client, Version 4

```
/* Auto Client, Version 4
   Anderson, Franceschi
*/

import java.text.DecimalFormat;
import java.text.NumberFormat;

public class AutoClient
{
   public static void main( String [ ] args )
   {
     Auto suv = new Auto( "Trailblazer", 7000, 437.5 );

     double mileage = suv.milesPerGallon( );
     DecimalFormat mpgFormat = new DecimalFormat( "0.0" );
     System.out.println( "Mileage for suv is "
                          + mpgFormat.format( mileage ) );

     double gasCost = suv.moneySpentOnGas( 2.79 );
     NumberFormat money = NumberFormat.getCurrencyInstance( );
     System.out.println( "Gas cost for suv is "
                          + money.format( gasCost ) );
   }
}
```

Description

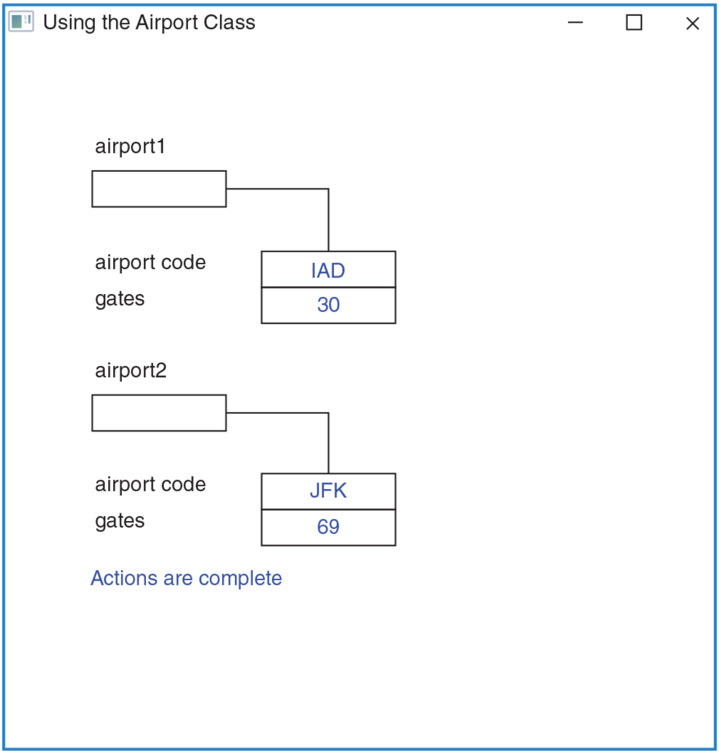
Using the Airport Class
airport1
null
airport2
null

Two airport object references declared:
Airport airport1, airport2;



Actions are complete

7.8 Programming Activity 1: Writing a Class Definition, Part 1

In this programming activity, you will write the methods for an *Airport* class. Then you will run a prewritten client program that instantiates several *Airport* objects, calls the methods that you have written, and displays the values of the objects' data.

The *Airport* class has two instance variables: the airport code and the number of gates.

In this chapter's Programming Activity 1 folder in the supplied code files, you will find multiple files. Copy these files to a folder on your computer. Note that all files should be in the same folder.

Load the *Airport.java* source file; you'll notice that the class already contains some source code. The method names and APIs are described in comments. Your job is to define the instance variables and write the methods. It is important that you define the method headers exactly as described, including method name, return value, and parameters, because our *AirportDrawing* class will call each method to test it. Search for five asterisks in a row (*****). This will position you at the seven places in the class definition where you will add your code. The *Airport.java* code is shown here in **Example 7.9**.

Example 7.9 *Airport.java*

```java
/* Airport class
   Anderson, Franceschi
*/

public class Airport
{
  // 1. ***** Define the instance variables  *****
  //  airportCode is a String
  //  gates is an integer

   // 2. ***** Write this method *****
   // Default constructor:
   // method name: Airport
   // return value:  none
   // parameters: none
   // function: sets the airportCode to an empty String

   // 3. ***** Write this method *****
   // Overloaded constructor:
   // method name: Airport
   // return value: none
   // parameters:  a String startAirportCode and an int startGates
   // function:
   //      calls the setAirportCode method,
   //      passing startAirportCode parameter;
   //      calls the setGates method, passing startGates parameter

   // 4. ***** Write this method *****
   // Accessor method for the airportCode instance variable
   // method name: getAirportCode
   // return value: String
   // parameters: none
   // function: returns airportCode

   // 5. ***** Write this method *****
   // Accessor method for the gates instance variable
   // method name: getGates
   // return value: int
   // parameters: none
   // function: returns gates

   // 6. ***** Write this method *****
   // Mutator method for the airportCode instance variable
   // method name: setAirportCode
   // return value: void
   // parameters: String newAirportCode
   // function: assigns airportCode the value of the
   //       newAirportCode parameter

   // 7. ***** Write this method *****
   // Mutator method for the gates instance variable
   // method name: setGates
   // return value:  void
   // parameters: int newGates
   // function: validates the newGates parameter.
   //   if newGates is greater than or equal to 0,
   //       sets gates to newGates;
   //       otherwise, does not change the value of gates

  }  // end of Airport class definition
```

Description

When you finish writing the methods for the *Airport* class, compile the source file. When *Airport.java* compiles without errors, load the *AirportPractice1Application.java* file. This source file contains *main*, so you will execute the application from this file. When the application begins, you should see the window shown in **Figure 7.5**.

Figure 7.5 Programming Activity 1 Opening Window

Description

As you can see, the *AirportDrawing* has declared two *Airport* object references, *airport1* and *airport2*. The references are *null* because no *Airport* objects have been instantiated.

The client application will instantiate the *Airport* objects and call the methods you have written for the *Airport* class. As the application does its work, it displays a status message at the bottom of the window that indicates which method it has called. It also displays the current values of both *Airport* objects. You can check your work by comparing the values in the objects with the status message. **Figure 7.6** shows the *AirportPractice1Application* application when it has finished instantiating *Airport* objects and calling *Airport* methods.

Figure 7.6 *AirportPractice1Application* When Complete

Description

DISCUSSION QUESTIONS

1. Why does the default constructor need to set a value for the airport code?
2. Explain the importance of using standard naming conventions for accessor and mutator methods.

```
car is Auto@4a574795
this is Auto@4a574795
Miles driven is 67
Gallons of gas is 3.4
```

7.9 The Object Reference *this*

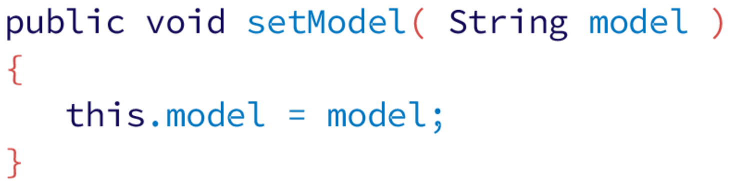
When an object is instantiated, a copy of each of the instance variables is created. However, all objects of a class share one copy of the methods. How, then, does a method know for which object the method was called? In other words, how does a method know which object's data it should get, set, or use to calculate a value? The answer is the special object reference named ***this***.

When a method begins executing, the JVM sets the object reference, *this*, to refer to the object for which the method has been called. That object reference is called the **implicit parameter**. When a method references an instance variable, it will access the instance variable that belongs to the object that the implicit parameter references. In other words, by default, any instance variable referred to by a method is considered to be *this.instanceVariable.*

Preceding an instance variable name with *this* is optional; when just the instance variable name is used (without any object reference), *this* is assumed. Consequently, we usually omit the *this* reference and use just the instance variable name.

However, in methods where you need to avoid ambiguity in variable names, you can precede an instance variable name with *this.* That approach comes in handy as a way to avoid one of the common errors we discussed earlier in the chapter: A parameter of a mutator method with the same name as the instance variable hides the instance variable. We can eliminate this problem by using the *this* reference with the instance variable, which effectively uncovers the instance variable name.

For example, some programmers would code the *setModel* mutator as follows:

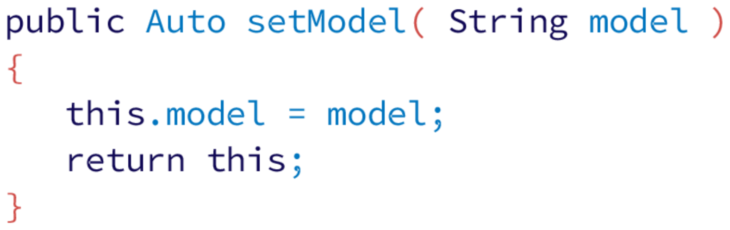


```
public void setModel( String model )
{
    this.model = model;
}
```

Description

Here we give the parameter, *model*, the same name as the instance variable it represents. Then in the assignment statement, we use the *this* reference to distinguish the instance variable from the parameter. Now it is clear that the parameter value, *model,* should be assigned to the instance variable, *this.model.*

Furthermore, some programmers, particularly in the Android community, would code the *setModel* mutator so that it returns a reference to *this Auto*, as follows:



```
public Auto setModel( String model )
{
    this.model = model;
    return this;
}
```

Description

The benefit of returning *this* is that we can chain method calls. For example, assuming the *setMilesDriven* and *setGallonsOfGas* mutators also return *this* and *sporty* is an *Auto* object, we could chain method calls as follows:

```
sporty.setGallonsOfGas( 3.4 ).setMilesDriven( 67 );
```

Description

Since the . (dot) operator associates left to right, the above statement is equivalent to:

```
( sporty.setGallonsOfGas( 3.4 ) ).setMilesDriven( 67 );
```

Description

Since the *setGallonsOfGas* method returns *this*—that is, the object reference that called it—it returns *sporty* in the above statement. Thus, the expression `sporty.setGallonsOfGas ( 3.4 )` evaluates to *sporty*, which in turns calls the method *setMilesDriven* with argument *67*, as shown below:

```
( sporty ).setMilesDriven( 67 );
```

Description

Example 7.10 shows Version 5 of our *Auto* class. The three mutators (lines 54–60, 62–70, and 72–81) all use and return the *this* reference. At line 77, we added an output statement inside the *setGallonsOfGas* method to help understand that *this* is a reference to the object reference that called the method.

Example 7.10 *Auto* Class, Version 5

```
/* Auto class, Version 5
   Anderson, Franceschi
*/

public class Auto
{
    // instance variables
    private String model;          //  model of auto
    private int milesDriven;       //  number of miles driven
    private double gallonsOfGas;   //  number of gallons of gas

    // Default constructor:
    //  initializes model to "unknown";
    //  milesDriven is autoinitialized to 0
    //        and gallonsOfGas to 0.0
    public Auto( )
    {
       model = "unknown";
    }

    // Overloaded constructor:
    // allows client to set beginning values for
    //   model, milesDriven, and gallonsOfGas.
    public Auto( String startModel,
                 int startMilesDriven,
                 double startGallonsOfGas )
    {
       model = startModel;
       setMilesDriven( startMilesDriven );
       setGallonsOfGas( startGallonsOfGas );
    }

    // Accessor method:
    // returns current value of model
    public String getModel( )
    {
       return model;
    }

    // Accessor method:
    // returns current value of milesDriven
    public int getMilesDriven( )
    {
       return milesDriven;
    }

    // Accessor method:
    // returns current value of gallonsOfGas
    public double getGallonsOfGas( )
    {
       return gallonsOfGas;
    }

    // Mutator method:
    // allows client to set model
    public Auto setModel( String model )
    {
       this.model = model;
       return this;
    }

    // Mutator method:
    // allows client to set value of milesDriven;
    // if new value is not less than 0
    public Auto setMilesDriven( int milesDriven )
    {
      if ( milesDriven >= 0 )
         this.milesDriven = milesDriven;
      return this;
    }

    // Mutator method:
    // allows client to set value of gallonsOfGas;
    // if new value is not less than 0.0
    public Auto setGallonsOfGas( double gallonsOfGas )
    {
      System.out.println( "this is " + this );
      if ( gallonsOfGas >= 0.0 )
         this.gallonsOfGas = gallonsOfGas;
      return this;
    }

    // Calculates miles per gallon.
    //  if no gallons of gas have been used, returns 0.0;
    //  otherwise, returns miles per gallon
    //        as milesDriven / gallonsOfGas
    public double milesPerGallon( )
    {
      if ( gallonsOfGas >= 0.0001 )
         return milesDriven / gallonsOfGas;
      else
         return 0.0;
    }

    // Calculates money spent on gas.
    //  returns price per gallon times gallons of gas
    public double moneySpentOnGas( double pricePerGallon )
    {
      return pricePerGallon * gallonsOfGas;
    }
 }
```

Description

At line 11 of **Example 7.11**, we demonstrate how we can chain calls to methods that return the *this* reference. At line 10, we output car. As we can see in **Figure 7.7**, the hexadecimal representation of *car* is the same as *this* inside the *setGallonsOfGas* method. This shows that *car* (in *main*) and *this* (in *setGallonsOfGas*) are the same object reference.

Example 7.11 *Auto* Client, Version 5

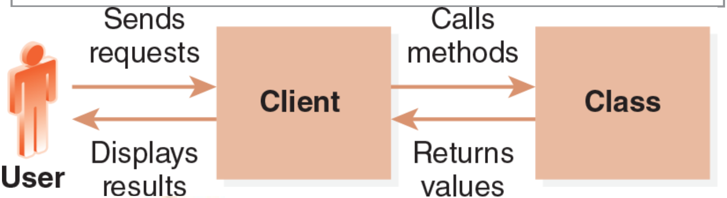
```
 1 /* Auto Client, Version 5
 2    Anderson, Franceschi
 3 */
 4
 5 public class AutoClient
 6 {
 7    public static void main( String [ ] args )
 8    {
 9      Auto car = new Auto( );
10      System.out.println( "car is " + car );
11      car.setGallonsOfGas( 3.4 ).setMilesDriven( 67 );
12
13      int carMiles = car.getMilesDriven( );
14      double carGallons = car.getGallonsOfGas( );
15
16      System.out.println( "Miles driven is " + carMiles
17              + "\nGallons of gas is " + carGallons );
18    }
19 }
```

Description

Figure 7.7 Output from *Auto* Client, Version 5

Description

```
Model: Spyder; miles driven: 0; gallons of gas: 0.00
Model: Accent; miles driven: 0; gallons of gas: 0.00
sporty and compact are not equal
```



7.10 The *toString* and *equals* Methods

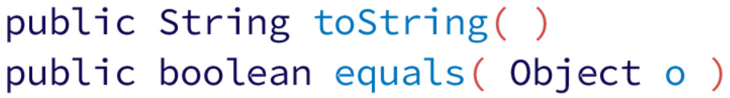
In addition to constructors, mutator methods, and accessor methods, a well-designed class usually implements the *toString* and *equals* methods.

The *toString* method is called automatically when an object reference is used as a *String*. For example, the *toString* method for an object is called when the object reference is used with, or as, a parameter to *System.out.println.* The function of the *toString* method is to return a printable representation of the object data.

The *equals* method is designed to compare two objects for equality; that is, it typically returns *true* if the corresponding instance variables in both objects are equal in value. The *equals* method takes an *Object* reference parameter that is expected to be an *Auto* reference and returns *true* if the values of its fields are equal to the values of the fields of this *Auto* object, *false* otherwise.

All classes inherit a version of the *toString* and the *equals* methods from the *Object* class, but these versions do not provide the functionality we described earlier. Thus, it is good practice to provide new versions of these methods. To do that, we use the same header as the methods in the *Object* class but provide a new method body. This is called **overriding a method.**

The APIs of the *toString* and *equals* methods are the following:



```
public String toString( )
public boolean equals( Object o )
```

Description

Example 7.12 shows the code added in Version 6 of the *Auto* class with implementations of the *toString* method (lines 103–112) and the *equals* method (lines 114–131). When overriding a method, a good programming practice is add the *@Override* annotation before the method header (lines 104 and 116). It tells the compiler that the method that follows is overriding a method inherited from another class. And in turn, the compiler warns us if our method header does not in fact override the inherited method.

Example 7.12 *Auto* Class, Version 6

```
  1 /* Auto class, Version 6
  2    Anderson, Franceschi
  3 */
  4
  5 import java.text.DecimalFormat;
  6
  7 public class Auto
  8 {
  9
       ...
103    // toString: returns a String of instance variable values
104    @Override
105    public String toString( )
106    {
107       DecimalFormat gallonsFormat = new DecimalFormat( "#0.00" );
108       return "Model: " + model
109             + "; miles driven: " + milesDriven
110             + "; gallons of gas: "
111             + gallonsFormat.format( gallonsOfGas );
112    }
113
114    // equals: returns true if fields of parameter object
115    //         are equal to fields in this object
116    @Override
117    public boolean equals( Object o )
118    {
119       if ( o instanceof Auto objAuto )
120       {
121          if ( model.equals( objAuto.model )
122               && milesDriven == objAuto.milesDriven
123               && Math.abs( gallonsOfGas - objAuto.gallonsOfGas )
124                                                 < 0.0001 )
125               return true;
126          else
127               return false;
128       }
129       else
130          return false;
131    }
132 }
```

Description

In the *toString* method (lines 103–111), we begin by instantiating a *DecimalFormat* object for formatting the gallons of gas as a floating-point number with one decimal place. Note that *gallonsFormat* is a local variable for the *toString* method; that is, only the *toString* method can use the *gallonsFormat* object. To use the *DecimalFormat* class, we import the class on line 5. We then build the *String* to return by concatenating labels for each instance variable with the values of the instance variables. The *toString* method can be used in a client class containing the *main* method, for instance, to print *Auto* objects using a single statement instead of calling all the class accessor methods.

To implement our *equals* method (lines 114–131), we first need to check that the parameter’s type is *Auto*. The ***instanceof*** binary operator, whose left operand is an object reference and right operand is a class, evaluates to *true* if the object reference can be cast to an instance of the class (for example, if it is an object reference of that class) and *false* otherwise (**Table 7.4**). We use the *instanceof* operator at line 119 to determine if the parameter *o* can be cast to an *Auto* object reference (most likely, when sent by a client, *o* will be an *Auto* reference). If it cannot, we return *false* (line 130). Otherwise, we can proceed with comparing *o*’s fields and this *Auto* object’s fields. Before performing the comparison, we must cast the *Object* reference *o* to an *Auto* (line 119). Otherwise, there would be a compiler error when trying to access the instance variable *model* with the *Object o*, because *model* is an instance variable of class *Auto* and not of class *Object*.

The *instanceof* Operator

Operator	Syntax	Operation
instanceof	*objectReference* instanceof *ClassName*	evaluates to *true* if *objectReference* is of *ClassName* type; *false* otherwise

Description

The pattern matching feature, recently added to Java, makes it possible to test if an object reference is of a certain data type and cast it to that data type in one expression, as done on line 119.

Previously, we had to do this in two steps: first, test if the object reference (*o*) is of a particular data type (*Auto*) using the *instanceof* operator, and second, cast *o* to an *Auto* object reference (*objAuto*), as in the following code:

```
if ( o instanceof Auto )
{
   Auto objAuto = ( Auto ) o;
   // call methods of the Auto class with objAuto
```

Description

We compare each instance variable in the parameter object, *objAuto*, with the same instance variable in this object. We return *true* if the corresponding instance variables in each object have the same values; otherwise, we return *false*.

Notice that line 121 calls the *equals* method of the *String* class to compare the values of *model* in the objects because *model* is a *String* object reference. Notice also that because instance variables are in scope for methods, our *equals* method is able to directly access the instance variables of both this object and the *Auto* object, *objAuto*.

Example 7.13 puts Version 6 of the *Auto* class to work. We instantiate two objects that differ only in the model. On line 10, we explicitly call *toString* to print the fields of the *sporty* object. On line 14, we implicitly call the *toString* method; *toString* is called automatically because the *compact* object is the argument sent to the *println* method. On lines 16–19, we compare the two objects using the *equals* method and print the results. The output is shown in **Figure 7.8**.

Example 7.13 *Auto* Client, Version 6

```
/* Auto Client, version 6
   Anderson, Franceschi
*/

public class AutoClient
{
  public static void main( String [ ] args )
  {
     Auto sporty = new Auto( "Spyder", 0, 0.0 );
     System.out.println( sporty.toString( ) );

     Auto compact = new Auto( "Accent", 0, 0.0 );
     System.out.println( );
     System.out.println( compact );

     if ( compact.equals( sporty ) )
       System.out.println( "\nsporty and compact are equal" );
     else
       System.out.println( "\nsporty and compact are not equal" );
  }
}
```

Description

Figure 7.8 Output from Example 7.13

Description

Notice that the *toString* method returns a *String*. It does not output the data itself using *System.out.println*. By returning the object values as a *String*, the class is more reusable. The client can choose how best to handle the returned values. If the client is a text application, it may indeed print the values using *System.out.println*. But if the client has a graphics window, it may want to display the data in a text box or by using the JavaFX *fillText* method. Notice also that the *equals* method does not output a message stating whether the two objects are equal. Instead, the *equals* method returns *true* or *false* so that the client can test the return value and change its behavior depending on whether the objects are equal or not equal. For similar reasons, the accessors return the values of the instance variables rather than outputting those values.

SOFTWARE ENGINEERING TIP

The class methods should communicate directly with the client, and the client should handle the communications with the user.

As a general software engineering principle, class methods should communicate only with the client. The client, in turn, communicates with the user. In particular, the class methods should not output anything; the decision on what to output should be left to the client of the class. Thus, the client accepts requests from the user, calls the class methods and receives the returned values from the class, and then communicates those results to the user, as appropriate. **Figure 7.9** illustrates this design principle.

Figure 7.9 Communication Flow among the User, Client, and Class

Description

CODE IN ACTION

Within the online resources, you will find a movie with step-by-step illustrations on how to define a class. Click on the link to start the movie.

© Hemera Technologies/Photos.com/Thinkstock

```
Before instantiating an Auto object:
the count of Auto objects is 0

After instantiating an Auto object:
the count of Auto objects is 1
```

7.11 *Static* Class Members

As we have mentioned, a separate set of instance variables is created for each object that is instantiated. In addition to instance variables, classes can define **class variables**, which are created only once, when the JVM initializes the class. Thus, class variables exist before any objects are instantiated, and each class has only one copy of its class variables.

You can designate a class variable by using the keyword *static* in its definition. Also, *static* variables that are constants are usually declared to be *public* because they typically are provided to make it easier to use the class. For example, the *PI* and *E static* constants in the *Math* class are provided so that our applications do not need to define those commonly used values. The *Color* class provides *public static* color constants, such as *RED,* for convenience when using common colors. Also, the maximum and minimum values for data types are made available as the *MAX_VALUE* and *MIN_VALUE public static* constants of the *Integer, Double*, and *Character* wrapper classes.

If, however, you define a *static* variable for your class that is not a constant, it is best to define it as *private* and provide accessor and mutator methods, as appropriate, for client access to the *static* variable.

We finish our *Auto* class, with Version 7, partially shown in **Example 7.14**, by defining a *private static* variable to count the number of objects that have been instantiated during the application. We call this class variable *countAutos* and initialize it to 0 (line 14). Because a constructor is called whenever an object is instantiated, we can update the count by incrementing the value of *countAutos* in the class constructors (lines 24 and 37).

Example 7.14 *Auto* Class, Version 7

```
  1 /* Auto class, Version 7
  2    Anderson, Franceschi
  3 */
  4 
  5 import java.text.DecimalFormat;
  6 
  7 public class Auto
  8 {
  9     // instance variables
 10     private String model;          //  model of auto
 11     private int milesDriven;       //  number of miles driven
 12     private double gallonsOfGas;   //  number of gallons of gas
 13 
 14     private static int countAutos = 0;  // static class variable
 15 
 16     // Constructors:
 17     //  initializes model to "unknown";
 18     //  milesDriven is autoinitialized to 0
 19     //        and gallonsOfGas to 0.0;
 20     // increments countAutos
 21     public Auto( )
 22     {
 23        model = "unknown";
 24        countAutos++;    // increment static count of Auto objects
 25     }
 26 
 27     // allows client to set beginning values for
 28     // model, milesDriven, and gallonsOfGas;
 29     // increments countAutos
 30     public Auto( String startModel,
 31                  int startMilesDriven,
 32                  double startGallonsOfGas )
 33     {
 34        model = startModel;
 35        setMilesDriven( startMilesDriven );
 36        setGallonsOfGas( startGallonsOfGas );
 37        countAutos++;    // increment static count of Auto objects
 38     }
        ...
 61     // Accessor method:
 62     // returns countAutos
 63     public static int getCountAutos( )
 64     {
 65       return countAutos;
 66     }
        ...
145 }
```

Description

When you define a *static* variable for your class, its accessor and mutator methods must be defined as ***static* methods**, also called **class methods**. To do this, insert the keyword *static* in the method headers after the access modifier. We provide a *static* accessor method for the client to get the count of *Auto* objects (lines 61–66). We do not provide a mutator method, however, because clients of the class should not be able to update the value of *countAutos.* The constructors update the count automatically.

Methods that are defined to be *static* are subject to the following important restrictions, which are summarized in **Table 7.5**:

Access Restrictions for *static* and Non-*static* Methods

	***static* Method**	**Non-*static* Method**
Access instance variables?	no	yes
Access *static* class variables?	yes	yes
Call *static* class methods?	yes	yes
Call non-*static* instance methods?	no	yes
Use the reference *this*?	no	yes

Description

- *static* methods can reference only *static* variables.
- *static* methods can call only *static* methods.
- *static* methods cannot use the object reference *this*.

Again, it makes sense that *static* methods cannot access instance variables because *static* methods are associated with the class, not with any object. Further, a *static* method can be called before any objects are instantiated, so there will be no instance variables to access. Attempting to access an instance variable *xxx* from a *static* method will generate this compiler error:

```
non-static variable xxx cannot be referenced from a static context
```

Description

Notice that the *getCountAutos* method (lines 61–66) is declared to be *static* and references only the *static countAutos* variable.

A non-*static*, or **instance**, method, on the other hand, can reference both class variables and instance variables, as well as class methods and instance methods.

Example 7.15 shows Version 7 of our *AutoClient* class. At line 11 we call the *getCountAutos* method before instantiating any objects, then in line 17 we call the *getCountAutos* method again after instantiating one object. As **Figure 7.10** shows, the *getCountAutos* method first returns 0, then 1. Notice that in both calls to the *static* method, we use the dot operator with the class name rather than an object reference.

Example 7.15 *Auto* Client, Version 7

```
 1 /* Auto Client, Version 7
 2    Anderson, Franceschi
 3 */
 4
 5 public class AutoClient
 6 {
 7   public static void main( String [ ] args )
 8   {
 9      System.out.println( "Before instantiating an Auto object:"
10                          + "\nthe count of Auto objects is "
11                          + Auto.getCountAutos( ) );
12
13      Auto sporty = new Auto( "Spyder", 0, 0.0 );
14
15      System.out.println( "\nAfter instantiating an Auto object:"
16                          + "\nthe count of Auto objects is "
17                          + Auto.getCountAutos( ) );
18   }
19 }
```

Description

Figure 7.10 Output from Example 7.15

Description

Well, there it is. We’ve finished defining our *Auto* class. Although it’s a large class, we were able to build the *Auto* class incrementally using stepwise refinement.

```
r1 = 5 / 3
r2 = 7
r3 = 0
r4 = -5 / 7
gcd( 1635, 75 ) = 15
gcd( 7 * 11 * 13, 3 * 7 * 11 ) = 77
r5 = 25 / 10
In lowest terms, r5 = 5 / 2
r6 = -2310 / 1771
In lowest terms, r6 = -30 / 23
5 / 3 + 6 / 4 = 19 / 6
5 / 3 * 6 / 4 = 5 / 2
```

7.12 Another Example: The *Rational* Class

A rational number can be represented by two integers: its numerator and its denominator. There are many operations that we can do with rational numbers: addition, subtraction, multiplication, division, reducing to lowest terms, and others. **Example 7.16** shows how we can encapsulate a rational number and these operations in a *Rational* class. It includes two instance variables storing the numerator and the denominator (lines 6 and 7), as well as many methods (the method headers are at lines 88, 101, 112) to perform some of these operations. Operations such as subtraction and division are left as exercises.

Example 7.16 The *Rational* Class

```java
/* Rational class
   Anderson, Franceschi
*/
public class Rational
{
 private int num;
 private int denom;

 /**
  * Default constructor; num is set to 0, denom is set to 1
  */
 public Rational( )
 {
   denom = 1;
 }

 /**
  * Overloaded constructor, denom is set to 1
  * @param num an int, the initial value for num
  */
 public Rational( int num )
 {
   denom = 1;
   setNum( num );
 }

 /**
  * Overloaded constructor
  * @param num an int, the initial value for num
  * @param denom an int, the initial value for denom
  */
 public Rational( int num, int denom )
 {
   this.denom = 1;
   setNum( num );
   setDenom( denom );
 }

 /**
  * Accessor for num
  * @return an int, the value of  num
  */
 public int getNum( )
 {
   return num;
 }

 /**
  * Accessor for denom
  * @return an int, the value of denom
  */
 public int getDenom( )
 {
   return denom;
 }

 /**
  * Mutator for num
  * @param num an int, the new value for num
  */
 public void setNum( int num )
 {
   this.num = num;
 }

 /**
  * Mutator for denom
  * @param denom an int, the new value for denom
  */
 public void setDenom( int denom )
 {
   if( denom != 0 )
   {
     this.denom = denom;
     if ( this.denom < 0 )
     {
       this.denom = -this.denom;
       this.num = -this.num;
     }
   }
 }

 /**
  * add method
  * @param r a Rational
  * @return a Rational, the sum of this Rational and r
  */
 public Rational add( Rational r )
 {
   Rational result = new Rational( );
   result.num = num * r.denom + denom * r.num;
   result.denom = denom * r.denom;
   return result;
 }

 /**
  * multiply method
  * @param r a Rational
  * @return a Rational, the product of this Rational and r
  */
 public Rational multiply( Rational r )
 {
   Rational result = new Rational( );
   result.num = num * r.num;
   result.denom = denom * r.denom;
   return result;
 }

 /**
  * simplify method; reduces this Rational to simplest terms
  */
 public void simplify( )
 {
   int g = Algebra.gcd( num, denom );
   num = num / g;
   denom = denom / g;
  }

 /**
  * toString method
  * @return a String, the fraction for this Rational
  */
 public String toString( )
 {
   String result = "" + num;
   if( num != 0 && denom != 1 )
     result += " / " + denom;
   return result;
 }

 /**
  * equals method
  * @param o an Object
  * @return a boolean, true if this Rational is equal to o,
  *                    false otherwise
  */
 public boolean equals( Object o )
 {
   if ( o instanceof Rational objRational )
     return num * objRational.denom == objRational.num * denom;
   else
     return false;
 }
}
```

Description

At lines 9–37, we provide three constructors. The *setDenom* method (lines 66–81) does more than set the denominator to a new value and enforce the constraint that the denominator must not be *0*. It also ensures that the denominator is always positive. This is a desirable feature, to mirror how a rational number is visualized and written in math. If the new denominator is negative (line 75), it changes the values of the numerator and denominator to their opposite values (lines 77–78). In this way, the denominator is always positive.

The *add* method is coded at lines 83–94. The *add* method only takes one parameter, a *Rational* object that we add to *this Rational* object (the object calling the *add* method in the *main*). Adding two rational numbers results in a rational number; thus, the *add* method returns a *Rational*. Inside the body of the method, we can start our code by declaring and instantiating a *Rational* object (line 90) and end our code with returning that *Rational* object (line 93). In between (lines 91–92), we define it. If the two rational numbers are `a / b` and `c / d`, adding them together results in `( a * d + b * c ) / ( b * d )` as explained below:

```
a / b + c / d = ( a * d ) / ( b * d ) + ( b * c ) / ( b * d ) =
( a * d + b * c ) / ( b * d )
```

Description

Thus, if *a / b* represents this *Rational* object and *c / d* represents the parameter *Rational* object, the equation translates into the code at lines 91–92.

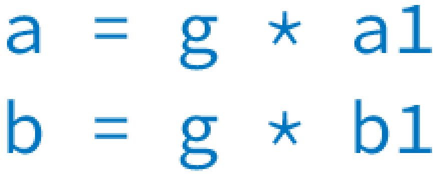
The *multiply* method is coded at lines 96–107, and implements the following equation:

```
( a / b ) * ( c / d ) = ( a * c ) / ( b * d )
```

Description

Its implementation is very similar to the *add* method: we first declare and instantiate a *Rational* object, then modify it, and finally return it.

In order to reduce a rational number to its lowest terms, we first need to calculate the greatest common divisor (gcd) between the numerator and the denominator. If the rational number is *a* / *b* and the gcd of *a* and *b* is *g*, then we have:



```
a = g * a1
b = g * b1
```

Description

where *a1* and *b1* are prime together.

Thus `a / b = ( g * a1 ) / ( g * b1 ) = a1 / b1` and is now in lowest terms.

The *simplify* method implements the above and is coded at lines 109–117. At line 114, we call the *static gcd* method of the *Algebra* class to calculate the gcd between *num* and *denom*. At lines 115 and 116, we update *num* and *denom* by dividing them by their gcd.

Calculating the gcd between two integers is independent of any *Rational* object; thus, we place that method in a new class, *Algebra* (**Example 7.17**), and declare the *gcd* method (lines 6–31) *static*. It accepts two *int* parameters and returns their gcd.

Example 7.17 The *Algebra* Class

```
 1 /* Algebra class
 2    Anderson, Franceschi
 3 */
 4 public class Algebra
 5 {
 6
 7   /**
 8    * gcd static method: computes and returns the gcd of a and b
 9    * @param a an int
10    * @param b an int
11    * @return an int, the gcd of a and b
12    */
13   public static int gcd( int a, int b )
14   {
15     // convert a and b to positive integers
16     a = Math.max( a, -a );
17     b = Math.max( b, -b );
18
19     if( b == 0 )
20       return a;
21     else
22     {
23       int r = a % b;
24       while( r != 0 )
25       {
26         a = b;
27         b = r;
28         r = a % b;
29       }
30       return b;
31     }
32   }
33 }
```

Description

At lines 15–17, we convert *a* and *b* to positive numbers, in case one of them is negative. Then, we implement the Euclid algorithm. If we divide *a* by *b*, we have: `a = b * q + r` where *q* is the quotient of the division and *r* is the remainder (`0 < = r < b`).

Euclid’s algorithm is based on the fact that the gcd of *a* and *b* is equal to the gcd of *b* and *r*. The proof is as follows:

Let’s call *g1* the gcd of *a* and *b*, and *g2* the gcd of *b* and *r*.

G1 divides *a* and *g1* divides *b*; thus, *g1* divides `a − b * q`, which is equal to *r*. Since *g1* divides *b* and *r*, *g1* is a common divisor of *b* and *r*. Thus, `g1 < = g2`, since *g2* is the greatest common divisor of *b* and *r*.

G2 divides *b* and *g2* divides *r*; thus, *g2* divides `b * q + r`, which is equal to *a*. Since *g2* divides *a* and *b*, *g2* is a common divisor of *a* and *b*. Thus, `g2 < =g1`, since *g1* is the greatest common divisor of *a* and *b*.

That means that *g1* and *g2* are equal.

In Euclid's algorithm, we keep performing the division of *a* by *b,* and we replace *a* by *b* and *b* by *r* as long as the remainder is not *0* (lines 23–28). When the remainder of the division is *0* (line 24), we have found the gcd and we exit the loop.

Here is a run of the algorithm computing the gcd of *1635* and *75*:

```
1635 = 75 * 21 + 60 (a = 1635, b = 75, q = 21, r = 60)
75 = 60 * 1 + 15 (a = 75, b = 60, q = 1, r = 15)
60 = 15 * 4 + 0 (a = 60, b = 15, q = 4, r = 0)
```

Description

Since the last value of *r* is *0*, the gcd is the last value of *b*, *15*.

Going back to Example 7.16 and the *toString* method (lines 119–129), we want to return a *String* representation of the *Rational* object that is similar to how we would write that rational number in math. For example, if the numerator is *5* and the denominator is *7*, we want to return *5 / 7*. But if the denominator is *1*, we just want to return the value of the numerator. And if the numerator is *0*, we just want to return *0*. At line 125, we initialize the *String result* with the value of *num*. If the denominator is not *1* and the numerator is not *0* (line 126), we append to *result* the */* character and *denom*.

There are many choices to be made when implementing the *Rational* class. For example, in our implementation, we never call the *simplify* method inside the *add*, *multiply*, mutators, or anywhere inside the class. We leave it to the client of the class to call *simplify* whenever appropriate. For example, a client might want to output something like:

```
10 / 5 in lowest terms is equal to 2
```

Description

With our implementation, we leave the flexibility of doing this to the client. In our *add* and *multiply* method, we also chose not to modify this *Rational*, but instead to return a new *Rational*.

Thus, a client can easily write code such as:

```
Rational r3 = r1.add( r2 ); // r1 and r2 are two existing Rationals
```

Description

And then easily output something like:

```
3 / 5 + 2 / 3 = 19 / 15
```

Description

Example 7.18 shows a client class calling the various methods of the *Rational* class. Its output is shown in **Figure 7.11**.

Example 7.18 The *RationalClient* Class

```
/* RationalClient class
   Anderson, Franceschi
*/
public class RationalClient
```

```java
/* RationalClient class
   Anderson, Franceschi
*/
public class RationalClient
{
  public static void main( String [] args )
  {
    Rational r1 = new Rational( 5, 3 );
    System.out.println( "r1 = " + r1 );
    Rational r2 = new Rational( 7 );
    System.out.println( "r2 = " + r2 );
    Rational r3 = new Rational( );
    System.out.println( "r3 = " + r3 );
    Rational r4 = new Rational( 5, -7 );
    System.out.println( "r4 = " + r4 );

    int g = Algebra.gcd( 45, 75 );
    System.out.println( "The gcd of 45 and 75 is " + g );
    g = Algebra.gcd( 3 * 7 * 11 * 10, 7 * 11 * 23 );
    System.out.println( "gcd( 7 * 11 * 13, 3 * 7 * 11 ) = " + g );

    Rational r5 = new Rational( 25, 10 );
    System.out.println( "r5 = " + r5 );
    r5.simplify( );
    System.out.println( "In lowest terms, r5 = " + r5 );

    Rational r6 = new Rational( 3 * 7 * 11 * 10, -7 * 11 * 23 );
    System.out.println( "r6 = " + r6 );
    r6.simplify( );
    System.out.println( "In lowest terms, r6 = " + r6 );

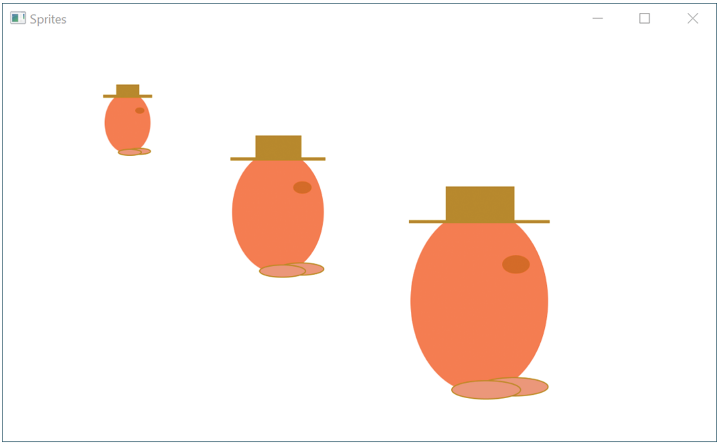
    Rational r7 = new Rational( 5, 3 );
    Rational r8 = new Rational( 6, 4 );
    Rational r9 = r7.add( r8 );
    r9.simplify( );
    System.out.println( r7 + " + " + r8 + " = " + r9 );

    Rational r10 = r7.multiply( r8 );
    r10.simplify( );
    System.out.println( r7 + " * " + r8 + " = " + r10 );
  }
}
```

Description

Figure 7.11 Output of *RationalClient*

Description



7.13 Graphical Objects

Now that we know how to design our own classes, we can separate a graphical object from an application. For example, we can define a sprite in its own *Sprite* class and write a client application that will instantiate and draw *Sprite* objects. This will allow us to encapsulate the sprite's data and the code for drawing the sprite within the *Sprite* class. It also promotes reuse of the *Sprite* class by other programmers who might want to create *Sprite* objects for different applications.

The *Sprite* class is shown in **Example 7.19**. We start by defining the instance variables. We need the starting (*x*, *y*) coordinate to draw the sprite, so we define two *int* instance variables to hold those values (lines 9–10). The *sX* variable is the leftmost point of the drawing (the upper-left corner of the rectangle enclosing the body), and *sY* represents the topmost point (the top of the sprite's hat).

Example 7.19 The *Sprite* Class

```java
/* Sprite class
   Anderson, Franceschi
*/
import javafx.scene.canvas.*;
import javafx.scene.paint.*;

public class Sprite
{
   private int sX;
   private int sY;
   private double scale;

   /** default constructor
   *  sX = sY = 0; scale is set to 1
   */
   public Sprite( )
   {
     scale = 1;
   }

   /* overloaded constructor
      accepts values for starting x and y coordinates
      and scale
   */
   public Sprite( int sX, int sY, double scale )
   {
      setCoordinates( sX, sY );
      setScale( scale );
   }

   /* setCoordinates
   * accepts new values for starting x and y;
   * returns a reference to this object
   */
   public Sprite setCoordinates( int sX, int sY )
   {
      this.sX = sX;
      this.sY = sY;
      return this;
   }

   /* mutator for scale
   * returns a reference to this object
   */
   public Sprite setScale( double scale )
   {
      this.scale = ( scale > 0 ? scale : this.scale );
      return this;
   }

   /* draw method
   *  draws Sprite at current sX and sY
   *  multiplying lengths by scale
   *  accepts GraphicsContext for canvas
   */
   public void draw( GraphicsContext gc )
   {
       gc.setFill( Color.CORAL ); // body
       gc.fillOval( sX, sY + 15 * scale, 90 * scale, 120 * scale );
       gc.setFill( Color.DARKGOLDENROD ); // hat
       gc.fillRect( sX + 23 * scale, sY, 45 * scale, 22 * scale );
       gc.setStroke( Color.DARKGOLDENROD ); // hat brim
       gc.setLineWidth( 3 );
       gc.strokeLine( sX, sY + 23 * scale,
                      sX + 90 * scale, sY + 23 * scale );
       gc.setFill( Color.CHOCOLATE ); // eye
       gc.fillOval( sX + 60 * scale, sY + 45 * scale,
                    18 * scale, 12 * scale );
       gc.setFill( Color.DARKSALMON ); // feet
       gc.setLineWidth( 1 );
       gc.fillOval( sX + 45 * scale, sY + 125 * scale,
                    45 * scale, 12 * scale );
       gc.strokeOval( sX + 45 * scale, sY + 125 * scale,
                      45 * scale, 12 * scale );
       gc.fillOval( sX + 27 * scale, sY + 127 * scale,
                    45 * scale, 12 * scale );
       gc.strokeOval( sX + 27 * scale, sY + 127 * scale,
                      45 * scale, 12 * scale );
   }
}
```

Description

In addition, we added one more instance variable, *scale* (line 11), to allow the client to draw sprites of different sizes. For example, a scaling factor of 1.0 will draw the sprite at full size, 0.5 will draw the sprite at half size, and 2.0 will draw a double-sized sprite.

We provide a default constructor (lines 13–19) that autoinitializes *sX* and *sY* to 0 and sets *scale* to 1. Our overloaded constructor (lines 21–29) accepts values for the three instance variables and passes those values to the appropriate mutator methods.

We provide one mutator method to change both *x* and *y* values (lines 31–40), as well as another mutator to change the scaling factor (lines 42–49).

We provide a method, *draw* (lines 51–79), that draws the sprite on a canvas. Because the sprite is drawn using methods of the *GraphicsContext* class, the application client needs to pass its *GraphicsContext* object as an argument to the *draw* method. In the *draw* method, we draw the sprite, multiplying any length measurement by the scaling factor.

We do not provide accessor methods, a *toString* method, or an *equals* method for the *Sprite* class. For a graphical object, these methods are less useful, given that the major purpose of graphical objects is to be drawn.

Now we can create the client application, *SpriteClient.java*, which is shown in **Example 7.20**. An advantage to separating the *Sprite* class from the *SpriteClient* class is that we can now easily draw two or more sprites with different sizes in different locations. The *SpriteClient* class defines three *Sprite* references as instance variables (line 11). We instantiate these *Sprite* objects with different starting coordinates and scales (lines 18–20). We call the *draw* method for each *Sprite* object (lines 22–24), passing to the *draw* method the *GraphicsContext* object reference *gc* that was returned by the *JIGraphicsUtility*'s *setUpGraphics* method (lines 16–17). The application window is shown in **Figure 7.12**.

Example 7.20 The *SpriteClient* Class

```
/* A client for the Sprite class
   Anderson, Franceschi
*/

import javafx.application.Application;
import javafx.scene.canvas.GraphicsContext;
import javafx.stage.Stage;

public class SpriteClient extends Application
{
    private Sprite s1, s2, s3;

    @Override
    public void start( Stage stage )
    {
        GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
                  stage, "Sprites", 700, 400 );
        s1 = new Sprite( 100, 50, .5 );
        s2 = new Sprite( 225, 100, 1 );
        s3 = new Sprite( ).setCoordinates( 400, 150 ).setScale( 1.5 );

        s1.draw( gc );
        s2.draw( gc );
        s3.draw( gc );
    }

    public static void main( String [ ] args )
    {
        launch( args );
    }
}
```

Description

Figure 7.12 The *SpriteClient* Window

Description

```
Comparing objects using equals
WED does not equal FRI

Comparing objects using compareTo
WED is less than FRI

Getting the ordinal value
The value of WED is 3

Converting a String to an object
The value of day is MON
```

```
Enter a day
(Sun, Mon, Tue, Wed, Thur, Fri, Sat) > Fri
The special for FRI is fish fillet
```

7.14 Enumeration Types

Enumeration types are designed to increase the readability of programs. The enumeration type *enum* is a special kind of class declaration. It allows us to define a set of named constant objects that can be used instead of numbers in a program.

Enum types are useful for managing ordered sets where each member of the set has a name. Examples are the days of the week, months of the year, and playing cards. To represent these sets in a program, we often use numbers, such as 1 through 7 for days of the week or 1 through 12 for months of the year. The problem is that to input or output these values, we need to convert between our internal numeric representation (for example, 1–7) and the words that users recognize (Sunday, Monday, Tuesday, etc.). The *enum* type allows us to instantiate a constant object for each value in a set. The set of objects will be ordered so that we can refer to the objects by name, without the need for using numbers.

The *enum* functionality is built into *java.lang*, so we can define *enum* types without using an *import* statement.

The syntax for creating a set of *enum* objects is

```
enum EnumName { obj1, obj2, . . . };
where obj1, obj2, etc. are names for the constant objects.
```

Description

For example, the following statement defines an *enum* type to represent the days of the week:

```
enum Days { SUN, MON, TUE, WED, THUR, FRI, SAT };
```

Description

When that statement is executed, an object is instantiated for each name in the list. Each name in the list, therefore, is a reference to an object of the *enum* type *Days*.

Note that the values in the initialization list are object references (*SUN*), not *String* literals ("*SUN*").

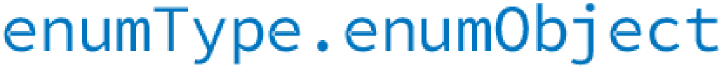
COMMON ERROR TRAP

Do not use *String* literals in the initialization list for *enum* types.

Each object has an instance variable that holds a numeric value, which is determined by its position in the list of *enum* objects. By default, the first object has the value 0, the second object has the value 1, and so on. Because the objects are an ordered set, for example, the object *THUR* is higher in value than *WED*. We can use the *enum* objects, however, without relying on the specific value of each object.

The *enum* objects are instantiated as constant objects, meaning that their values cannot be changed.

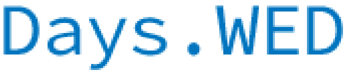
To refer to any of the constant objects in an *enum* type, we use the following dot syntax:



```
enumType.enumObject
```

Description

Thus, to refer to the *WED* object in our *Days enum* type, we use this syntax:



```
Days.WED
```

Description

Once we have defined an *enum* type, we can declare an object reference of that type. For example, the following statement defines a *Days* object reference *d*:

```
Days d;
```

Like any other object reference, the value of *d* will be *null* initially. To assign a value to the reference *d*—for example, *THUR*—we use the following statement:

```
d = Days.THUR;
```

Table 7.6 lists some useful methods that can be called with *enum* objects, and **Example 7.21** demonstrates the use of these methods.

Useful Methods for *enum* Objects

Useful Methods for *enum* Objects

Return type	**Method name and argument list**
`int`	`compareTo( Enum eObj )` compares two *enum* objects and returns a negative number if *this* object is less than the argument, a positive number if *this* object is greater than the argument, and 0 if the two objects are the same
`boolean`	`equals( Object eObj )` returns *true* if this object is equal to the argument *eObj*; returns *false* otherwise
`int`	`ordinal( )` returns the numeric value of the *enum* object; by default, the value of the first object in the list is 0, the value of the second object is 1, and

	so on
`String`	`toString( )` returns the name of the *enum* constant
`enum`	`valueOf( String enumName )` *static* method that returns the *enum* object whose name is the same as the *String* argument *enumName*

Description

Example 7.21 A Demonstration of *enum* Methods

```
 1 /* Demonstration of enum
 2    Anderson, Franceschi
 3 */
 4
 5 public class EnumDemo
 6 {
 7   public enum Days { SUN, MON, TUE, WED, THUR, FRI, SAT };
 8
 9   public static void main( String [ ] args )
10   {
11      Days d1, d2;  // declare two Days object references
12
13      d1 = Days.WED;
14      d2 = Days.FRI;
15
16      System.out.println( "Comparing objects using equals" );
17      if ( d1.equals( d2 ) )
18        System.out.println( d1 + " equals " + d2 );
19      else
20        System.out.println( d1 + " does not equal " + d2 );
21
22      System.out.println( "\nComparing objects using compareTo" );
23      if ( d1.compareTo( d2 ) > 0 )
24        System.out.println( d1 + " is greater than " + d2 );
25      else if ( d1.compareTo( d2 ) < 0 )
26        System.out.println( d1 + " is less than " + d2 );
27      else
28        System.out.println( d1 + " is equal to " + d2 );
29
30      System.out.println( "\nGetting the  ordinal value" );
31      System.out.println( "The value of " + d1 + " is "
32                       + d1.ordinal( ) );
33
34      System.out.println( "\nConverting a String to an object" );
35      Days day = Days.valueOf( "MON" );
36      System.out.println( "The value of day is " + day );
37   }
38 }
```

Description

Line 7 defines the *enum* type *Days*; this instantiates the seven constant objects representing the days of the week. On line 11, we declare two object references of the *Days enum* type. Then on lines 13 and 14, we assign *d1* a reference to the *WED* object, and we assign *d2* a reference to the *FRI* object.

Line 17 compares *d1* and *d2* using the *equals* method. Because *WED* and *FRI* are different objects, the *equals* method returns *false*. Lines 18 and 20 implicitly call the *toString* method, which prints the name of the objects.

Lines 23 and 25 call the *compareTo* method, which returns a negative number, indicating that *WED* is lower in value than

FRI.

We then retrieve the value of the *d1* object by calling the *ordinal* method (lines 31–32), which returns 3 because *WED* is the fourth object in the *enum* list.

Finally, line 35 converts from a *String* to an *enum* object using the *valueOf* method. Notice that the *valueOf* method is *static*, so we call it using our *enum* type, *Days*.

If the *String* passed to the *valueOf* method is not a name in our set of defined *enum* objects, the *valueOf* method generates an *IllegalArgumentException*.

The output from Example 7.21 is shown in **Figure 7.13**.

Figure 7.13 Output from Example 7.21

Description

We can use *enum* objects in *switch* statements to make the *case* constants more meaningful, which in turn makes the code more readable. **Example 7.22** uses our *Days enum* class to display the daily specials offered in the cafeteria.

Example 7.22 *DailySpecials* Class

```
 1 /** Specials of the Day
 2     Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6
 7 public class DailySpecials
 8 {
 9   public enum Days { SUN, MON, TUE, WED, THUR, FRI, SAT };
10
11   public static void main( String [ ] args )
12   {
13     Scanner scan = new Scanner( System.in );
14
15     System.out.print( "Enter a day\n"
16                     + "(Sun, Mon, Tue, Wed, Thur, Fri, Sat) > " );
17     String inputDay = scan.next( ).toUpperCase( );
18     Days day = Days.valueOf( inputDay );
19
20     switch ( day )
21     {
22       case MON,WED -> System.out.println( "The special for "
23                                  + day + " is barbeque chicken" );
24       case TUE,THUR -> System.out.println( "The special for "
25                                  + day + " is tacos" );
26       case FRI -> System.out.println( "The special for "
27                                  + day + " is fish fillet" );
28       case SUN,SAT -> System.out.println( "Sorry, we're closed on "
29                                  + day );
30     }
31   }
32 }
```

Description

Figure 7.14 shows the output from Example 7.22 when the user enters *Fri*.

Figure 7.14 Output from *DailySpecials*

Description

In the *DailySpecials* program, we prompt the user for a day (lines 15–17), then read the *String* entered by the user and attempt to convert it to an *enum* object by calling the *valueOf* method at line 18.

Once we have a valid *enum* value, we can use it as a *switch* variable (line 20).

Notice that we use each *enum* object name in a *case* label without qualifying it with the *Days* type. Including the *enum* type in a *switch* statement generates the following compiler error:

```
an enum switch case label must be the unqualified name of an enumeration constant
```

Description

Notice also that if the user enters a *String* that does not match one of the seven valid day values, the call to the *valueOf* method at line 18 will cause an *IllegalArgumentException* to occur at run time. And finally, notice that we do not need a *default* case in our *switch* statement because all our cases are exhaustive.

countAirports
0
airport1
null
airport2
null

Two airport object references declared:

Airport airport1, airport2;

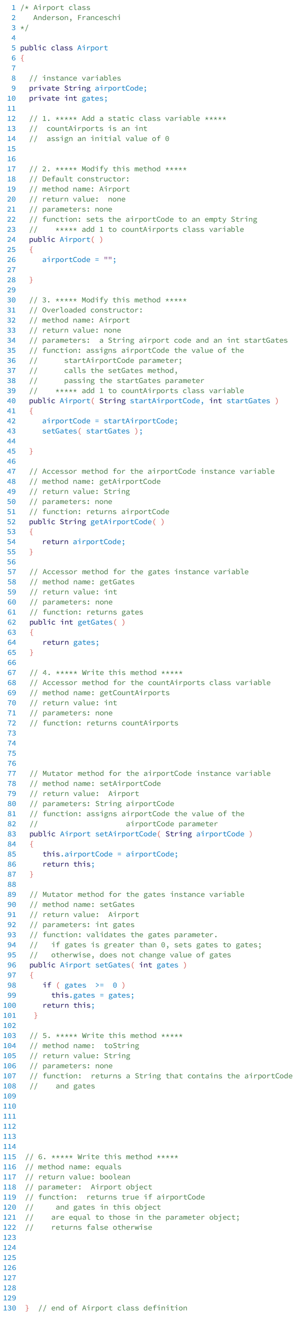
7.15 Programming Activity 2: Writing a Class Definition, Part 2

In this programming activity, you will complete the definition of the *Airport* class. Then you will run a prewritten client program that instantiates several *Airport* objects, calls the methods that you have written, and displays the values of the objects' data.

Copy into a folder on your computer all the files from this chapter's Programming Activity 2 folder in the supplied code files. Note that all files should be in the same folder.

Load the *Airport.java* source file; you'll notice that the class already contains the class definition from Programming Activity 1. Your job is to complete the class definition by adding a *static* class variable (and its supporting code) and writing the *toString* and *equals* methods. It is important to define the *static* class variable and the methods exactly as described in the comments, because the *AirportDrawing* class will call each method to test its implementation. Searching for five asterisks in a row (*****) will position you at the six places in the class definition where you will add your code. The *Airport.java* code is shown here in **Example 7.23**.

Example 7.23 The *Airport.java* File



```
/* Airport class
   Anderson, Franceschi
*/

public class Airport
{

  // instance variables
  private String airportCode;
  private int gates;

  // 1. ***** Add a static class variable *****
  //  countAirports is an int
  //  assign an initial value of 0

  // 2. ***** Modify this method *****
  // Default constructor:
  // method name: Airport
  // return value:  none
  // parameters: none
  // function: sets the airportCode to an empty String
  //    ***** add 1 to countAirports class variable
  public Airport( )
  {
     airportCode = "";

  }

  // 3. ***** Modify this method *****
  // Overloaded constructor:
  // method name: Airport
  // return value: none
  // parameters:  a String airport code and an int startGates
  // function: assigns airportCode the value of the
  //      startAirportCode parameter;
  //      calls the setGates method,
  //      passing the startGates parameter
  //    ***** add 1 to countAirports class variable
  public Airport( String startAirportCode, int startGates )
  {
     airportCode = startAirportCode;
     setGates( startGates );

  }

  // Accessor method for the airportCode instance variable
  // method name: getAirportCode
  // return value: String
  // parameters: none
  // function: returns airportCode
  public String getAirportCode( )
  {
     return airportCode;
  }

  // Accessor method for the gates instance variable
  // method name: getGates
  // return value: int
  // parameters: none
  // function: returns gates
  public int getGates( )
  {
     return gates;
  }

  // 4. ***** Write this method *****
  // Accessor method for the countAirports class variable
  // method name: getCountAirports
  // return value: int
  // parameters: none
  // function: returns countAirports

  // Mutator method for the airportCode instance variable
  // method name: setAirportCode
  // return value:  Airport
  // parameters: String airportCode
  // function: assigns airportCode the value of the
  //                    airportCode parameter
  public Airport setAirportCode( String airportCode )
  {
     this.airportCode = airportCode;
     return this;
  }

  // Mutator method for the gates instance variable
  // method name: setGates
  // return value:  Airport
  // parameters: int gates
  // function: validates the gates parameter.
  //   if gates is greater than 0, sets gates to gates;
  //   otherwise, does not change value of gates
  public Airport setGates( int gates )
  {
     if ( gates  >=  0 )
       this.gates = gates;
     return this;
   }

  // 5. ***** Write this method *****
  // method name:  toString
  // return value: String
  // parameters: none
  // function:  returns a String that contains the airportCode
  //    and gates

 // 6. ***** Write this method *****
 // method name: equals
 // return value: boolean
 // parameter:  Airport object
 // function:  returns true if airportCode
 //     and gates in this object
 //    are equal to those in the parameter object;
 //    returns false otherwise

 }  // end of Airport class definition
```

Description

When you finish modifying the *Airport* class, compile the source file. When *Airport.java* compiles without any errors, load and compile the *AirportPractice2Application.java* file. This source file contains *main*, so you will execute the application from this file. When the application begins, you should see the window shown in **Figure 7.15**.

Figure 7.15 *AirportPractice2Application* Opening Window

Description

As you can see, the client class has declared two *Airport* object references, *airport1* and *airport2*. The references are *null* because no *Airport* objects have been instantiated. Note also that the value of the *countAirports* class variable is displayed.

The client class will call methods of the *Airport* class to instantiate the two *Airport* objects, call the *toString* and *equals* methods, and get the value of the *static* class variable, *countAirports*. As the application does its work, it displays a status message at the bottom of the window indicating which method has been called, and it also displays the current state of the *Airport* objects. You can check your work by comparing the state of the objects with the status message.

DISCUSSION QUESTIONS

1. Explain why the *countAirports* class variable has a value of 0 before any *Airport* objects have been instantiated.
2. How does a client call the *getCountAirports* method?
3. Explain why when directly comparing the object references *airport1* and *airport2* using the following *if* statement:

   
   ```
   if ( airport1 == airport2 )
   ```

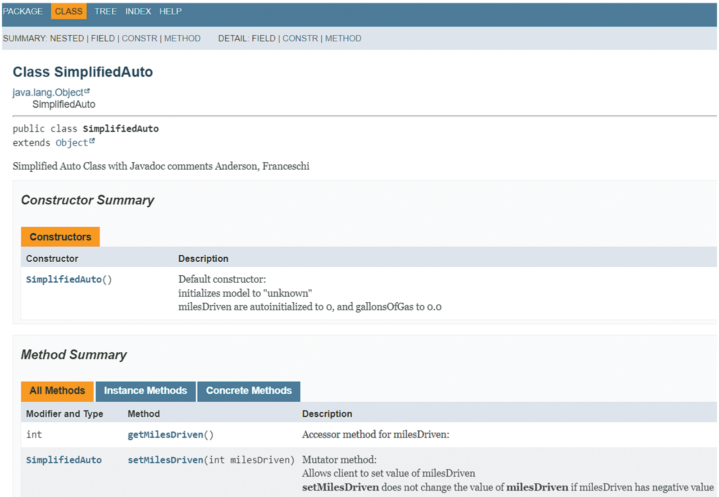
   Description

   the condition evaluates to *false*?

7.16 Creating Packages

As we have mentioned, one of the advantages of a well-written class is that it can be reused. Ideally, as you write programs, you will look for functionality that is common to many programs. It is a good practice to encapsulate this functionality into a class so that you can reuse that code in future programs. Java provides the concept of a package for easily reusing classes.

A **package** is a collection of related classes that can be imported into programs. We have imported classes from multiple Java packages: *java.util*, *java.text*, and others. We can also create our own packages, which allows us to reuse a class without needing to physically store that class in the same folder as our other source files. Instead, we create the package and *import* the class from that package into our source file. For instructions on how to create a package, please see our additional resources online.



PACKAGE

Class SimplifiedAuto

java.lang.Object
SimplifiedAuto

```
public class SimplifiedAuto
extends Object
```

Simplified Auto Class with Javadoc comments Anderson, Franceschi

Constructor Summary

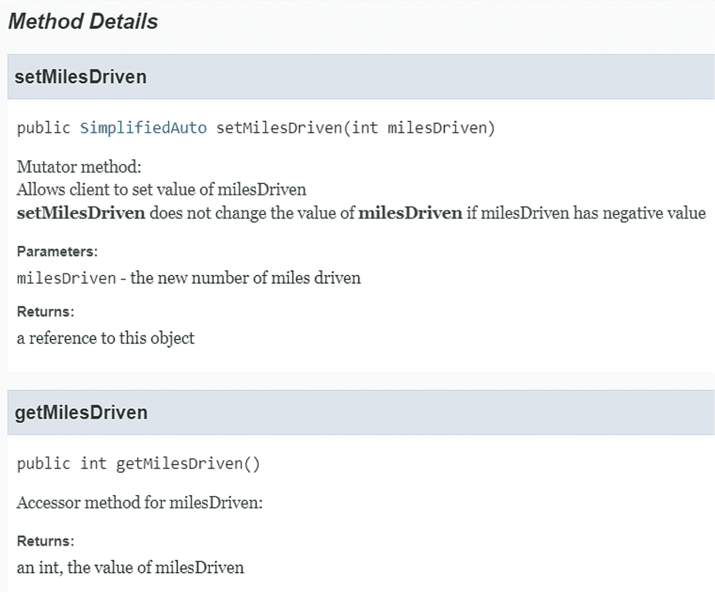
Constructors

Constructor	Description
`SimplifiedAuto()`	Default constructor: initializes model to "unknown" milesDriven are autoinitialized to 0, and gallonsOfGas to 0.0

Method Summary

All Methods
Instance Methods
Concrete Methods

Modifier and Type	Method	Description
`int`	`getMilesDriven()`	Accessor method for milesDriven:
`SimplifiedAuto`	`setMilesDriven(int milesDriven)`	Mutator method: Allows client to set value of milesDriven **setMilesDriven** does not change the value of **milesDriven** if milesDriven has negative value



Method Details

setMilesDriven

```
public SimplifiedAuto setMilesDriven(int milesDriven)
```

Mutator method:
Allows client to set value of milesDriven
setMilesDriven does not change the value of **milesDriven** if milesDriven has negative value

Parameters:

`milesDriven` - the new number of miles driven

Returns:

a reference to this object

getMilesDriven

```
public int getMilesDriven()
```

Accessor method for milesDriven:

Returns:

an int, the value of milesDriven

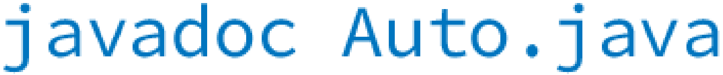
7.17 Generating Web-Style Documentation with Javadoc

In most corporations and organizations, programmers share code and frequently use classes developed by another programmer. If the class is well designed and well documented, it will be easy for others to use that class. After all, that is essentially what we have been doing by using existing Java classes. It has been easy to understand what functions these existing classes perform, what they encapsulate, how the constructors work, what the methods do, and how to use the classes. The reason that these classes are easy to understand and use is not only that they are well designed and written, but also that the available documentation, particularly on Oracle's Java website, is clear, easy to understand, complete, and represents these classes well.

We, too, will learn how to produce HTML-based documentation similar to the documentation available on Oracle's Java website.

There is a tool called **Javadoc**, provided in the Java Development Kit (JDK), to do just that. Javadoc is an executable program (actually *javadoc.exe*) located in the *bin* folder. It is invoked much the same way as the *javac* compiler, except that instead of creating *.class* files, it creates *.html* files that document the class.

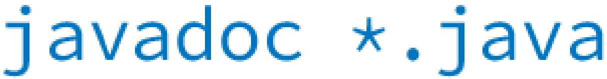
For instance, to generate documentation for our *Auto* class, we would type the following at the command line:



```
javadoc Auto.java
```

Description

If we want to generate documentation for all the source files in the directory, we would type:



```
javadoc *.java
```

Description

Your IDE may provide easy access to Javadoc through its menus.

Table 7.7 shows some of the files generated for the *Auto* class.

Selected HTML Files Generated by Javadoc

File Name	**Short Description**
Auto.html	*Auto* class documentation
allclasses-index.html	List of the classes with links
index.html	*Auto* class documentation (with frames)
package-summary.html	Class hierarchy
script	Javascript file
stylesheet.css	Style sheet

Description

If you double-click on *index.html*, you will open a webpage with the same look as the ones on Oracle's Java website.

REFERENCE POINT

The full documentation for using Javadoc can be found at *www.oracle.com/technetwork/java*.

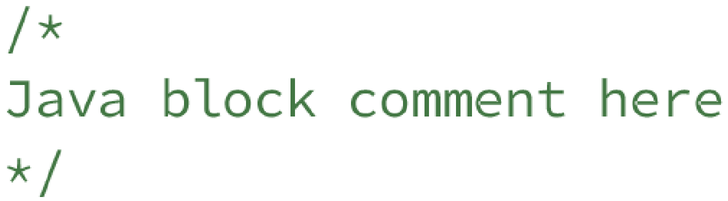
We will review a few basic Javadoc features here. Full documentation on Javadoc is available on Oracle's website.

To write comments that will be included in the Javadoc documentation, we use a special form of block comment ahead of any class, field, constructor, or method. The syntax for including Javadoc comments follows.

```
/**
Javadoc comment here
*/
```

Description

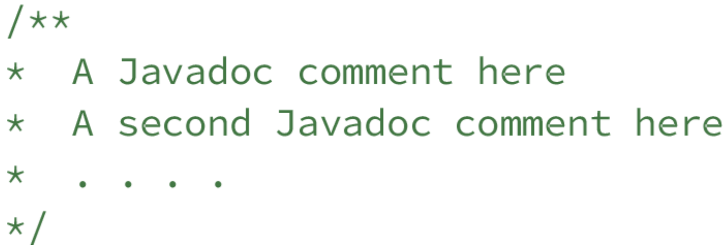
As we already know, the syntax for a Java block comment is



```
/*
Java block comment here
*/
```

Description

A Javadoc comment is just a special Java block comment. The *javac* compiler will simply ignore it, but the Javadoc executable will look for it and generate the appropriate documentation. Javadoc discards all white space characters and the * at the beginning of each line until a character other than white space or * is encountered. The industry convention is to start every line of a Javadoc comment with an *. Therefore, we recommend the following syntax:



```
/**
*  A Javadoc comment here
*  A second Javadoc comment here
*  . . . .
*/
```

Description

Class documentation comprises two parts:

- A description section
- A tag section

SOFTWARE ENGINEERING TIP

When coding a documentation block, use an * at the beginning of each line to indicate that this is a documentation comment.

Javadoc recognizes two types of tags: block tags and inline tags. We will discuss block tags only.

Block tags start with the character @. **Table 7.8** lists two block tags, *@param* and *@return*, along with an explanation of each.

Selected Javadoc Tags

Tag	Most Common Syntax	Explanation
`@param`	`@param variableName description`	Adds a parameter to the parameter section
`@return`	`@return text`	Adds a description for the return type

Description

In the description section and inside the tag section, the text should be written in HTML; therefore, HTML tags such as <br> (break) or (bold) can be used. The tag <br> inserts a new line; the tag will change the text style to bold until the end tag is encountered. Starting with Java 9, Javadoc supports HTML5.

Example 7.24 shows a simplified version of our *Auto* class incorporating some documentation comments.

Example 7.24 The *SimplifiedAuto* Class

```
/**  Simplified Auto Class with Javadoc comments
     Anderson, Franceschi
*/

public class SimplifiedAuto
{
 private String model;
 private int milesDriven;
 private double gallonsOfGas;

 /**
 * Default constructor:<br>
 * initializes model to "unknown"<br>
 * milesDriven are autoinitialized to 0, and gallonsOfGas to 0.0
 */
 public SimplifiedAuto( )
 {
    model = "unknown";
 }

 /**
 * Mutator method:<br>
 * Allows client to set value of milesDriven<br>
 * <strong>setMilesDriven</strong> does not change the value
 * of <strong>milesDriven</strong> if newMilesDriven has negative value
 * @param milesDriven the new number of miles driven
 * @return a reference to this object
 */
 public SimplifiedAuto setMilesDriven( int milesDriven )
 {
    if ( milesDriven > 0 )
        this.milesDriven = milesDriven;
    return this;
 }

 /**
 * Accessor method for milesDriven:<br>
 * @return an int, the value of milesDriven
 */
 public int getMilesDriven( )
 {
    return milesDriven;
 }
}
```

Description

SOFTWARE ENGINEERING TIP

When you write a class, add a few documentation comments and generate the web-style documentation. Show the webpages to friends or colleagues and ask them if they fully understand what the class encapsulates and what it is about. Ask them a few questions about the constructor and the methods. This is a good way to check if your class is well designed and ready for reuse.

Figure 7.16 shows part of the generated *index.html* file, and

Figure 7.17 shows the generated documentation for the *setMilesDriven* and *getMilesDriven* methods.

Figure 7.16 *SimplifiedAuto* Class Web-Style Documentation

CHAPTER REVIEW

7.18 Chapter Summary

- The members of a Java class include its instance variables, class variables, and methods.
- One copy of each instance variable is created for every object instantiated from the class. One copy of each class variable and method is shared by all objects of the class.
- By convention, class names are nouns and begin with a capital letter; all internal words begin with a capital letter, and other letters are lowercase. Method names are verbs and begin with a lowercase letter; internal words begin with a capital letter, and all other letters are lowercase. Nonconstant instance variables are nouns and follow the same capitalization rules as methods. Constant fields have all capital letters with internal words separated by an underscore.
- The *public* access modifier allows the class or member to be accessed by other classes. The *private* access modifier specifies that the class or member can be accessed only by other members of the same class. Package access allows other classes in the same package or folder to access the class or class members.
- Classes, constructors, *final* class variables, and class methods typically are declared as *public*, and instance variables typically are declared as *private*.

- Instance variables reflect the properties that all objects will have in common. Instance variables are defined by specifying an access modifier, data type, identifier, and, optionally, an initial value. Instance variables can be declared to be *final*.
- A method is defined by providing a method header, which specifies the access modifier, a return type, the method name, and a parameter list. The method body is enclosed in curly braces. Value-returning methods return the result of the method using one or more *return* statements. A method with a *void* return type does not return a value.
- Instance variables and methods have class scope in that they can be accessed anywhere in the class.
- A method can reference the instance variables of its class, the parameters sent to the method, and local variables declared by the method, and it can call other methods of its class.
- A method can be overloaded by defining another method with the same name but a different signature; that is, with a different number of parameters or with parameters of different data types.
- Constructors are responsible for initializing the instance variables of the class.
- If we don't provide a constructor, the compiler provides a default constructor, which is a constructor that takes no arguments. This default constructor assigns default initial values to all the instance variables. Numeric variables are given the value of 0, characters are given the value of the Unicode null character, *boolean* variables are given the value of *false*, and object references are given the value of *null*. Local variables declared in methods are not given initial values automatically.
- Accessor methods are named *getIV*, where *IV* is an instance variable name; the return data type is the same as the instance variable, and the body of the method simply returns the value of the instance variable.
- Mutator methods are named *setIV*, where *IV* is an instance variable name; the return data type is *void* or a reference to

this object, and the method takes one argument, which is the same data type as the instance variable and contains the new value for the instance variable. The body of the method should validate the new value and, if the new value is valid, assign the new value to the instance variable.

- When a method begins executing, the JVM sets the object reference *this* to refer to the object for which the method has been called.
- The *toString* method is called automatically when an object reference is used as a *String*, and its job is to provide a printable representation of the object data.
- The *equals* method compares two objects for equality; that is, it should return *true* only if the corresponding instance variables in both objects are equal in value, and *false* otherwise.
- *Static* class variables are created when the class is initialized. Thus, class variables exist before any objects are instantiated, and each class has only one copy of the class variables. *Static* variables that are constants are usually declared to be *public* because they typically are provided to allow the client to set preferences for the operations of a class.
- *Static* class methods can reference only *static* variables, can call only *static* methods, and cannot use the object reference *this*.
- A non-*static*, or instance, method can reference both class and instance variables, as well as class and instance methods, and the reference *this*.
- A graphical object usually has instance variables for the starting (*x*, *y*) coordinate. It also provides a *draw* method that takes a *GraphicsContext* object as a parameter and includes the code to draw the graphical object.
- Enumeration types can be defined to give meaning to ordered sets that are represented in a program by numbers. For each name in an *enum* type initialization list, a constant object is created with an instance variable having a sequential numeric value. References can be defined of the *enum* type. Objects of the *enum* type can be

compared, printed, and requested to return their numeric value.

- Javadoc, which is part of the JDK, generates documentation for classes. To use Javadoc, you enclose a description of each class, method, and field in a block comment beginning with /** and ending with */. In addition, you can describe each parameter using the *@param* tag and return value using the *@return* tag.

7.19 Exercises, Problems, and Projects

7.19.1 Multiple Choice Exercises

1. What can you say about the name of a class?

    - It must start with an uppercase letter.
    - The convention is to start with an uppercase letter.

4. What can you say about the name of constructors?

    - They must be the same name as the class name.
    - They can be any name, just like other methods.

7. What is a constructor's return type?

    - *void*
    - *Object*
    - The class name
    - A constructor does not have a return type.

12. It is legal to have more than one constructor in a given class.

    - true
    - false

15. In a class, if a field is *private*,

    - it can be accessed directly from any class.
    - it can be accessed directly only from inside its class.

18. In a typical class, what is the general recommendation for access modifiers?

- Instance variables are *private* and methods are *private*.
- Instance variables are *private* and methods are *public*.
- Instance variables are *public* and methods are *private*.
- Instance variables are *public* and methods are *public*.

23. In a class, fields

- can only be basic data types.
- can only be basic data types or existing Java types (from existing classes).
- can be basic data types, existing Java types, or user-defined types (from user-defined classes).

27. Accessors and mutators are

- instance variables of a class.
- used to access and modify field variables of a class from outside the class.
- constructor methods.

31. Accessor methods typically take

- no parameter.
- one parameter, of the same type as the corresponding field.

34. Mutator methods typically take

- no parameter.
- one parameter, of the same type as the corresponding field.

37. Accessor methods typically

- are *void* methods.
- return the same type as the corresponding field.

40. To enable method chaining, mutator methods

    - return a reference to *this* object.
    - return the same type as the corresponding field.

43. When coding a method that performs calculations on fields of that class,

    - these fields must be passed as parameters to the method.
    - these fields do not need to be passed as parameters to the methods because the class methods have direct access to them.

46. What is the keyword used for declaring a constant?

    - *static*
    - *final*
    - *constant*

50. What is the keyword used for declaring a class variable or method?

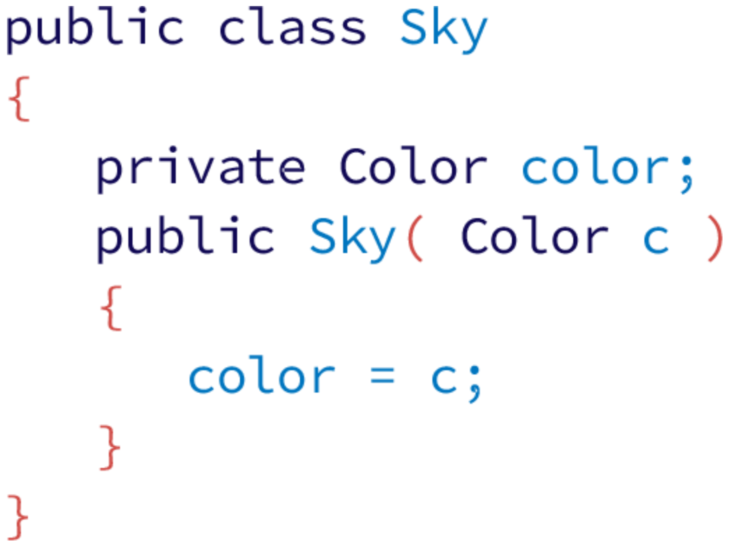
    - *static*
    - *final*
    - *class*

54. What can you say about *enum*?

    - It is part of the package *java.lang*.
    - It can be used for self-documentation, improving the readability of your code.
    - An *enum* object is a constant object.
    - All of the above.

7.19.2 Reading and Understanding Code

For Questions 17 and 18, consider that inside the class *Sky*, we have already coded the following:



```
public class Sky
{
    private Color color;
    public Sky( Color c )
    {
        color = c;
    }
}
```

Description

1. Consider the following method header:

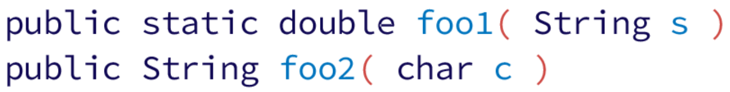
   
   ```
   public Color getColor( )
   ```

   Description
   Is this method a constructor, mutator, or accessor?
2. Consider the following method header:

   
   ```
   public void setColor( Color c )
   ```

   Description
   Is this method a constructor, mutator, or accessor?

For Questions 19 through 24, consider that the class *Airplane* has two methods with the following method headers; we also have a default constructor already coded.



```
public static double foo1( String s )
public String foo2( char c )
```

Description

1. What is the return type of method *foo1*?
2. What is the return type of method *foo2*?
3. Is method *foo1* a class or instance method? Explain.
4. Is method *foo2* a class or instance method? Explain.
5. Write a line or two of code to call method *foo1* from a client class.
6. Write a line or two of code to call method *foo2* from a client class. Assume we have instantiated an object named *a1*.
7. Inside method *main*, we see code like

   
   ```
   Airplane.foo3( 34.6 );
   ```

   Description
   From this, reconstruct the header of method *foo3* (which belongs to the class *Airplane*); make appropriate assumptions if necessary.
8. Inside method *main*, we see code like

   
   ```
   Airplane a = new Airplane( );
   int n = a.foo4( "Hello" );
   ```

   Description
   From this, reconstruct the header of method *foo4* (which belongs to class *Airplane*).
9. If you have defined the following *enum* constants

   
   ```
   enum Seasons { Winter, Spring, Summer, Fall };
   ```

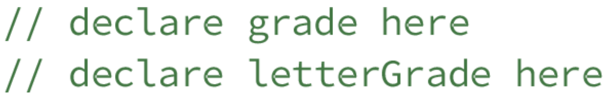
   Description
   what is the output of the following code sequence?

   
   ```
   System.out.println( Seasons.Spring.ordinal( ) );
   ```

Description

7.19.3 Fill In the Code

1. Declare two instance variables: *grade*, which is an integer, and *letterGrade*, which is a *char*.



```
// declare grade here
// declare letterGrade here
```

Description

2. Declare a class field for a federal tax rate, a constant, with value .07.

```
// declare federal tax rate constant; value is 0.07
```

Description

For Questions 30 through 37, we will assume that class *TelevisionChannel* has three fields: *name*, a *String*; *number*, an integer; and *cable*, a *boolean*, which represents whether the channel is a cable channel.

1. Code a default constructor for that class: initialize the fields to an empty string, 0, and *false*, respectively.

```
// your default constructor code goes here
```

Description

2. Code a constructor for that class that takes three parameters.

```
// your constructor code goes here
```

Description

3. Code the three accessors for that class.

```
// your code goes here
```

Description

4. Code the three mutators for that class.

```
// your code goes here
```

Description

5. Code the *toString* method.

```
// your code goes here
```

Description

6. Code the *equals* method.

```
// your code goes here
```

Description

7. Code a method returning the number of digits in the channel number. For instance, if the channel number is 21, the method returns 2; if the channel number is 412, the method returns 3.

```
// your code goes here
```

Description

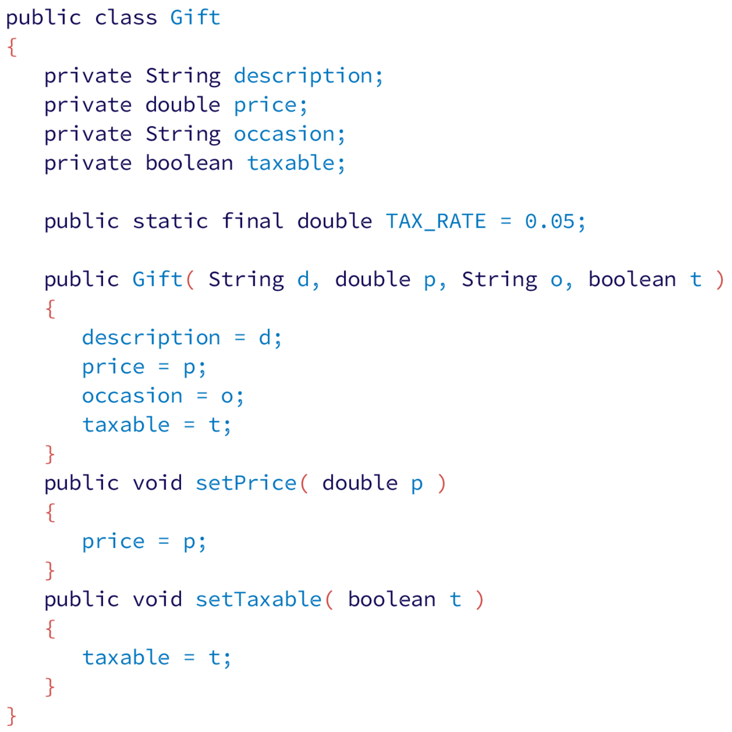
8. Code a method returning the word *cable* if the current object represents a cable channel and returning the word *network* if the current object does not represent a cable channel.

```
// your code goes here
```

Description

7.19.4 Identifying Errors in Code

For Questions 38 through 45, consider that inside the class *Gift*, we have already coded the following:



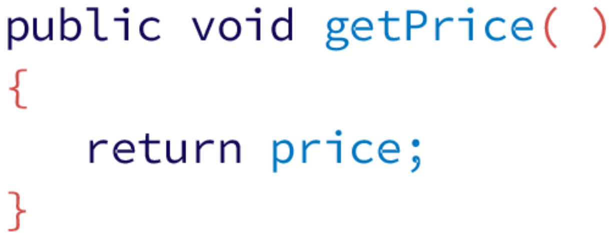
```
public class Gift
{
   private String description;
   private double price;
   private String occasion;
   private boolean taxable;

   public static final double TAX_RATE = 0.05;

   public Gift( String d, double p, String o, boolean t )
   {
      description = d;
      price = p;
      occasion = o;
      taxable = t;
   }
   public void setPrice( double p )
   {
      price = p;
   }
   public void setTaxable( boolean t )
   {
      taxable = t;
   }
}
```

Description

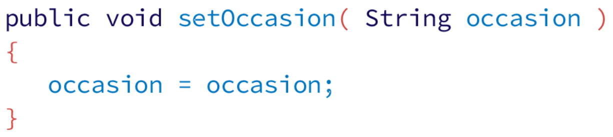
1. We are coding the following inside the class *Gift*; where is the error?



```
public void getPrice( )
{
    return price;
}
```

Description

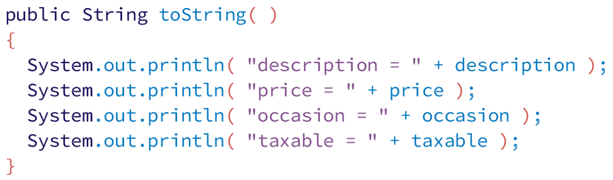
2. We are coding the following inside the class *Gift*; where is the error?



```
public void setOccasion( String occasion )
{
    occasion = occasion;
}
```

Description

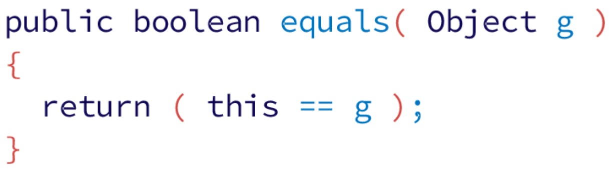
3. We are coding the following inside the class *Gift*; where is the error?



```
public String toString( )
{
  System.out.println( "description = " + description );
  System.out.println( "price = " + price );
  System.out.println( "occasion = " + occasion );
  System.out.println( "taxable = " + taxable );
}
```

Description

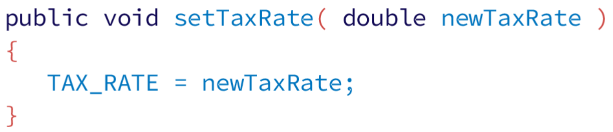
4. We are coding the following inside the class *Gift*; where is the error?



```
public boolean equals( Object g )
{
  return ( this == g );
}
```

Description

5. We are coding the following inside the class *Gift*; where is the error?



```
public void setTaxRate( double newTaxRate )
{
    TAX_RATE = newTaxRate;
}
```

Description

6. We are coding the following inside the class *Gift*; where is

the error?

```
public double calcTax( TAX_RATE )
{
  return ( TAX_RATE * price );
}
```

Description

7. We are coding the following in the *main* method inside the class *GiftClient*; where is the error?

```
Gift g = new Gift( "radio", 59.99, "Birthday", false );
Gift.setPrice( 99.99 );
```

Description

8. We are coding the following in the *main* method inside the class *GiftClient*; where is the error?

```
Gift g = new Gift( "radio", 59.99, "Birthday", false );
g.setTaxable( ) = true;
```

Description

9. Where are the errors in the following statement?

```
enum Months = { "January", "February", "March" };
```

Description

7.19.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

For Questions 47 and 48, consider the following class *Grade*:

```
public class Grade
{
  private char letterGrade;
    public Grade( char lg )
```

Description

```
public class Grade
{
  private char letterGrade;
     public Grade( char lg )
  {
    letterGrade = lg;
  }
  public char getLetterGrade( )
  {
    return  letterGrade;
  }
  public void setLetterGrade( char lg )
  {
    letterGrade = lg;
  }
}
```

1. In the *main* method of the class *GradeClient*, you have coded

   ```
   Grade g = new Grade( 'B' );
   g.letterGrade = 'A';          // line 10
   ```

   Description

   When you compile, you get the following message:

   ```
   GradeClient.java:10: error: letterGrade has private access
   in Grade
   g.letterGrade = 'A';          // line 10
    ^
   1 error
   ```

   Description

   Explain what the problem is and how to fix it.

2. In the *main* method of the class *GradeClient*, you have coded

```
Grade g = new Grade( "A" );   // line 10
```

Description

When you compile, you get the following message:

```
GradeClient.java:10: error: incompatible types: String
cannot be converted to char
Grade g = new Grade ( "A" ); // line 10
                      ^
Note: Some messages have been simplified; recompile with
-Xdiags:verbose to get full output
1 error
```

Description

Explain what the problem is and how to fix it.

3. You coded the following definition for the class *Grade*:

```
public class Grade
{
    private char letterGrade;
    public char Grade( char startLetter )
    {
       letterGrade = startLetter;
    } // line 8
}
```

Description

When you compile, you get the following message:

```
Grade.java:8: error: missing return statement
 } // line 8
 ^
1 error
```

Description

Explain what the problem is and how to fix it.

4. You coded the following definition for the class *Grade*:

```
public class Grade
{
  private char letterGrade;

  public Grade( char lg )
  {
    letterGrade = lg;
  }
  public String toString( )     // line 10
  {                             // line 11
     return letterGrade;        // line 12
  }                             // line 13
}
```

Description

When you compile, you get the following message:

```
Grade.java:12: error: incompatible types: char cannot be
converted to String
return letterGrade; // line 12
       ^
1 error
```

Description

Explain what the problem is and how to fix it.

5. You coded the following definition for the *Grade* class:

```
public class Grade
{
  private char letterGrade;
  public Grade( char lg )
  {
    letterGrade = lg;
  }
  public String toString( )  // line 10
  {                          // line 11
    return lg;               // line 12
  }                          // line 13
}
```

Description

When you compile, you get the following message:

```
Grade.java:12: error: cannot find symbol
 return lg; // line 12
        ^
   symbol  : variable lg
   location: class Grade
1 error
```

Description

Explain what the problem is and how to fix it.

6. You coded the following definition for the *Grade* class:

```
public class Grade
{
  private int numberGrade;
  public Grade( int numberGrade )
  {
    numberGrade = numberGrade;
  }
  public int getGrade( )
  {
    return numberGrade;
  }
}
```

Description

In the *main* method of the *GradeClient* class, you have coded:

```
Grade g1 = new Grade( 95 );
System.out.println( g1.getGrade( ) );
```

Description

The code compiles properly and runs, but the result is not what you expected.

The client’s output is 0, not 95.

Explain what the problem is and how to fix it.

7. You have defined the following *enum* constants:

```
enum Seasons { Winter, Spring, Summer, Fall };
```

Description

In the *main* method of the class *Test*, you have coded:

```
Seasons s = Seasons.Spring;
if ( s.equals( Winter ) )    // line 10
      System.out.println( "It is cold" );
else
      System.out.println( "The weather is fine" );
```

Description

When you compile, you get the following message:

```
Test.java:10: error: cannot find symbol
  if ( s.equals( Winter ) )  // line 10
                  ^
   symbol  : variable Winter
   location: class Test
1 error
```

Description

Explain what the problem is and how to fix it.

8. You have defined the following *enum* constants:

```
enum Seasons { Winter, Spring, Summer, Fall };
```

Description

In the *main* method of the class Test, you have coded

```
Seasons.Fall = Autumn; // line 10
```

Description

When you compile, you get the following message:

```
Test.java:10: error: cannot assign a value to final variable
Fall
  Seasons.Fall = Autumn;  // line 10
         ^
Test.java:10: cannot find symbol
  Seasons.Fall = Autumn;  // line 10
                 ^
   symbol  : variable Autumn
   location: class Test
2 errors
```

Description
Explain what the problem is and how to fix it.

7.19.6 Write a Short Program

1. Write a class encapsulating the concept of a team (for example, “Orioles”), assuming a team has only one attribute: the team name. Include a constructor, the accessor and mutator, and methods *toString* and *equals*. Write a client class to test all the methods in your class.
2. Write a class encapsulating the concept of a television set, assuming a television set has the following attributes: a brand and a price. Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Write a client class to test all the methods in your class.
3. Write a class encapsulating the concept of a course grade, assuming a course grade has the following attributes: a course name and a letter grade. Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Write a client class to test all the methods in your class.
4. Write a class encapsulating the concept of a course, assuming a course has the following attributes: a code (for instance, CS1), a description, and a number of credits (for instance, 3). Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Write a client class to test all the methods in your class.
5. Write a class encapsulating the concept of a student, assuming a student has the following attributes: a name, a Social Security number, and a GPA (for instance, 3.5). Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Write a client class to test all the methods in your class.

6. Write a class encapsulating the concept of website statistics, assuming website statistics have the following attributes: number of visitors and type of site (commercial, government, etc.). Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Write a client class to test all the methods in your class.
7. Write a class encapsulating the concept of a corporate name (for example, “IBM”), assuming a corporate name has only one attribute: the corporate name itself. Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Also include a method returning a potential domain name by adding *www.* at the beginning and *.com* at the end of the corporate name (for instance, if the corporate name is IBM, that method should return *www.ibm.com*). Write a client class to test all the methods in your class.
8. Write a class encapsulating the concept of a file, assuming a file has only a single attribute: the name of the file. Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Also, code a method returning the extension of the file; that is, the letters after the last dot in the file (for instance, if the file name is *Test.java*, then the method should return *java*); if there is no dot in the file name, then the method should return “*unknown extension*.” Write a client class to test all the methods in your class.
9. Writing *System.out.println* every time we want to output a message is annoying. Write a class that enables us to write *S.pln(“Hello world”)* instead. Test your class in a client.
10. Write a class that enables us to write code like:

```
int number = Utility.getInt( "Enter an int", '>' );
```

Description
to replace something like:

```
System.out.println( "Enter an int > " );
Scanner scan = new Scanner( System.in );
int number = scan.nextInt( );
```

Description
Test your class in a client.

7.19.7 Programming Projects

1. Write a class encapsulating the concept of the weather forecast, assuming that it has the following attributes: the temperature and the sky conditions, which could be sunny, snowy, cloudy, or rainy. Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Temperature, in Fahrenheit, should be between –50 and +150; the default value is 70, if needed. The default sky condition is sunny. Include a method that converts Fahrenheit to Celsius. Celsius temperature = (Fahrenheit temperature – 32) * 5 / 9. Also include a method that checks whether the weather attributes are consistent (there are two cases where they are not consistent: when the temperature is above 32 and it is snowy, and when the temperature is below 32 and it is rainy). Write a client class to test all the methods in your class.
2. Write a class encapsulating the concept of a domain name, assuming a domain name has a single attribute: the domain name itself (for instance, *www.yahoo.com*). Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Also include the following methods: one returning whether the domain name starts with *www*; another returning the extension of the domain name (i.e.,

the letters after the last dot, for instance *com*, *gov*, or *edu*; if there is no dot in the domain name, then you should return "*unknown*"); and another returning the name itself (which will be the characters between *www* and the extension; for instance, *yahoo* if the domain is *www.yahoo.com*—if there are fewer than two dots in the domain name, then your method should return "*unknown*"). Write a client class to test all the methods in your class.

3. Write a class encapsulating the concept of an HTML page, assuming an HTML statement has only a single attribute: the HTML code for the page. Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Include the following methods: one checking that there is a > character following each < character, one counting how many images are on the page (i.e., the number of *img* tags), and one counting how many links are on the page (i.e., the number of times we have "*a href*"). Write a client class to test all the methods in your class.
4. Write a class encapsulating the concept of coins, assuming that coins have the following attributes: a number of quarters, a number of dimes, a number of nickels, and a number of pennies. Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Also code the following methods: one returning the total amount of money in dollar notation with two significant digits after the decimal point, and others returning the money in quarters (for instance, 0.75 if there are three quarters), in dimes, in nickels, and in pennies. Write a client class to test all the methods in your class.
5. Write a class encapsulating the concept of a user-defined *double*, assuming a user-defined *double* has only a single

attribute: a *double*. Include a constructor, the accessor and mutator, and methods *toString* and *equals*. Add a method, taking one parameter specifying how many significant digits we want to have, and returning a *double* representing the original *double* truncated so that it includes the specified number of significant digits after the decimal point (for instance, if the original *double* is 6.9872 and the argument of the method is 2, this method will return 6.98). Write a client class to test all the methods in your class.

6. Write a class encapsulating the concept of a circle, assuming a circle has the following attributes: a *Point* representing the center of the circle, and an integer, the radius of the circle. Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Also include methods returning the perimeter (2 * π * radius) and area (π * radius^2) of the circle. Write a client class to test all the methods in your class.
7. Write a class encapsulating the concept of a rational number, assuming a rational number has the following attributes: an integer representing the numerator of the rational number, and another integer representing the denominator of the rational number. Include a constructor, the accessors and mutators, and methods *toString* and *equals*. You should not allow the denominator to be equal to 0; you should give it the default value 1 in case the corresponding argument of the constructor or a method is 0. Also include methods performing multiplication of a rational number by another and addition of a rational number to another, returning the resulting rational number in both cases. Write a client class to test all the methods in your class.

8. Write a class encapsulating the concept of an investment, assuming the investment has the following attributes: the amount of the investment and the interest rate at which the investment will be compounded. Include a constructor, the accessors and mutators, and methods *toString* and *equals*. Also include a method returning the future value of the investment depending on how many years we hold it before selling it, which can be calculated using the following formula:

   $$\text{future value} = \text{investment}\ (\ 1 + \text{interest rate}\ )^{\text{numberOfYears}}$$

   We will assume that the interest rate is compounded annually. Write a client class to test all the methods in your class.

9. Write a class encapsulating the concept of a telephone number, assuming a telephone number has only a single attribute: a *String* representing the telephone number. Include a constructor, the accessor and mutator, and methods *toString* and *equals*. Also include methods returning the area code (the first three digits/characters of the phone number; if there are fewer than three characters in the phone number or if the first three characters are not digits, then this method should return “*unknown area code*”). Write a client class to test all the methods in your class. Look up the *getClass* method in the *Object* class and the *getName* method in the *Class* class and use them in

your client.

10. Write a class that encapsulates the concept of a tennis match score (best of 3 sets). It has the following instance variables: two *ints* for the score in the first set, two *ints* for the score in the second set, two *ints* for the score in the third set, and two *Strings* for the score in the current game. You do not need to keep track of who is serving. Your score should comply with basic tennis rules (a game score for a given player is either LOVE, 15, 30, 40, or AD). A set must be won by 2 (there is no tie breaker in this format). Write the following methods: a default constructor, *toString*, a method to update the score (when a player wins a point), and a method to check if the game is over. The method that updates the score takes one parameter, a *boolean*; if it is *true*, the first player won the point, if it is *false*, the second player won the point. Furthermore, if the game is over, the score should not be changed. The method that checks if the game is over returns *0* if the game is not over,

1 if the first player won, and *2* if the second player won. Write a client that enables the user to play.

11. Write a class that encapsulates an icon for your favorite TV channel or Internet website. Your icon should be made of a minimum of three colors and three shapes. It should be scalable by specifying the value of one instance variable, and the client should be able to change the colors easily. Your class should include a constructor, a draw method, and mutators to enable the user to change the scale, to change the colors in the icon, and to change the top-left coordinates of the icon.

7.19.8 Technical Writing

1. An advantage of object-oriented programming is code reuse, not just by the programmer who wrote the class, but by other programmers. Describe the importance of proper documentation and how you would document a class so that other programmers can use it easily.
2. Java has a number of naming conventions for classes, methods, and field variables. Is this important? Why is it good to respect these conventions?

7.19.9 Group Project (for a group of 1, 2, or 3 students)

1. Write a program that solves a quadratic equation in all cases, including when both roots are complex numbers. For this, you need to set up the following classes:

   Complex, which encapsulates a complex number
   ComplexPair, which encapsulates a pair of complex numbers
   Quadratic, which encapsulates a quadratic equation

SolveEquation, which contains the *main* method

Along with the usual constructors, accessors, and mutators, you will need to code additional methods:

In the *Complex* class, a method that determines whether a complex object is real

In the *ComplexPair* class, a method that determines whether both complex numbers are identical

In the *Quadratic* class, a method to solve the quadratic equation and return a *ComplexPair* object

Additionally, you need to include code in the *main* method to solve several examples of quadratic equations input from the keyboard. Your output should make comments as to what type of roots we get (double real root, distinct real roots, distinct complex roots). You should check that your code works in all four basic cases:

- The quadratic equation is actually a linear equation.
- Both roots are complex.
- There is a double real root.
- There are two distinct real roots.

Introduction

Up to this point, we have been working with individual, or scalar, variables; that is, each variable has held one value at a time. To process a group of variables of the same type—for example, counting the number of odd integers entered by the user—we used a *while* loop or a *for* loop.

Thus, to find the average high temperature for the last year, we would use a *for* loop:

```
double dailyTemp;
double total = 0.0;
for ( int i = 1; i <= 365; i++ )
{
   System.out.print( "Enter a temperature" );
   dailyTemp = scan.nextDouble( );
   total += dailyTemp;
}
double average = total / 365;
```

Description

We defined one variable, *dailyTemp*, to hold the data. We read each temperature into our *dailyTemp* variable, added the temperature to our total, then read the next value into the *dailyTemp* variable, added that temperature to the total, and so on, until we finished reading and processing all the temperatures. Each time we read a new temperature, it overwrote the previous temperature, so that at the end of the loop, we had access to the last temperature only.

But suppose we want to perform multiple operations on those temperatures. Perhaps we want to find the highest or lowest temperature or find the median. Or suppose we don’t know what operations we will perform, or in what order, until the user chooses them from a menu. In those cases, one scalar variable, *dailyTemp*, won’t work; we want to store all the temperatures in memory at the same time. An array allows us to do just that without declaring 365 variables individually.

An **array** is a sequence of variables of the same data type. The data type could be any Java primitive data type, such as *int, float, double, byte, boolean, char, short*, or *long*, or it could be a class. Each variable in the array, called an **element**, is accessed using the array name and a subscript, called an **index**, which refers to the element's position in the array.

Arrays are useful for many applications: for example, calculating statistics on a group of data values or processing data stored in tables, such as matrices or game boards.

8.1 Declaring and Instantiating Arrays

In Java, arrays are implemented as objects, so creating an array takes two steps:

1. Declaring the object reference for the array.
2. Instantiating the array.

In arrays of primitive types, each element in the array contains a value of that type. For example, in an array of *doubles*, each element contains a *double* value. In arrays of objects, each element is an object reference, which stores the location of an object.

8.1.1 Declaring Arrays

To declare an array, we specify the name of the array and the data type, as we would for any other variable. Adding an empty set of brackets ([ ]) indicates that the variable is an array.

Here is the syntax for declaring an array:

```
datatype [ ] arrayName;
```

Description

For example, the following statement creates a reference to an array that will hold daily high temperatures:

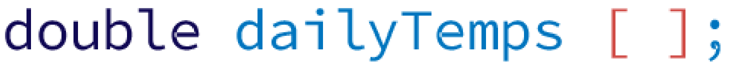
```
double [ ] dailyTemps; // each element is a double
```

The brackets can be placed before or after the array name. So the following syntax is also valid:

```
datatype arrayName [ ];
```

Description

Thus, we could have declared the preceding array using the following statement:



```
double dailyTemps [ ];
```

Although Java code can be written using either syntax, we prefer the first format with the brackets right after the data type, because it’s easier to read as “a *double* array.”

To declare an array to hold the titles of all tracks on a CD, we might declare it this way:

```
String [ ] cdTracks; // each element is a String object reference
```

Description

Similarly, this statement declares an array to hold the answers to a true/false test:

```
boolean [ ] answers; // each element is a boolean value
```

Description

Assuming we have written an *Auto* class, this statement declares an array to hold *Auto* objects:

```
Auto [ ] cars; // each element is an Auto object reference
```

Description

We can declare multiple arrays of the same data type in one statement by inserting a comma after each array name, using this syntax:

```
datatype [ ] arrayName1, arrayName2;
```

Description

For example, the following statement will declare three integer arrays to hold quiz scores for current courses:

```
int [ ] cs101, bio201, hist102; // all elements are int values
```

Description

Note that an array declaration does not specify how many elements the arrays will have. The declaration simply specifies an object reference for the array and the data type of the elements. Thus, **declaring an array does not allocate memory for the array**.

COMMON ERROR TRAP

Putting the size of the array inside the brackets in the array declaration will generate a compiler error.

8.1.2 Instantiating Arrays

As we mentioned earlier, Java arrays are objects, so to allocate memory for an array, we need to instantiate the array using the *new* keyword. Here is the syntax for instantiating an array:

```
arrayName = new datatype [size];
      where size is an expression that evaluates to an integer and
      specifies the number of elements in the array.
```

Description

The following statements will instantiate the arrays declared earlier:

```
dailyTemps = new double [365]; // dailyTemps has 365 elements
cdTracks = new String [15];    // cdTracks has 15 elements
int numberOfQuestions = 30;
answers = new boolean [numberOfQuestions]; // answers has 30 elements
cars = new Auto [3];           // cars has 3 elements
cs101 = new int [5];           // cs101 has 5 elements
bio201 = new int [4];          // bio201 has 4 elements
hist102 = new int [6];         // hist102 has 6 elements
```

Description

When an array is instantiated, the elements are given initial values automatically.

Numeric elements are set to 0, *boolean* elements are set to *false, char* elements are set to the Unicode null character, and object references are set to *null*, as shown in **Table 8.1**.

Default Initial Values of Array Elements

Element Data Type	**Initial Value**
double	0.0
float	0.0
int, long, short, byte	0
char	null character (‘\u0000’)
boolean	*false*
object reference	*null*

Description

Thus, all the elements in the *dailyTemps* array are given an initial value of 0.0; the elements in the *cs101, bio201*, and *hist102* arrays are given an initial value of 0; the elements of the *answers* array are given an initial value of *false*; and the elements of the *cdTracks* and *cars* arrays are given an initial value of *null*.

8.1.3 Combining the Declaration and Instantiation of Arrays

Arrays also can be instantiated when they are declared. To combine the declaration and instantiation of an array, we use this syntax:

```
datatype [ ] arrayName = new datatype [size];
      where size is an expression that evaluates to an integer and
      specifies the number of elements in the array.
```

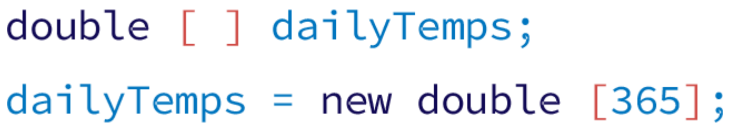
Description

Thus, this statement:

```
double [ ] dailyTemps = new double [365];
```

Description

is equivalent to:



```
double [ ] dailyTemps;
dailyTemps = new double [365];
```

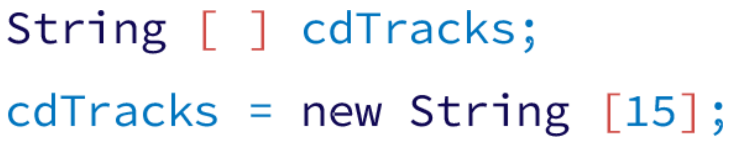
Description

Similarly, this statement:

```
String [ ] cdTracks = new String [15];
```

Description

is equivalent to:

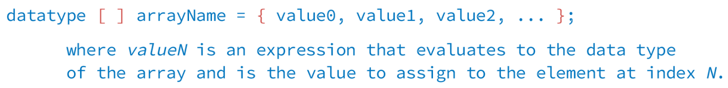


```
String [ ] cdTracks;
cdTracks = new String [15];
```

Description

8.1.4 Assigning Initial Values to Arrays

Java also allows us to instantiate an array by assigning initial values when the array is declared. To do this, we specify the initial values using a comma-separated list within curly braces:



```
datatype [ ] arrayName = { value0, value1, value2, ... };
      where valueN is an expression that evaluates to the data type
      of the array and is the value to assign to the element at index N.
```

Description

Note that we do not use the *new* keyword and we do not specify a size for the array. The number of elements in the array is determined by the number of values in the initialization list.

COMMON ERROR TRAP

An initialization list can be given only when the array is declared. Attempting to assign values to an array using an initialization list after the array is instantiated will generate a compiler error.

For example, this statement declares and instantiates an array of odd numbers:

```
int nine = 9;
int [ ] oddNumbers = { 1, 3, 5, 7, nine, nine + 2, 13, 15, 17, 19 };
```

Description

Because 10 values are given in the initialization list, this array has 10 elements. Notice that the values can be an expression, for example, *nine* and *nine + 2*.

COMMON ERROR TRAP

The *new* keyword is not used when an array is instantiated using an initialization list. No size is given; the number of values in the list specifies the size of the array.

Similarly, we can declare and instantiate an array of objects by providing objects in the list, as shown next. The *cars* array of *Auto* objects has three elements.

```
Auto sportsCar = new Auto( "Ferrari", 0, 0.0 );
Auto [ ] cars = { new Auto( "BMW", 100, 15.0 ), sportsCar, new Auto( ) };
```

Exception in thread "main" java.lang.NullPointerException:
     Cannot invoke "Auto.getModel( )" because "<local1>[2]" is null
     at AutoArray.main(AutoArray.java:26)
```

8.2 Accessing Array Elements

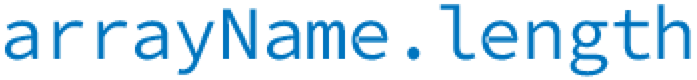
Elements of an array are accessed using this syntax:

```
arrayName[exp]
    where exp is an expression that evaluates to an integer.
```

Description

Exp is the element’s position, or **index**, within the array. The index of the first element in the array is always 0; the index of the last element is always 1 less than the number of elements.

Arrays have a read-only, integer instance variable, **length**, which holds the number of elements in the array. To access the number of elements in an array named *arrayName*, use this syntax:



```
arrayName.length
```

Description

Thus, to access the last element of an array, use this syntax:

```
arrayName[arrayName.length - 1]
```

Description

Note that regardless of the data type of the elements in an array, the *length* of an array is always an integer, because *length* represents the number of elements in the array.

Table 8.2 summarizes the syntax for accessing elements of an array.

Accessing Array Elements

Element	**Syntax**
Element 0	`arrayName[0]`
Element *i*	`arrayName[i]`
Last element	`arrayName[arrayName.length - 1]`

Description

COMMON ERROR TRAP

Note that for an array, *length*—with no parentheses—is an instance variable, whereas for *Strings, length( )*—with parentheses—is a method. Note also that the instance variable is named *length*, rather than *size*.

For example, suppose we want to analyze our monthly cell phone bills for the past six months. We want to calculate the average bill, the total payments for the six months, and the lowest and highest bills. We can use an array of *doubles* with six elements, as shown in **Example 8.1**.

Example 8.1 The *cellBills* Array

```
 1 /* Array of Cell Phone Bills
 2    Anderson, Franceschi
 3 */
 4
 5 public class CellBills
 6 {
 7   public static void main( String [ ] args )
 8   {
 9      // declare and instantiate the array
10      double [ ] cellBills = new double [6];
11
12      // assign values to array elements
13      cellBills[0] = 45.24;
14      cellBills[1] = 54.67;
15      cellBills[2] = 42.55;
16      cellBills[3] = 44.61;
17      cellBills[4] = 65.29;
18      cellBills[5] = 49.75;
19
20      System.out.println( "The first monthly cell bill is "
21                          + cellBills[0] );
22      System.out.println( "The last monthly cell bill is "
23                          + cellBills[cellBills.length - 1] );
24   }
25 }
```

Description

In lines 9–10, we declare and instantiate the *cellBills* array. Because the elements of *cellBills* are *doubles*, instantiating the array also initializes each element to 0.0 and sets the value of *cellBills.length* to 6. Thus, **Figure 8.1** represents the *cellBills* array after line 10 is executed.

Figure 8.1 The *cellBills* Array After Instantiation

Description

Lines 12–18 store values into each element of the array. The element at index *i* of the array is *cellBills[i]*. Remember that the first element of an array is always at index 0. Thus, the last element is *cellBills[5]*, or equivalently, *cellBills[cellBills.length – 1]*. **Figure 8.2** shows how the *cellBills* array looks after lines 13–18 are executed.

Figure 8.2 The *cellBills* Array After Assigning Values

Description

Lines 20–21 print the value of the first element, and lines 22–23 print the value of the last element. The output of Example 8.1 is shown in **Figure 8.3**.

Figure 8.3 Output of Example 8.1

Description

Array indexes *must* be between 0 and *arrayName.length – 1*. Attempting to access an element of an array using an index less than 0 or greater than *arrayName.length – 1* will compile without errors, but will generate an *ArrayIndexOutOfBoundsException* at run time. By default, this exception halts execution of the program.

For example, all the following expressions are invalid:

COMMON ERROR TRAP

Attempting to access an element of an array using an index less than 0 or an index greater than *arrayName.length – 1* will generate an *ArrayIndex-OutOfBounds-Exception* at run time.

```
// invalid indexes for the cellBills array!!
cellBills[-1]                 // the lowest valid index is 0
cellBills[cellBills.length]   // the highest valid index is
                              // cellBills.length - 1
cellBills[150]                // the highest valid index is 5
```

Description

Instantiating an array with a class data type involves two steps:

1. Instantiate the array.

2. Instantiate the objects.

Remember that the elements of an array with a class data type are object references. When the array is instantiated, all elements are set to *null*. Thus, the second step needs to be instantiating each object and assigning its reference to an array element.

Example 8.2 illustrates how to work with an array of objects. In this example, we use an *Auto* class whose API is shown in **Table 8.3**.

Example 8.2 Working with an Array of Objects

```java
/* Working with an Array of Objects
   Anderson, Franceschi
*/

public class AutoArray
{
  public static void main( String [ ] args )
  {
    // 1. instantiate cars array
    Auto [ ] cars = new Auto [3];

    // 2. instantiate Auto objects
    Auto sportsCar = new Auto( "Ferrari", 100, 15.0 );
    cars[0] = sportsCar;     // assign sportsCar to element 0
    cars[1] = new Auto( );   // default Auto object
    // cars[2] has not been instantiated and is null

    // call Auto methods
    System.out.println( "cars[0] is a " + cars[0].getModel( ) );

    Auto myCar = cars[1];
    System.out.println( "myCar has used " + myCar.getGallonsOfGas( )
                         + " gallons of gas" );

    // attempt to call method when Auto object is not instantiated
    System.out.println( "cars[2] is a " + cars[2].getModel( ) );
  }
}
```

Description

The *Auto* Class API

Auto Class Constructor Summary

`Auto( )`

creates an *Auto* object with initial default values of “unknown,” 0, and 0.0.

`Auto( String model, int milesDriven, double gallonsOfGas )`

creates an *Auto* object with the initial values of *model, milesDriven,* and *gallonsOfGas*

Auto Class Method Summary

Return value	**Method name and argument list**
`String`	`getModel( )` returns the value of *model*
`int`	`getMilesDriven( )` returns the value of *milesDriven*
`double`	`getGallonsOfGas( )` returns the value of *gallonsOfGas*
`Auto`	`setModel( String model )` mutator for *model*
`Auto`	`setMilesDriven( int milesDriven )` mutator for *milesDriven*
`Auto`	`setGallonsOfGas( double gallonsOfGas )` mutator for *gallonsOfGas*
`double`	`milesPerGallon( )` returns the gas mileage for this *Auto* object
`String`	`toString( )` returns a *String* representation of this object
`boolean`	`equals( Object obj )` compares this *Auto* object to another object

Description

At lines 9–10, we declare and instantiate *cars*, an array of three *Auto* objects. At this point, each element has the value of *null*. Thus, our second step is to instantiate objects of the *Auto* class and assign their references to the array elements.

At lines 13–14, we instantiate the *Auto* object *sportsCar* and assign the *sportsCar* reference to element 0. At line 15, we instantiate a default *Auto* object and assign its reference to element 1. We do not instantiate an object for element 2, which remains *null*.

COMMON ERROR TRAP

With an array of objects, be sure that an array element points to an instantiated object before attempting to use that element to call a method of the class. Otherwise, a *NullPointer-Exception* will be generated.

We then call methods of the *Auto* class. Because the array elements are object references, to call a method for an object in an array, we use the array name and index, along with the dot notation. This is illustrated in line 19, where we print the model of element 0 by calling the *getModel* method. In lines 21–23, we assign element 1 to the *Auto* reference *myCar*, then call the *getGallonsOfGas* method using the *myCar* reference.

Finally, line 26 attempts to retrieve the model of element 2; however, because *cars[2]* is *null*, a *NullPointerException* is generated. **Figure 8.4** shows the output of this program.

8.3 Aggregate Array Operations

Once the array is declared and instantiated, it would be convenient if we could just use the array name to perform operations on the whole array, such as printing the array, copying the array to another array, inputting values to the array, and so on. Unfortunately, Java does not support these aggregate operations on arrays.

For example, attempting to print the array using the array name will *not* print all the elements of the array. Instead, this statement:

```
System.out.println( cellBills ); // incorrect attempt to print array!
```

Description

calls the *toString* method of the *Array* class, which simply prints the name of the object's class and the hash code of the array name, for example, `[D@310d42`.

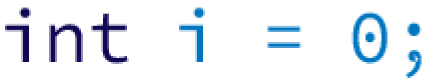
8.3.1 Printing Array Elements

To print all elements of an array, we need to use a loop that prints each element individually. A *for* loop is custom made for processing all elements of an array in order. In fact, the following *for* loop header is a standard way to process all array elements with the loop control variable representing each index in the array:

```
for ( int i = 0; i < arrayName.length; i++ )
```

Description

Note that the initialization statement:



```
int i = 0;
```

Description

sets *i* to the index of the first element of the array.

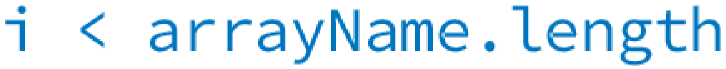
The loop update

```
i++
```

Description

increments *i* to the next index so that we process each element in order.

The loop condition:



```
i < arrayName.length
```

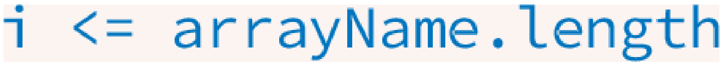
Description

continues execution of the loop as long as the index is less than the *length* of the array.

Note that we use the *less than* operator (<) in the condition. Using the *less than or equal to* operator (<=) would cause us to attempt to reference an element with an index of *arrayName.length*, which is beyond the end of the array.

COMMON ERROR TRAP

In a *for* loop, using the condition:

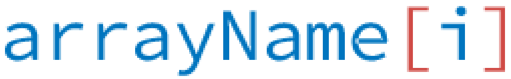


```
i <= arrayName.length
```

Description

will generate an *ArrayIndex-OutOfBounds-Exception* because the index of the last element of an array is *arrayName.length – 1.*

Inside the *for* loop, we refer to the current element being processed as



```
arrayName[i]
```

Description

Example 8.3, whose output is shown in **Figure 8.5**, demonstrates how to print each element in an array.

Example 8.3 Printing All Elements of an Array

```
 1 /* Printing Array Elements
 2    Anderson, Franceschi
 3 */
 4
 5 public class PrintingArrayElements
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     double [ ] cellBills = new double [6];
10     cellBills[0] = 45.24;
11     cellBills[1] = 54.67;
12     cellBills[2] = 42.55;
13     cellBills[3] = 44.61;
14     cellBills[4] = 65.29;
15     cellBills[5] = 49.75;
16
17     System.out.println( "Element\tValue" );
18     for ( int i = 0; i < cellBills.length; i++ )
19     {
20       System.out.println( i + "\t" + cellBills[i] );
21     }
22   }
23 }
```

Description

Figure 8.5 Output of Example 8.3

Description

In lines 9–15, we instantiate the *cellBills* array and assign values to its six elements. In line 18, we use the standard *for* loop header. Inside the *for* loop (line 20), we print each element’s index and value.

8.3.2 Reading Data into an Array

Similarly, we can use the standard *for* loop to input data into an array. In **Example 8.4**, we use a *for* loop to prompt the user for each monthly cell phone bill and to assign the input value to the appropriate array elements.

Example 8.4 Reading Data from the Keyboard into an

Array

```
 1 /* Reading data into an array
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6
 7 public class ReadingDataIntoAnArray
 8 {
 9   public static void main( String [ ] args )
10   {
11     Scanner scan = new Scanner( System.in );
12
13     double [ ] cellBills = new double[6];
14     for ( int i = 0; i < cellBills.length; i++ )
15     {
16       System.out.print( "Enter bill amount for month "
17                         + ( i + 1 ) + "\t" );
18       cellBills[i] = scan.nextDouble( ); // read current bill
19     }
20   }
21 }
```

Description

At lines 14–19, our *for* loop prompts the user for a value for each element in the *cellBills* array. Note that our prompt uses the expression (*i* + 1) for the month number. Although array indexes start at 0, people start counting at 1. If we used the array index in the prompt, we would ask the user for the bills for months 0 to 5. By adding 1 to the array index, we are able to prompt the user for months 1 through 6, which are the month numbers that the user expects.

SOFTWARE ENGINEERING TIP

Prompt for data in terms the user understands.

The output of Example 8.4 is shown in **Figure 8.6.**

Figure 8.6 Reading Data into an Array

Description

8.3.3 Summing the Elements of an Array

To sum the elements of the array, we again use the standard *for* loop, as shown in **Example 8.5.**

Example 8.5 Summing the Elements of an Array

```
 1 /* Summing Array Elements
 2    Anderson, Franceschi
 3 */
 4
 5 import java.text.NumberFormat;
 6
 7 public class SummingArrayElements
 8 {
 9  public static void main( String [ ] args )
10  {
11    double [ ] cellBills = new double [6];
12    cellBills[0] = 45.24;
13    cellBills[1] = 54.67;
14    cellBills[2] = 42.55;
15    cellBills[3] = 44.61;
16    cellBills[4] = 65.29;
17    cellBills[5] = 49.75;
18
19    double totalBills = 0.0; // initialize total
20    for ( int i = 0; i < cellBills.length; i++ )
21    {
22      totalBills += cellBills[i];
23    }
24
25    NumberFormat priceFormat = NumberFormat.getCurrencyInstance( );
26    System.out.println( "Total for the bills: "
27                         + priceFormat.format( totalBills ) );
28   }
29 }
```

Description

We fill the *cellBills* array with values at lines 12–17. We declare the *double* variable *totalBills* and initialize it to 0.0 at line 19. The *for* loop, at lines 20–23, adds each element of the array to *totalBills*. We use the *NumberFormat* class to format the value of *totalBills* as currency for output (lines 25–27). The output of Example 8.5 is shown in **Figure 8.7**.

Figure 8.7 Calculating the Total of All Elements

Description

8.3.4 Finding Maximum or Minimum Values

Suppose we want to find the month that has the lowest bill. That would require finding a minimum value in the array and noting its index. Similarly, to find a month with the highest bill, we would need to find a maximum value in the array and note its index.

To find a maximum or minimum value in an array, we use a variation of the standard *for* loop. **Example 8.6** finds the highest array value and its array index for our *cellBills* array of monthly cell bills.

Example 8.6 Finding a Maximum Value in an Array

```
 1 /* Finding the maximum array value
 2    Anderson, Franceschi
 3 */
 4
 5 import java.text.NumberFormat;
 6
 7 public class MaxArrayValue
 8 {
 9  public static void main( String [ ] args )
10  {
11    double [ ] cellBills = new double [6];
12    cellBills[0] = 45.24;
13    cellBills[1] = 54.67;
14    cellBills[2] = 42.55;
15    cellBills[3] = 44.61;
16    cellBills[4] = 65.29;
17    cellBills[5] = 49.75;
18
19    int maxIndex = 0; // initialize to index of first element
20    for ( int i = 1; i < cellBills.length; i++ )
21    {
22     if ( cellBills[i] > cellBills[maxIndex] )
23       maxIndex = i; // save index of maximum value
24    }
25
26    NumberFormat priceFormat = NumberFormat.getCurrencyInstance( );
27    System.out.println ( "The highest bill, "
28                         + priceFormat.format( cellBills[maxIndex] )
29                         + ", was found at index " + maxIndex );
30  }
31 }
```

Description

We start by assuming that the first element is a maximum value. So we initialize an integer variable, *maxIndex*, to 0, at line 19. Then, at lines 20–24, starting at element 1, we step through the array, comparing the value of each element with the element at *maxIndex*. Whenever we find a value higher than the current maximum, we assign its index to *maxIndex* (line 23). When the *for* loop completes, *maxIndex* holds the index of the array element with the highest value. We then print both that index and the corresponding array value at lines 26–29. The output is shown in **Figure 8.8**.

Figure 8.8 Output of Example 8.6

Description

What happens if the array has only one value? Will we still get the correct result? The answer is yes, because the single element will be at index 0. We start by assigning 0 to *maxIndex*. Then the *for* loop body will not execute because the condition will evaluate to *false*. So *maxIndex* will not be changed and remains set to 0.

What happens if more than one element holds the highest value? We find the index of the first element only, because our condition requires that the element value must be greater than the current maximum to change *maxIndex*.

8.3.5 Copying Arrays

Suppose we create a second array to hold a copy of our cell phone bills, as shown in the following statement:

```
double [ ] billsBackup = new double [6];
```

Description

At this point, all elements of the *billsBackup* array are initialized automatically to 0.0. **Figure 8.9** shows the current state of the *cellBills* and *billsBackup* arrays.

Figure 8.9 The *cellBills* and *billsBackup* Arrays

Description

Then, if we want to copy the elements of the *cellBills* array to the corresponding elements of the *billsBackup* array, we might be tempted to use the assignment operator:

```
billsBackup = cellBills; // incorrect attempt to copy array elements!
```

Description

This won't work. Because arrays are objects, the assignment operator copies the *cellBills* object reference to the *billsBackup* object reference. Both *cellBills* and *billsBackup* now point to the same object. The array data was not copied. In fact, we just lost the original *billsBackup* array. With no object reference pointing to it, the array is a candidate for garbage collection, as shown in **Figure 8.10**.

Figure 8.10 Assigning *cellBills* to *billsBackup*

Description

If we were to assign a new value to an element in the *billsBackup* array, we would in fact change the element in the *cellBills* array, because they are now the same array.

This statement:

```
billsBackup[4] = 38.00;
```

Description

has the effect shown in **Figure 8.11**.

Figure 8.11 Altering *billsBackup* Alters *cellBills* Array

Description

Example 8.7 shows how to copy the elements in one array to another array.

Example 8.7 Copying Array Elements into Another Array

```
 1 /* Copying Array Elements to Another Array
 2    Anderson, Franceschi
 3 */
 4
 5 public class CopyingArrayElements
 6 {
 7  public static void main( String [ ] args )
 8  {
 9    double [ ] cellBills = { 45.24, 54.67, 42.55, 44.61, 65.29, 49.75 };
10
11    double billsBackup [ ] = new double [cellBills.length];
12    for ( int i = 0; i < cellBills.length; i++ )
13    {
14      billsBackup[i] = cellBills[i]; // copy each element
15    }
16
17    billsBackup[4] = 38.00; // change value in billsBackup
18
19    System.out.println( "cellBills\nElement\tValue " );
20    for ( int i = 0; i < cellBills.length; i++ )
21    {
22      System.out.println ( i + "\t" + cellBills[i] );
23    }
24
25    System.out.println( "\nbillsBackup\nElement\tValue " );
26    for ( int i = 0; i < billsBackup.length; i++ )
27    {
28      System.out.println ( i + "\t" + billsBackup[i] );
29    }
30  }
31 }
```

Description

At line 9, we instantiate the array *cellBills* using an initialization list. At line 11, we declare and instantiate the array *billsBackup* to have the same size as the original array *cellBills*. At lines 12–15, we use a standard *for* loop to copy one element at a time from the *cellBills* array to the corresponding element in the *billsBackup* array.

Now the *billsBackup* array and the *cellBills* array are separate arrays with their own copies of the element values, as shown in **Figure 8.12**. Changing an element in one array will have no effect on the value of the corresponding element in the other array.

Figure 8.12 Arrays After Copying Each Element

Description

We illustrate this by assigning a new value to an element in the array *billsBackup* (line 17). Finally, we use two *for* loops to print the contents of both arrays. As **Figure 8.13** shows, the value for element 4 is changed only in the array *billsBackup*.

Figure 8.13 Output of Example 8.7

Description

Be aware, however, that when we copy an array whose elements are objects, even using the *for* loop structure, we are copying object references. The result is that the corresponding elements of each array will point to the same object. If an object's data in one array is changed, that change will be reflected in the other array as well.

8.3.6 Changing the Size of an Array

Arrays are assigned a length when they are instantiated, and the *length* of an array becomes a constant value. But what if we want to change the number of elements in an array after it has been instantiated?

For example, our *cellBills* array contains six elements, holding six months' worth of cell phone bills. If we decide to collect a year's worth of cell phone bills, we would need an array with 12 elements. We could instantiate a new version of the *cellBills* array with 12 elements, using this statement:

```
cellBills = new double [12];
```

Description

That statement instantiates a new array of *doubles* all initialized to 0.0. But what happened to the original array of six elements? Since the *cellBills* reference now refers to the new, 12-element array, the 6-element array has no object reference pointing to it, so there is no way we can access the array's values. That is not the result we intended!

To expand the size of an array while maintaining the values of the original array, we can use the following technique:

1. Instantiate an array with the new size, giving the new array

a temporary reference.

2. Copy the elements from the original array to the new array.
3. Point the original array reference to the new array.
4. Assign a *null* value to the temporary array reference.

Thus, instead of immediately pointing *cellBills* to the new array, we should instantiate a 12-element array using a temporary array name, copy the six elements from the *cellBills* array into the 12-element array, assign the *cellBills* reference to the new array, and assign *null* to the temporary array reference. The following code will do that:

```
double [ ] temp = new double [12]; //instantiate new array

// copy all elements from cellBills to temp
for ( int i = 0; i < cellBills.length; i++ )
{
      temp[i] = cellBills[i]; // copy each element
}
cellBills = temp; // assign temp to cellBills
temp = null;      // temp no longer points to cellBills
```

Description

The last statement sets *temp* to *null* so that we don't have two references to the *cellBills* array.

8.3.7 Comparing Arrays for Equality

To compare whether two arrays are equal, first determine if they are equal in length, and then use a *for* loop to compare the corresponding elements in each array. That is, compare element 0 in the first array to element 0 in the second array; compare element 1 in the first array to element 1 in the second array; and so on. If all elements in the first array are equal to the corresponding elements in the second array, then the arrays are equal. **Example 8.8** compares two arrays of *doubles*, a primitive data type.

Example 8.8 Comparing Arrays of Primitive Data Types

```
 1 /* Comparing Arrays of primitive data types
 2    Anderson, Franceschi
 3 */
 4
 5 public class ComparingArrays
 6 {
 7  public static void main( String [ ] args )
 8  {
 9   double [ ] cellBills1 = { 45.24, 54.67, 42.55, 44.61, 65.29, 49.75 };
10   double [ ] cellBills2 = { 45.24, 54.67, 41.99, 44.61, 65.29, 49.75 };
11
12   boolean isEqual = true;
13   if ( cellBills1.length != cellBills2.length )
14   {
15     isEqual = false; // arrays are not the same size
16   }
17   else
18   {
19     for ( int i = 0; i < cellBills1.length && isEqual; i++ )
20     {
21       if ( Math.abs( cellBills1[i] - cellBills2[i] ) > 0.001 )
22       {
23          isEqual = false; // elements are not equal
24       }
25     }
26   }
27
28  if ( isEqual )
29     System.out.println( "cellBills1 and cellBills2 are equal" );
30   else
31     System.out.println( "cellBills1 and cellBills2 are not equal" );
32  }
33 }
```

Description

Before we begin the *for* loop, we declare at line 12 a *boolean* variable, *isEqual*, and set it to *true*. In this way, we assume the arrays are equal. Then, our first step is to compare whether the two arrays have the same length (line 13). If they are not the same size, the arrays cannot be equal, so we set *isEqual* to *false* and execution skips to line 28. If the two arrays are the same size, we use a *for* loop at lines 19–25 to test whether the corresponding elements in each array are equal. Note that we have added a second test to the *for* loop condition (*isEqual*). If any corresponding elements are not equal, we set *isEqual* to *false* at line 23. This will cause the condition of the *for* loop to evaluate to *false*, and we exit the *for* loop. Thus, when the *for* loop finishes executing, if any corresponding elements did not match, *isEqual* will be *false*. If both arrays are the same size and all corresponding elements are equal, we never change the value of *isEqual*, so it remains *true*. The output from this example is shown in **Figure 8.14**.

Figure 8.14 Output of Example 8.8

Description

Naturally, if the elements of the arrays are *ints, booleans,* or *chars*, we would use the equality operator (!=) at line 21 as in:

```
if ( intArray1[i] != intArray2[i] )
```

Description

assuming the two arrays we are comparing have names *intArray1* and *intArray2*.

If the elements of the arrays are objects, our *for* loop should call the *equals* method of the objects' class. Thus, to compare two arrays of *Auto* objects, named *cars1* and *cars2*, we would use the following code instead of the condition at line 21:

```
if ( ! cars1[i].equals( cars2[i] ) )
```

Description

A pitfall to avoid is attempting to test whether two arrays are equal using the equality operator (==). This code:

```
if ( cellBills == billsBackup )
```

Description

will not compare the data of the two arrays. It will compare whether the *cellBills* and *billsBackup* object references are equal; that is, whether they point to the same array.

COMMON ERROR TRAP

Because arrays are objects, attempting to compare two arrays using the equality operator (==) will compare whether the two array references point to the same array in memory, not whether the data in the two arrays are equal. Calling the *equals* method inherited from the *Object* class yields similar results.

Similarly, the *equals* method inherited from *Object* also returns the wrong results.

This code:

```
if ( cellBills.equals( billsBackup ) )
```

Description

will return *true* only if both object references point to the same array.

8.3.8 Displaying Array Data as a Bar Chart

One way to display array data is graphically, by drawing a bar chart. For example, the bar chart in **Figure 8.15** displays the data in the *cellBills* array.

Figure 8.15 The *cellBills* Array as a Bar Chart

Description

Each bar is simply a rectangle. **Example 8.9** shows the code to generate Figure 8.15.

Example 8.9 Displaying Array Values as a Bar Chart

```java
 1 /* A bar chart application
 2    Anderson, Franceschi
 3 */
 4
 5 import javafx.application.Application;
 6 import javafx.stage.Stage;
 7 import javafx.scene.canvas.GraphicsContext;
 8 import javafx.scene.paint.Color;
 9
10 public class BarChartApplication extends Application
11 {
12   final int LEFT_MARGIN = 35;         // starting x coordinate
13   final int BASE_Y_BAR  = 150;        // bottom of the bars
14   final int BASE_Y_VALUE = 175;       // bottom of the values
15   final int BAR_WIDTH = 30;           // width of each bar
16   final int SPACE_BETWEEN_BARS = 10;  // pixels between bars
17
18   private double [ ] cellBills
19     = { 45.24, 54.67, 42.55, 44.61, 65.29, 49.75 };
20   private String [ ] months
21       = { "March", "April", "May", "June", "July", "August" };
22
23   @Override
24   public void start( Stage stage )
25   {
26     // set up window title and size
27     GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
28                   stage, "Bar Chart", 350, 200 );
29
30     gc.setFill( Color.BLUE );          // bars will be blue
31     int xStart = LEFT_MARGIN;          // x value for first bar
32
33     for ( int i = 0; i < cellBills.length; i++ )
34     {
35       gc.fillRect( xStart, BASE_Y_BAR - cellBills[i],
36                    BAR_WIDTH, cellBills[i] );
37
38       gc.fillText( Double.toString( cellBills[i] ),
39                    xStart, BASE_Y_VALUE );
40
41       // move to starting x value for next bar
42       xStart += BAR_WIDTH + SPACE_BETWEEN_BARS;
43     }
44   }
45
46   public static void main( String [ ] args )
47   {
48     launch( args );
49   }
50 }
```

Description

To create the bar chart, we use our standard *for* loop at lines 31–41 in the *start* method and call the *fillRect* method of the

GraphicsContext class to draw a rectangle for each element (lines 33–34). We use the *fillText* method at lines 36–37 to display the value of each element.

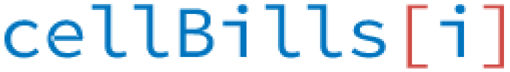
The *fillRect* method takes four arguments: the upper-left *x* value, the upper-left *y* value, the rectangle's width, and the rectangle's height.

We can determine the argument values for the *fillRect* method for each element using the following approach, as illustrated in **Figure 8.16**:

Figure 8.16 Arguments for Drawing Each Bar

Description

- Width: The width of the bar is a constant value. For our bar chart, we chose a width of 30 pixels; the constant *BAR_WIDTH* stores that value (line 15).
- Height: The height for each bar is the value of the array element being charted. Thus, in the *fillRect* method call (lines 35–36), we represent the height of a bar as:



```
cellBills[i]
```

- Upper-left *y* value: Similarly, the upper-left *y* value will be the height of the bar subtracted from the base *y* value for all the bars; the base *y* value for all the bars is the constant *BASE_Y_BAR* defined in line 13. We subtract the value of the element from the base of the bar because *y* values increase from the top of the window to the bottom. Thus, in our *fillRect* method call, we represent the upper-left *y* value of a bar as:

```
BASE_Y_BAR - cellBills[i]
```

- Upper-left *x* value: We'll start the first bar at the left side of the window, plus a left margin value, represented by the constant *LEFT_MARGIN* (line 12). After we draw each bar, our *for* loop needs to move the starting *x* value to the position of the next bar. To do this, at line 42, we increment the starting *x* value by the width of the bar, *BAR_WIDTH* (defined on line 15), plus the space between bars, *SPACE_BETWEEN_BARS* (defined on line 16).

The arguments to the *fillText* method of the *GraphicsContext* class are the *String* to display and the base *x* and *y* values. At line 36, we convert the *cellBills* element to a *String* using the *toString* method of the *Double* wrapper class. The base *x* value is the same as the starting *x* value for the element's bar, and the base *y* coordinate, *BASE_Y_VALUE*, is the base position for printing the array values (defined on line 14).

CODE IN ACTION

Within the online resources, you will find a movie with step-by-step illustrations of working with arrays. Click on the link for this chapter to start the movie.

8.4 Programming Activity 1: Working with Arrays

In this activity, you will work with a 15-element integer array. Specifically, you will write the code to perform the following operations:

1. fill the array with random numbers between 30 and 99
2. print the array
3. set every array element to a specified value
4. count the number of elements with a specified value
5. find the minimum value in the array

The framework for this Programming Activity will animate your algorithm so that you can check the accuracy of your code.

For example, **Figure 8.17** shows the application counting the elements having the value 73.

Figure 8.17 Animation of the Programming Activity

Description

At this point, the application has found the value 73 in element 0 and is comparing the value 73 with the value 69 in element 4.

Instructions

In this chapter's Programming Activity 1 folder in the supplied code files, you will find the source files needed to complete this activity. Copy all the files to a folder on your computer. Note that all files should be in the same folder.

Open the *ArrayPractice1Controller.java* source file. Searching for five asterisks (*****) in the source code will position you at the sample method and the four other locations where you will add your code. We have provided the sample code for task number 1, which you can use as a model for completing the other tasks. In every task, you will fill in the code for a method that will manipulate an existing array of 15 integers. You should not instantiate the array; we have done that for you. **Example 8.10** shows the section of the *ArrayPractice1Controller* source code where you will add your code.

Example 8.10 Location of Student Code in *ArrayPractice1Controller*

```
// ***** 1. The first method has been coded as an example
/**  Fills the array with random numbers between 50 and 80.
*    The instance variable arr is the integer array
*    to be filled with values
*/
public void fillValues( )
{
     Random rand = new Random( );
      for ( int i = 0; i < arr.length; i++ )
    {
       arr[i] = rand.nextInt( 31 ) + 50;
       animate( i, arr[i] ); // needed to create visual feedback
    }
}
// end of fillValues method

// ***** 2. student writes this method
/** Prints the array to the console with elements separated
*     by a space
*    The instance variable arr is the integer array to be printed
*/
public void printArray( )
{
 // Note: to animate the algorithm, put this method call as the
 // last statement in your for loop:
 //                  animate( i, arr[i] );
 //     where i is the index of the current array element
 // Write your code here:

} // end of printArray method

// ***** 3. student writes this method
/** Sets all the elements in the array to parameter value
*    The instance variable arr is the integer array to be processed
*    @param value the value to which to set the array elements
*/
public void setValues( int value )
{
 // Note: to animate the algorithm, put this method call as the
 // last statement in your for loop
 //            animate( i arr[i] );
 //      where i is the index of the current array element
 // Write your code here:

} // end of setValues method
  // ***** 4. student writes this method
  /** Counts number of elements equal to parameter value
  *    The instance variable arr is the integer array to be processed
  *      @param value the value to count
  *      @return the number of elements equal to value
  */
  public int countFrequency( int value )
  {
   // Note: to animate the algorithm, put this method call as the
   // last statement in your for loop
   //          animate( i, count );
   //         where i is the index of the current array element
   //                 count is the variable holding the frequency
   // Write your code here:

     return 0; // replace this line with your return statement

  } // end of countFrequency method

  // ***** 5. student writes this method
  /** Finds and returns the minimum value in arr
  *    The instance variable arr is the integer array to be processed
  *     @return the minimum value found in arr
  */
  public int findMinimum( )
  {
   // Note: to animate the algorithm, put this method call as the
   // last statement in your for loop
   //        animate( i, minimum );
   //            where i is the index of the current array element
   //               minimum is the variable holding the minimum
   // Write your code here:

     return 0; // replace this line with your return statement

  } // end of findMinimum method

    // End of student code
```

Description

Note that for the *countFrequency* and *findMinimum* methods, we provide a dummy *return* statement (*return 0;*) We do this so that the source code will compile. In this way, you can write and test each method separately, using stepwise refinement. When you are ready to write the *countFrequency* and *findMinimum* methods, just replace the dummy *return* statements with the appropriate *return* statement for that method.

Our framework will animate your algorithm so that you can watch your code work. For this to happen, be sure that your *for* loop calls the *animate* method. The arguments that you send to *animate* will differ depending on the task you are coding. Detailed instructions for each task are included in the code.

To test your code, compile *ArrayPractice1Controller.java* and run the *ArrayPractice1Application* source code. **Figure 8.18** shows the graphics window when the program begins. Because the values of the array are randomly generated, the values will be different each time the program runs. To test any method, click the appropriate button.

Figure 8.18 The Graphics Window When the Application Begins

Description

Troubleshooting

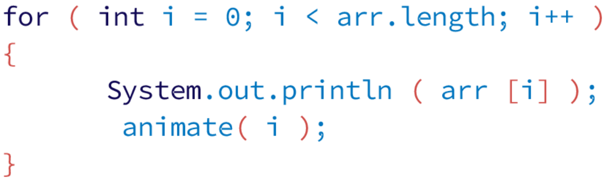
If your method implementation does not animate, follow these tips:

- Verify that the last statement in your *for* loop is a call to the *animate* method and that you passed the appropriate arguments to the *animate* method.
- Verify that your *for* loop has curly braces. For example, the *animate* method call is outside the body of this *for* loop:

```
for ( int i = 0; i< arr.length; i++ )
      System.out.println ( arr [i] );
      animate( i ); // this statement is outside the for loop
```

Description

Remember that without curly braces, the *for* loop body consists of only the first statement following the *for* loop header. Enclosing both statements within curly braces will make the *animate* method call part of the *for* loop body.



```
for ( int i = 0; i < arr.length; i++ )
{
       System.out.println ( arr [i] );
        animate( i );
}
```

Description

- Verify that you did not instantiate a new array. Perform all operations on the instance variable array named *arr*.

DISCUSSION QUESTIONS

1. Could you use the following *for* loop header in every method? Explain why or why not.

```
for ( int i = 0; i < arr.length; i++ )
```

Description

2. How would you modify the *findMinimum* method to return the index of the minimum value?

```
c1 =
$0.00 $0.00 $0.00 $0.00 $0.00 $0.00

c2 = 555-555-5555
$24.60 $48.75 $62.50

The highest bill is $62.50

The total of all bills is $135.85

c2 and c3 are equal

after client changes original array
c2 = 555-555-5555
$24.60 $48.75 $62.50

after client changes returned array
c2 = 555-555-5555
$24.60 $48.75 $62.50
```

```
The number of parameters is 2
args[0]: input.txt
args[1]: output.txt
```

8.5 Using Arrays in Classes

8.5.1 Using Arrays in User-Defined Classes

An array can be used inside a user-defined class just like any other variable. In particular,

- an array can be an instance variable.
- an array can be a parameter to a method.
- a method can return an array.
- an array can be a local variable inside a method.

To define a method that takes an array as a parameter, use this syntax:

```
accessModifier returnType methodName( dataType [ ] arrayName )
```

Description

The syntax for a method header that returns an array is

```
accessModifier dataType [ ] methodName( parameterList )
```

Description

To pass an array as an argument to a method, just use the array name without brackets as the argument value:

```
methodName( arrayName )
```

Description

COMMON ERROR TRAP

If we think of the brackets as being part of the data type of the array, then it’s easy to remember that the brackets are included in the method header—where the data types of parameters are given—but that brackets are not included in method calls, where the data itself is given.

In **Example 8.11**, we define a class named *CellPhone* that illustrates the use of arrays in a class.

Example 8.11 The *CellPhone* Class

```java
/** CellPhone class
*   Anderson, Franceschi
*/

import java.text.DecimalFormat;

public class CellPhone
{
  public final int MONTHS = 6; // default number of months
  private String phoneNumber;
  private double [ ] cellBills;

  /** Default constructor
  *   creates cellBills with MONTHS elements
  */
  public CellPhone( )
  {
     phoneNumber = "";
     cellBills = new double [MONTHS];
  }

  /** Constructor
  *  @param phoneNumber cell phone number
  *  @param cellBills array of monthly bills
  */
  public CellPhone( String phoneNumber, double [ ] cellBills )
  {
    this.phoneNumber = phoneNumber;

    // instantiate array with same length as parameter
    this.cellBills = new double [cellBills.length];

    // copy parameter array to cellBills array
    for ( int i = 0; i < cellBills.length; i++ )
    {
      this.cellBills[i] = cellBills[i];
    }
  }

  /** Accessor for the phone number
  *   @return the phone number
  */
  public String getPhoneNumber( )
  {
    return phoneNumber;
  }

  /** Accessor for the cell phone bills
  *   @return copy of cellBills array
  */
  public double [ ] getCellBills( )
  {
    double [ ] temp = new double [cellBills.length];
    for ( int i = 0; i < cellBills.length; i ++ )
    {
      temp[i] = cellBills[i];
    }
    return temp;
  }

  /**  Calculates total of all cell phone bills
  *    @return total of all elements in cellBills array
  */
  public double calcTotalBills( )
  {
     double total = 0.0; // initialize total to 0.0

     for ( int i = 0; i < cellBills.length; i++ )
     {
       total += cellBills[i]; // add current element to total
     }
     return total;
  }

  /** Finds a maximum bill
  *  @return largest value in cellBills array
  */
  public double findMaximumBill( )
  {
     double max = cellBills[0]; // assume first element is max

     for ( int i = 1; i < cellBills.length; i++ )
     {
        if ( cellBills[i] > max )
           max = cellBills[i]; // save new maximum
     }
     return max;
  }

   /** Returns printable version of CellPhone object
   *   @return phone number plus each month's bill
   */
   @Override
   public String toString( )
   {
     String returnValue = phoneNumber + "\n";
     DecimalFormat money = new DecimalFormat( "$##0.00" );
    for ( int i = 0; i < cellBills.length; i++ )
    {
        returnValue += money.format( cellBills[i] ) + "\t";
    }
    returnValue += "\n";

    return returnValue;
  }

  /**  Compares two CellPhone objects for equality
  *   @param c CellPhone object
  *   @return true if objects are equal; false, otherwise
  */
  @Override
  public boolean equals( Object c )
  {
    if ( !( c instanceof CellPhone ) )
        return false;
    else
    {
        CellPhone objCP = ( CellPhone ) c;
        if ( !( phoneNumber.equals( objCP.phoneNumber ) ) )
          return false;

        if ( cellBills.length != objCP.cellBills.length )
          return false; // arrays are not the same length

        for ( int i = 0; i < cellBills.length; i++ )
        {
           if ( cellBills[i] != objCP.cellBills[i] )
             return false;
        }
        return true;
    }
  }
}
```

Description

Our *CellPhone* class defines three instance variables in lines 9–11: the phone number (a *String* named *phoneNumber*), monthly bills (an array of *doubles* named *cellBills*), and a constant named *MONTHS*, whose value, 6, represents the number of monthly cell bills, and therefore the length of the *cellBills* array if a *CellPhone* object is instantiated using the default constructor. Note that since *MONTHS* is a constant, we made it *public*.

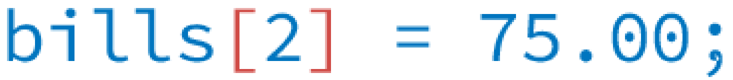
When our class has instance variables that are arrays, we need to take a little extra care to ensure that encapsulation is not violated.

Let's start with initialization of the array. The overloaded constructor of the *CellPhone* class, whose method header is at line 26, includes an array parameter. With parameters of primitive types, the constructor can simply assign the value of the parameter to the instance variable. As we have seen, however, the name of an array is an object reference, which contains the location of the array in memory. If the constructor merely assigns the array parameter, *cellBills*, to our array instance variable, *cellBills*, as in the following code:

```
this.cellBills = cellBills; // incorrect! Client still has reference!
```

Description

then the parameter *cellBills* and the instance variable *cellBills* would point to the same array. That means that the client still has a reference to the array, and the client can change the array values without going through the mutator methods of the class. For example, if the client executes this statement:



```
bills[2] = 75.00;
```

Description

then *cellBills[2]* also gets the value 75.00, because they are the same array. This is clearly a violation of encapsulation, which means that a client should be able to change the *private* fields of a class only by calling the mutator methods of the class.

SOFTWARE ENGINEERING TIP

Sharing array references with the client violates encapsulation. To return an array from a method, copy the elements of the instance variable array to a temporary array and return a reference to the temporary array. Similarly, to accept an array as a parameter to a method, instantiate a new array and copy the elements of the parameter array to the new array.

To avoid this problem, our constructor instantiates a new *cellBills* array that is the same size as the array passed as a parameter, and then copies the elements of the parameter array into the new *cellBills* array (lines 30–37).

There are similar considerations in implementing the accessor method of an array instance variable. With instance variables of primitive types, the accessor methods simply return the value of the instance variable. Our accessor for *cellBills* (lines 48–59) has an array as a return value. If we return the *cellBills* reference, however, we run into the same problem with encapsulation; that is, if our accessor for the *cellBills* instance variable uses this statement:

```
return cellBills; // incorrect! Client has reference to instance variable
```

Description

we give the client a reference to the *cellBills* array, and the client can directly change the values of the array without calling the mutator methods of the class. Just as the constructor instantiated a new array and copied the parameter array's value to the new array, the accessor method should instantiate a new array, copy the *cellBills* array to it, and return a reference to the new array. Thus, at line 53, we declare and instantiate a local array variable named *temp*. At lines 54–57, we copy the contents of *cellBills* into *temp*, and return *temp* at line 58.

We also provide a method *calcTotalBills* (lines 61–73) that calculates the total of the monthly bills using the accumulation technique discussed earlier in the chapter and a *findMaximumBill* method (lines 75–88), which finds a maximum value in the *cellBills* array, also using techniques discussed earlier in the chapter.

Our *toString* method (lines 90–105) builds up a *String* named *returnValue* by first including *phoneNumber*, then formatting each bill using a *DecimalFormat* pattern for money and concatenating that value, plus a tab, to *returnValue*.

The *equals* method (lines 107–132) compares the phone number and each element of the *cellBills* array in the object with the phone number and corresponding element in the *cellBills* array in the parameter object.

We can test our *CellPhone* class with the client class shown in **Example 8.12**. The output is shown in **Figure 8.19**.

Example 8.12 The *CellPhoneClient* Class

```java
/**  Client to exercise the CellPhone class
*    Anderson, Franceschi
*/

import java.text.DecimalFormat;

public class CellPhoneClient
{
   public static void main( String [ ] args )
   {
     double [ ] bills = new double[3]; // array of cell phone bills
     bills[0] = 24.60; // assign values
     bills[1] = 48.75;
     bills[2] = 62.50;

     // instantiate CellPhone object using default constructor
     CellPhone c1 = new CellPhone( );

     // instantiate two identical CellPhone objects
     CellPhone c2 = new CellPhone( "555-555-5555", bills );
     CellPhone c3 = new CellPhone( "555-555-5555", bills );

     // print data from c1 and c2
     System.out.println( "c1 = " + c1.toString( ) );
     System.out.println( "c2 = " + c2.toString( ) );

     // find and print maximum bill
     DecimalFormat money = new DecimalFormat( "$##0.00" );
     System.out.println( "\nThe highest bill is "
                    + money.format( c2.findMaximumBill( ) ) );

     // find and print total of all bills
     System.out.println( "\nThe total of all bills is "
                    + money.format( c2.calcTotalBills( ) ) );

     System.out.println( ); // print blank line
     // call equals method
     if ( c2.equals( c3 ) )
         System.out.println( "c2 and c3 are equal" );
     else
         System.out.println( "c2 and c3 are not equal" );

     // test encapsulation
     // set new value in original array
     bills[2] = 100.00;
     // print c2 to show value in object not changed
     System.out.println( "\nafter client changes original array\n"
                           + "c2 = " + c2.toString( ) );

     // test encapsulation further
     // get array of cell bills and store in new array
     double [ ] billsCopy = c2.getCellBills( );

     billsCopy[1] = 50.00; // change value of one element
     // print c2 to show value in object not changed
     System.out.println( "\nafter client changes returned array\n"
                        + "c2 = " + c2.toString( ) );
  }
}
```

Description

Figure 8.19 Output from the *CellPhoneClient* Class

Description

In the *CellPhoneClient*, we instantiate three *CellPhone* objects. We instantiate *c1* using the default constructor (line 17), giving it an empty phone number and six months of bills initialized to 0.00, as shown in line 24, when we use the *toString* method to print *c1's* data. We set up a *bills* array with three values (lines 11–14) and pass *bills* to the overloaded constructor (lines 20–21) to instantiate *c2* and *c3* with identical data. We then use *toString* to print *c2's* data (line 25).

We then call the *findMaximumBill* method and print its return value (lines 27–30). Next, we call the *calcTotalBills* method and print its return value (lines 32–34).

A call to the *equals* method to compare *c2* and *c3* (lines 37–41) returns a value of *true*, because the two objects have the same data.

Finally, we test encapsulation two ways. First, we change a value in the *bills* array, then print *c2* again to verify that its data has not changed (lines 43–48). Second, we call the accessor method for the *cellBills* array and change a value in the array returned from the method call. We again print *c2* to verify that its data is unchanged (lines 50–57). Testing the *CellPhone* class with such an example is helpful in checking that we have correctly implemented the class.

8.5.2 Retrieving Command Line Arguments

The syntax of an array parameter for a method might look familiar to you. We've seen it repeatedly in Java applications in the header for the *main* method:

```
public static void main( String [ ] args )
```

Description

As we can see, *main* receives a *String* array as a parameter. That array of *Strings* holds the arguments, if any, that the user sends to the program from the command line. An argument might be the name of a file for the program to read or some configuration parameters that specify preferences in how the application should perform its function.

The sample program in **Example 8.13** demonstrates how to retrieve the parameters sent to a Java application. Because *args* is a *String* array, we can use the *length* field to get the number of parameters (lines 8–9), and we use our standard *for* loop format (lines 10–13) to retrieve and print each parameter, as shown in **Figure 8.20**.

Example 8.13 Retrieving Command Line Arguments

```
 1 /** Print Command Line arguments
 2 *   Anderson, Franceschi
 3 */
 4 public class CommandLineArguments
 5 {
 6   public static void main( String [ ] args )
 7   {
 8     System.out.println( "The number of parameters is "
 9                              + args.length );
10     for ( int i = 0; i < args.length; i ++ )
11     {
12         System.out.println( "args[" + i + "]: " + args[i] );
13     }
14   }
15 }
```

Description

Figure 8.20 Output from Example 8.13

Description

Figure 8.20 shows the output produced when we invoke the program as

```
java CommandLineArguments input.txt output.txt
```

8.6 Searching and Sorting Arrays

Arrays are great instruments for storing a large number of related values. As seen earlier in this chapter, we can use arrays to store daily temperatures, CD titles, telephone bills, quiz grades, and other sets of related values. Once the data is stored in an array, we will want to manipulate that data. A very common operation is searching an array for a specific value.

8.6.1 Sequential Search of an Unsorted Array

Let's assume we manage a movie theater. We give each customer a frequent moviegoer card with a unique member ID. We have decided to pick four member IDs at random and give those members a free gift the next time they visit the theater. So we set up a *MovieWinners* class with two array instance variables:

- An array of *ints* that holds the member IDs of the winners
- An array of *Strings* that holds the corresponding prizes

Note that both arrays have four elements and that there is a one-to-one correspondence between the two arrays. Winner #1 will receive prize #1, winner #2 will receive prize #2, and so on. This programming technique is called using **parallel arrays**.

We fill the *winners* array with member IDs chosen randomly. We fill the *prizes* array with *Strings* representing prize descriptions. When a member buys a movie ticket, we look through the *winners* array for the member's ID. If the member's ID is in the *winners* array, we use its index to retrieve the corresponding prize from the *prizes* array that the member won. If the member ID is not found in the array, we know the member is not a winner.

The *MovieWinners* class is shown in **Example 8.14**.

Example 8.14 The *MovieWinners* Class

```java
/** Winners of Free Movies and Other Prizes
*   Anderson, Franceschi
*/

import java.util.Random;

public class MovieWinners
{
   public final int MEMBERS = 5000;
   // array to hold winning member numbers chosen at random
   private int [ ] winners;
   // parallel array that holds prizes
   private String [ ] prizes = { "2 free movie tickets!",
                                 "1 free movie ticket!",
                                 "free popcorn!",
                                 "free box of candy!" };
   /** Default constructor instantiates winners array
   * and randomly generates winning member IDs
   */
   public MovieWinners( )
   {
     winners = new int [prizes.length];
     fillWinners( ); // generate winner member IDs
   }

   /** Utility method generates winner member IDs
   *     and stores them in the winners array
   */
   private void fillWinners( )
   {
     Random rand = new Random( );
     for ( int i = 0; i < winners.length; i++ )
     {
       winners[i] = rand.nextInt( MEMBERS ) + 1;
     }
   }

   /** Calls indexOfWinner with the member number
   *   then translates return value into the prize won
   *   @param memberNumber value to find
   *   @return prize
   */
   public String getPrize( int memberNumber )
   {
     int prizeIndex = indexOfWinner( memberNumber );
     if ( prizeIndex == -1 )
         return "Sorry, member is not a winner.";
     else
         return "You win " + prizes[prizeIndex];
   }

   /** Performs sequential search of winners array
   *   @param key member ID to find in winners array
   *   @return index of key if found, -1 if not found
   */
   private int indexOfWinner( int key )
   {
     for ( int i = 0; i < winners.length; i++ )
     {
        if ( winners[i] == key )
           return i;
     }
     return -1;
   }

   /** Returns printable version of MovieWinners object
   *   @return winning numbers separated by a tab
   */
  @Override
  public String toString( )
  {
     String returnValue = "";
     for ( int i = 0; i < winners.length; i++ )
     {
       returnValue += winners[i] + "\t";
     }
     return returnValue;
   }
}
```

Description

The constructor randomly generates values to fill the array by calling the utility method, *fillWinners* (lines 26–36). In the interest of keeping things simple, we have coded the *fillWinners* method in such a way that it does not necessarily generate different numbers; however, the likelihood of two winning numbers being equal is very small. We declare the *fillWinners* method as *private* because it is designed to be called only by the methods of this class.

Our *indexOfWinner* method (lines 52–64) performs a **Sequential Search**, which compares the member ID to each element in the array one by one. The *indexOfWinner* method accepts a parameter, *key*, which is the member ID to search for in the array. If *key* is found, *indexOfWinner* returns the index of that array element. If *key* is not found, that is, if none of the elements in the array matches the value of *key*, *indexOfWinner* returns −1. Since −1 is not a valid array index, it’s a good value to use to indicate that the search was unsuccessful.

Notice that if the current array element matches the *key*, the *indexOfWinner* method returns immediately to the caller (line 61); that is, the method stops executing. The return value is the index of the element that matched the *key*. If, however, the method finishes executing all iterations of the *for* loop, then the method has looked at every element in the array without finding a match. In that case, the method returns −1 (line 63), indicating that the *key* was not found.

Our *getPrize* method (lines 38–50) calls *indexOfWinner* to check if its *memberNumber* parameter is a winning number; if it is, it uses the array index returned by *indexOfWinner* to return the corresponding element in the array *prizes* (line 49).

Example 8.15 shows a client application that uses our *MovieWinners* class.

Example 8.15 Client Application for the *MovieWinners* Class

```
 1 /** Client for the MovieWinners class
 2     Anderson, Franceschi
 3 */
 4 import java.util.Scanner;
 5
 6 public class MovieWinnersClient
 7 {
 8   public static void main( String [ ] args )
 9   {
10     // instantiate the winningIDs array
11     MovieWinners winningIDs = new MovieWinners( );
12
13     // prompt for the member ID
14     Scanner scan = new Scanner( System.in );
15     System.out.print( "Enter the member's ID "
16                           + "or 0 to stop > " );
17     int searchID = scan.nextInt( );
18
19     while ( searchID != 0 )
20     {
21       // determine whether member is a winner
22       System.out.println( winningIDs.getPrize( searchID ) );
23
24       System.out.print( "\nEnter the next member's ID "
25                             + "or 0 to stop > " );
26       searchID = scan.nextInt( );
27     }
28
29     System.out.println( "\nThe winners were "
30                            + winningIDs.toString( ) );
31   }
32 }
```

Description

SOFTWARE ENGINEERING TIP

When you write a class that uses corresponding lists of items with different data types, consider using parallel arrays.

We instantiate a *MovieWinners* object reference named *winningIDs* (lines 10–11). We then prompt for a member ID (lines 15–17) and call the *getPrize* method (line 22) in order to output any prize that may have been won by the current member. **Figure 8.21** shows a possible output of running the *MovieWinnersClient* application.

Figure 8.21 Output of Example 8.15

Description

8.6.2 Selection Sort

The member IDs in the preceding *winners* array were in random order, so when a member was not a winner, our *findWinners* method needed to look at every element in the array before discovering that the ID we were looking for was not in the array. This is not efficient, since most members are not winners. The larger the array, the more inefficient a sequential search becomes. We could simplify the search by arranging the elements in numeric order, which is called **sorting the array**. Once the array is sorted, we can use various algorithms to speed up a search. Later in this chapter, we discuss how to search a sorted array.

In this chapter, we present two basic sorting algorithms, **Selection Sort** and **Insertion Sort**.

Selection Sort derives its name from the algorithm used to sort the array. We select the largest element in the array and place it at the end of the array. Then we select the next-largest element and put it in the next-to-last position in the array. To do this, we consider the unsorted portion of the array as a **subarray**. We repeatedly select the largest value in the current subarray and move it to the end of the subarray, then consider a new subarray by eliminating the elements that are in their sorted locations, until the subarray has only one element. At that time, the array is sorted.

In more formal terms, we can state the Selection Sort algorithm, presented here in pseudocode, in this way:

```
To sort an array with n elements in ascending order:
1. Consider m elements as a subarray with m = n elements.
2. Find the index of the largest value in this subarray.
3. Swap the values of the element with the largest value and the
   element in the last position in the subarray.
4. Consider a new subarray of m = m - 1 elements by eliminating
   the last element in the previous subarray.
5. Repeat steps 2 through 4 until m = 1.
```

Description

For example, let’s walk through a Selection Sort on the following array. At the beginning, the entire array is the subarray (shown here with shading).

We begin by considering the entire array as an unsorted subarray. We find that the largest element is 26 at index 1.

Description

Next we move element 1 to the last element by swapping the values of the elements at indexes 1 and 3.

The value 26 is now in the right place, and we consider elements 0 through 2 as the unsorted subarray.

Description

The largest element in the new subarray is 17 at index 0. So we move element 0 to the last index of the subarray (index 2) by swapping the elements at indexes 0 and 2.

The value 17 is now in the right place, and we consider elements 0 and 1 as the new unsorted subarray.

Description

The largest element in the new subarray is 5 at index 0. We move element 0 to the last index of the subarray (index 1) by swapping the elements at indexes 0 and 1.

The value 5 is now in the right place, and we consider element 0 as the new subarray. But because there is only one element in the subarray, the subarray is sorted. Thus the whole array is sorted, and our job is done.

Description

A critical operation in a Selection Sort is swapping two array elements. Before going further, let’s examine the algorithm for swapping two array elements.

To swap two values, we need to define a temporary variable that is of the same data type as the values being swapped. This variable will temporarily hold the value of one of the elements, so that we don’t lose the value during the swap.

The algorithm, presented here in pseudocode, involves three steps:

```
To swap elements a and b:
1. Assign the value of element a to the temporary variable.
2. Assign the value of element b to element a.
3. Assign the value in the temporary variable to element b.
```

Description

For instance, if an *array* named *array* has *int* elements, and we want to swap the element at index 3 with the element at index 6, we will use the following code:

Description

The order of these operations is critical; changing the order might result in loss of data and erroneous data stored in the array.

The following illustrates line by line what happens during the swap:

Before line 1 is executed, our array looks like this:

Description

Line 1 assigns the value of element 3 to *temp*. After line 1 is executed, the value of *temp* is 33. The array is unchanged.

Description

Line 2 assigns the value of element 6 (82) to element 3. After line 2 is executed, both element 6 and element 3 have the same value. But that's OK, because we saved the value of element 3 in *temp*.

Description

COMMON ERROR TRAP

When swapping elements, be sure to save a value before replacing it with another value to avoid losing data.

Line 3 assigns the value we saved in *temp* to element 6. After line 3 is executed, the values of elements 3 and 6 have been successfully swapped.

Description

Example 8.16 shows the *Sorter* class, which provides a *static selectionSort* method for an integer array.

Example 8.16 The *Sorter* Class

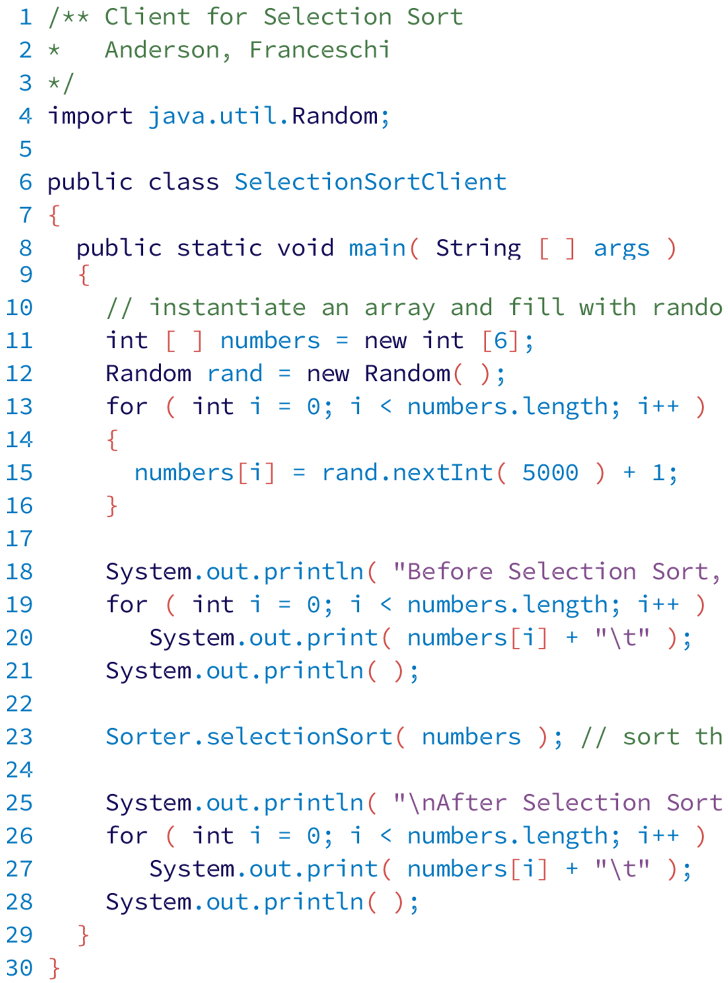
```
 1 /* Sort Utility Class
 2 *  Anderson, Franceschi
 3 */
 4
 5 public class Sorter
 6 {
 7   /**  Uses Selection Sort to sort
 8   *      an integer array in ascending order
 9   *    @param array the array to sort
10   */
11   public static void selectionSort( int [ ] array )
12   {
13     int temp; // temporary location for swap
14     int max; // index of maximum value in subarray
15
16     for ( int i = 0; i < array.length - 1; i++ )
17     {
18       // find index of largest value in subarray
19       max = indexOfLargestElement( array, array.length - i );
20
21       // swap array[max] and array[array.length - i - 1]
22       temp = array[max];
23       array[max] = array[array.length - i - 1];
24       array[array.length - i - 1] = temp;
25     }
26   }
27
28   /**  Finds index of largest element
29   *    @param    size the size of the subarray
30   *    @param    array the array to search
31   *    @return   the index of the largest element in the subarray
32   */
33   private static int indexOfLargestElement( int [ ] array, int size )
34   {
35     int index = 0;
36     for ( int i = 1; i < size; i++ )
37     {
38        if ( array[i] > array[index] )
39           index = i;
40     }
41     return index;
42   }
43 }
```

Description

Part of the Selection Sort algorithm is finding the index of the largest element in a subarray, so we implement the Selection Sort with two methods. At lines 7–26 is the *selectionSort* method, which implements the Selection Sort algorithm. To perform its work, the *selectionSort* method calls the utility method, *indexOfLargestElement* (lines 28–42), which returns the index of the largest element in a subarray. This method uses the algorithm discussed earlier in the chapter for finding a maximum value in an array. We declare this method *private* because its only function is to provide a service to the *selectionSort* method. The *indexOfLargestElement* method must also be declared as *static* because the *selectionSort* method is *static*, and thus can call only *static* methods.

In **Example 8.17**, the client code instantiates an integer array and prints the array before and after the Selection Sort is performed. Because *selectionSort* is a *static* method, we call it using the *Sorter* class name. The output of a sample run is shown in **Figure 8.22**.

Example 8.17 Using Selection Sort



```java
/** Client for Selection Sort
*   Anderson, Franceschi
*/
import java.util.Random;

public class SelectionSortClient
{
  public static void main( String [ ] args )
  {
    // instantiate an array and fill with rando
    int [ ] numbers = new int [6];
    Random rand = new Random( );
    for ( int i = 0; i < numbers.length; i++ )
    {
      numbers[i] = rand.nextInt( 5000 ) + 1;
    }

    System.out.println( "Before Selection Sort,
    for ( int i = 0; i < numbers.length; i++ )
       System.out.print( numbers[i] + "\t" );
    System.out.println( );

    Sorter.selectionSort( numbers ); // sort th

    System.out.println( "\nAfter Selection Sort
    for ( int i = 0; i < numbers.length; i++ )
       System.out.print( numbers[i] + "\t" );
    System.out.println( );
  }
}
```

Description

Figure 8.22 Using Selection Sort

Description

8.6.3 Insertion Sort

Like Selection Sort, Insertion Sort derives its name from the algorithm used to sort the array. The basic approach to an Insertion Sort is to sort elements much like a card player arranges the cards in sorted order in his or her hand. The player inserts cards one at a time in such a way that the cards on the left side of his or her hand are sorted at all times; the cards on the right side of his or her hand have not yet been inserted into the sorted part of the hand. As **Figure 8.23a** shows, the three yellow cards on the left (3, 5, and 9) are already arranged in sorted order, and the white cards on the right (4, 2, and 8) have yet to be inserted into their correct location. Note that the "sorted" yellow cards on the left side are not necessarily in their final position yet. We will now insert the 4. We first compare it to the 9; since 4 is smaller than 9, we shift the 9 to the right (Figure 8.23b). We then compare the 4 to the 5; since 4 is smaller than 5, we shift the 5 to the right (Figure 8.23c). We then compare the 4 to the 3; since 4 is larger than 3, the 3 stays in place and we insert the 4 in the empty slot (Figure 8.23d). We are now ready to insert the next card, the 2.

Figure 8.23a The next card to insert is a 4

Description

Figure 8.23b 9 is shifted to the right

Description

Figure 8.23c 5 is shifted to the right

Description

Figure 8.23d 4 is inserted

Description

To sort an array of *n* elements in ascending order, Insertion Sort implements a double loop:

- The outer loop executes $n - 1$ times and iterates through the array elements from indexes 1 through $n - 1$. If the variable *i* represents the counter of the outer loop, the array can be thought of as made of three parts:
    - a sorted subarray (although the elements may not be in their final position yet) from index 0 to $i - 1$,

  - the array element (at index *i*) that we are currently inserting, and
  - a subarray (from index *i* + 1 to *n* – 1) of elements that have not yet been inserted.

- At each iteration of the outer loop, we insert the current array element at its proper place within the sorted subarray. The inner loop compares the current array element to the elements of the sorted array from right to left and shifts these elements to the right until it finds the proper insert location.
- After all elements have been inserted, the array is sorted.

The pseudocode for the Insertion Sort is

```
for i = 1 to last array index by 1
     j = i
     temp = element at index i
     while ( j != 0 and value of element at index j - 1 > temp)
           shift element at index j - 1 to the right
           decrement j by 1
     assign value stored in temp to element at index j
```

Description

For example, let's walk through an Insertion Sort on the following array. At the beginning, the unsorted array is

Description

The first element of the array, 17, is automatically in the correct position when we consider the subarray as consisting of that element only. The value of the outer loop counter (*i*) is 1, and we will now insert the second array element, 26, into the left subarray. First, we save the value of the element to be inserted by storing it in *temp*. We need to save the value because it is possible that we will shift other values, in which case we would overwrite that element. The value of the inner loop counter (*j*) is set to the value of the outer loop counter (*i*), i.e., 1. We compare elements 26 (index *j* = 1) and 17 (index *j* – 1 = 0). Since 26 is larger than 17, we exit the inner loop (and therefore we do not shift 17 to the right). We then assign the value of the current element, 26, stored in *temp*, to the element at index *j* = 1; in this case, there is no change to the array. The value 26 has been inserted.

The outer loop counter (*i*) is incremented, and its value is 2. We will now insert the third array element, 5, into the left subarray (at this point comprised of the two inserted elements, 17 and 26).

Description

The value of the inner loop counter (*j*) is set to the value of the outer loop counter (*i*), i.e., 2. We compare the current element, 5, stored in *temp*, and 26 (index *j* – 1 = 1). Since 5 is smaller than 26, we shift 26 to the right and decrement *j* by 1; *j* now has the value 1.

Description

We then compare the current element, 5, stored in *temp*, and 17 (index *j* – 1 = 0). Since 5 is smaller than 17, we shift 17 to the right and decrement *j* by 1; *j* now has the value 0.

Description

Since *j* is 0, we exit the inner loop and assign the value of the current element, 5, stored in *temp,* to the array element at index *j* = 0. The value 5 has now been inserted.

Description

The outer loop counter (*i*) is incremented, and its value is 3. We will now insert the fourth array element, 12, into the left subarray (at this point comprising the three inserted elements, 5, 17, and 26).

Description

The value of the inner loop counter (*j*) is set to the value of the outer loop counter (i), i.e., 3. We compare the current element, 12, stored in *temp,* and 26 (index *j* – 1 = 2). Since 12 is smaller than 26, we shift 26 to the right and decrement *j* by 1; *j* now has the value 2.

Description

We then compare the current element, 12, stored in *temp,* and 17 (index *j* – 1 = 1). Since 12 is smaller than 17, we shift 17 to the right and decrement *j* by 1; *j* now has the value 1.

Description

We then compare the current element, 12, stored in *temp,* and 5 (index *j* – 1 = 0). Since 12 is not smaller than 5, we exit the inner loop; we then assign the value of the current element, stored in *temp,* to the element at index *j* = 1; the value 12 has been inserted.

Description

The outer loop counter (*i*) is incremented, and its value is 4, which causes the outer loop to terminate. All the elements have been inserted; the array is now sorted.

COMMON ERROR TRAP

When looping through an array, be careful not to access an element outside the bounds of the array. Your code will compile, but will generate an *ArrayIndexOutOfBoundsException* at run time.

Example 8.18 shows our *Sorter* class with the Insertion Sort algorithm implemented in lines 43–63.

Example 8.18 *Sorter* Class with Insertion Sort

```
/* Sort Utility Class
   Anderson, Franceschi
*/

public class Sorter
{
  /**  Performs a Selection Sort on
  *      an integer array
  *    @param the array to sort
 */
 public static void selectionSort( int [ ] array )
 {
    int temp; // temporary location for swap
    int max; // index of maximum value in subarray

    for ( int i = 0; i < array.length - 1; i++ )
    {
      // find index of largest value in subarray
      max = indexOfLargestElement( array, array.length - i );

      // swap array[max] and array[array.length - i - 1]
      temp = array[max];
      array[max] = array[array.length - i - 1];
      array[array.length - i - 1] = temp;
    }
  }

  /**  Finds index of largest element
  *    @param     size the size of the subarray
  *    @return    the index of the largest element in the subarray
  */
  private static int indexOfLargestElement( int [ ] array, int size )
  {
     int index = 0;
     for ( int i = 1; i < size; i++ )
     {
         if ( array[i] > array[index] )
            index = i;
     }
     return index;
  }

  /**  Performs an Insertion Sort on an integer array
  *    @param array array to sort
  */
  public static void insertionSort( int [ ] array )
  {
    int j, temp;

    for ( int i = 1; i < array.length; i++ )
    {
       j = i;
       temp = array[i];

       while ( j != 0 && array[j - 1] > temp )
       {
          array[j] = array[j - 1];
          j--;
       }

       array[j] = temp;
    }
  }
}
```

Description

Example 8.19 shows a client program that instantiates an integer array, fills it with random values, and then prints the array before and after performing the Insertion Sort. **Figure 8.24**. shows a sample run, using the Insertion Sort algorithm to sort an array of integers.

Example 8.19 Using Insertion Sort

```
/** Client for Insertion Sort
*   Anderson, Franceschi
*/
import java.util.Random;

public class InsertionSortClient
{
  public static void main( String [ ] args )
  {
    // instantiate an array and fill with random values
    int [ ] numbers = new int [6];
    Random rand = new Random( );
    for ( int i = 0; i < numbers.length; i++ )
    {
      numbers[i] = rand.nextInt( 5000 ) + 1;
    }

    System.out.println( "Before Insertion Sort, the array is" );
    for ( int i = 0; i < numbers.length; i++ )
       System.out.print( numbers[i] + "\t" );
    System.out.println( );

    Sorter.insertionSort( numbers ); // sort the array

    System.out.println( "\nAfter Insertion Sort, the array is" );
    for ( int i = 0; i < numbers.length; i++ )
         System.out.print( numbers[i] + "\t" );
    System.out.println( );
  }
}
```

Description

Figure 8.24 Using Insertion Sort

Description

8.6.4 Sorting Arrays of Objects

We saw earlier in the chapter that data items to be sorted can be primitive data types, such as integers or *doubles*. But they can also be objects. With an array of objects, it is important to understand that we need to sort the objects themselves, not the array elements, which are merely the object references, or memory locations of the objects.

Arrays of objects are sorted using a sort key, which is one or more of the instance variables of the objects. For instance, if we have email objects, they can be sorted by date received, by author, by subject, and so on. It is important to note that when we sort objects, the integrity of the objects must be respected; for instance, when we sort a collection of email objects by sender, we sort a collection of email objects, not a collection of senders.

Thus, to perform the Insertion Sort on the *cars* array of *Auto* objects, we need to decide which field (or fields) of the *Auto* object determines the order of the objects. If we say that the *model* is the sort field, then the comparison statement would compare the models in two objects, that is, two *Strings*. The *compareTo* method of the *String* class compares the values of two *Strings.* It returns a positive number if the *String* for which the method is invoked is greater than the *String* passed as an argument.

To sort the *cars* array using an Insertion Sort, we would need to make several revisions to the *InsertionSort* method. First, the data type of the array must be declared as an *Auto* in the parameter list. Second, *temp* needs to be defined as an *Auto* reference, and finally, we need to substitute the *compareTo* method in the condition that compares array elements.

The revised Insertion Sort code becomes:

```
   /* * Insertion sorts an array of Autos
   *      @param arr an array of Autos
   */
   public static void insertionSort( Auto [ ] arr )
   {
      Auto temp;
      int j;

   for ( int i = 1; i < arr.length; i++ )
   {
       j = i;
       temp = arr[i];

       while ( j != 0 && ( temp.getModel( ) ).compareTo(
               arr[j - 1].getModel( ) ) < 0 )
       {
            arr[j] = arr[j - 1];
            j--;
       } // end while loop

       arr[j] = temp;

   } // end for loop
}    // end InsertionSort method
```

Description

8.6.5 Sequential Search of a Sorted Array

Earlier in the chapter, the *MovieWinners* class sequentially searched an array. The algorithm assumed the elements were not in order. If we sort the array, a Sequential Search can be implemented more efficiently for the case when the search key is not present in the array. Instead of searching the entire array before discovering that the search key is not in the array, we can stop as soon as we pass the location where that element would be if it were in the array. In other words, if the array is sorted in ascending order, we can recognize an unsuccessful search when we find an element in the array that is greater than the search key. Because the array is sorted in ascending order, all the elements after that array element are larger than that element, and therefore are also larger than the search key.

To implement this algorithm, we can add another test to the *for* loop condition, so that we exit the loop as soon as we find an element that is greater than the search key. The improved algorithm shown next could be used to replace the *indexOfWinner* method shown in Example 8.14 for Sequential Search of a sorted *winners* array:

```
public int indexOfWinner( int key )
{
  for ( int i = 0; i < winners.length && winners[i] <= key; i++ )
  {
    if ( winners[i] == key )
    return i;
  }

  return -1; // end of array reached without finding key
             // or an element larger than the key was found
}
```

Description

In fact, if the array is sorted, it can be searched even more efficiently using an algorithm called Binary Search, which we explain in the next section.

8.6.6 Binary Search of a Sorted Array

If you've played the "Guess a Number" game, you probably have used the concept of a **Binary Search.** In this game, someone asks you to guess a secret number between 1 and 100. For each number you guess, they tell you whether the secret number is larger or smaller than your guess. A good strategy is to guess the number in the middle, which in this example is 50. Whether the secret number is larger or smaller than 50, you will have eliminated half of the possible values. If the secret number is greater than 50, then you know your next guess should be 75 (halfway between 50 and 100). If the secret number is less than 50, your next guess should be 25 (halfway between 1 and 50). If you continue eliminating half the possible numbers with each guess, you will quickly guess the secret number. This approach works because we are "searching" a sorted set of numbers (1 to 100).

Similarly, a Binary Search of a sorted array works by eliminating half the remaining elements with each comparison. First, we look at the middle element of the array. If the value of that element is the search key, we return its index. If, however, the value of the middle element is greater than the search key, then the search key cannot be found in elements with array indexes higher than that element. Therefore, we will search the left half of the array only. Similarly, if the value of the middle element is lower than the search key, then the search key cannot be found in elements with array indexes lower than the middle element. Therefore, we will search in the right half of the array only. As we keep searching, the subarray we search keeps shrinking in size. In fact, the size of the subarray we search is cut in half at every iteration.

If the search key is not in the array, the subarray we search will eventually become empty. At that point, we know that we will not find our search key, and we return –1.

Example 8.20 shows our Binary Search algorithm.

Example 8.20 Binary Search of a Sorted Array

```
 1 /** Binary Search
 2 *   Anderson, Franceschi
 3 */
 4
 5  import java.util.Scanner;
 6
 7  public class BinarySearcher
 8  {
 9    public static void main( String [ ] args )
10    {
11      // define an array sorted in ascending order
12      int [ ] numbers = { 3, 6, 7, 8, 12, 15, 22, 36, 45,
13                         48, 51, 53, 64, 69, 72, 89, 95 };
14
15      Scanner scan = new Scanner( System.in );
16      System.out.print( "Enter a value to search for > " );
17      int key = scan.nextInt( );
18
19      int index = binarySearch( numbers, key );
20      if ( index != -1 )
21           System.out.println( key + " found at index " + index );
22      else
23           System.out.println( key + " not found" );
24    }
25
26    public static int binarySearch( int [ ] arr, int key )
27    {
28      int start = 0;
29      int end = arr.length - 1;
30      int middle;
31
32      while ( end >= start )
33      {
34        middle = ( start + end ) / 2; // element in middle of array
35
36        if ( arr[middle] == key )
37        {
38           return middle; // key found at middle
39        }
40        else if ( arr[middle] > key )
41        {
42           end = middle - 1; // search left side of array
43        }
44        else
45        {
46           start = middle + 1; // search right side of array
47        }
48      }
49      return -1;
50    }
51 }
```

Description

We start by declaring and initializing an integer array with 17 sorted elements (lines 12–13). We then prompt the user for a search key and call the *binarySearch* method (lines 16–19).

The *binarySearch* method is coded at lines 26–50. The local variables *start* and *end* store the first and last index of the subarray to search. Because we begin by searching the entire array, we initialize these to the indexes of the first and last element of the array that was passed as a parameter. The local variable *middle,* declared at line 30, will store the index of the middle element in the subarray to search.

The search is performed in a *while* loop (lines 32–48), whose condition determines whether the subarray is empty. If the subarray is not empty, we calculate the value for *middle* by adding the indexes of the first and last elements and dividing by 2 (line 34). Next we test whether the value at the *middle* index is equal to the key. If so, we have found the key and we return its index, which is *middle* (lines 36–39). If not, we test whether the value in the middle of the subarray is greater than the key. If so, if the key is in the array, it will be found in the left half of the array. Thus, we reduce the subarray to the elements with indexes less than *middle* (lines 40–43) and greater than or equal to *start.* If the value in the middle of the subarray is less than the key, then if the key is in the array, it will be found in the right half of the array. Thus, we reduce the subarray to the elements with indexes greater than *middle* (lines 44–47) and smaller than or equal to *end.*

When the *while* loop continues, we continue making our comparisons and either returning the index of the search key or reducing the size of the subarray. If the search key is not in the array, the subarray eventually becomes empty, and we exit the *while* loop and return –1 (line 49). **Figure 8.25** shows the output when the search key is found.

Figure 8.25 Output from Example 8.20

Description

Let’s run through the Binary Search algorithm on the key 7 to illustrate how the algorithm works when the key is found in the array. Here is the array *numbers:*

Description

When the *binarySearch* method is called, it sets *start* to 0 and *end to arr.length – 1,* which is 16. Thus, the value of *middle* is 8.

The element at index 8 (45) is greater than 7, so we set *end* to 7 (*middle* – 1), and we will now search the left subarray, highlighted next. The value of middle is now 3 ((0 + 7) / 2).

Description

The element at index 3 (8) is greater than 7, so we set *end* to 2 (*middle* – 1) and keep searching in the left subarray, highlighted next. The value of *middle* is now 1 ((0 + 2) / 2).

Description

The element at index 1 (6) is smaller than 7, so we set *start* to 2 (*middle* + 1) and search in the right subarray, highlighted next. The value of *middle* is now 2 ((2 + 2) / 2).

Description

The element at index 2 (7) is equal to 7. We have found the value and return its index, 2.

Let's now run the preceding example on the key 34 to illustrate how the algorithm works when the key is not found in the array.

Here is the array *numbers* again:

Description

Again, when the *binarySearch* method is called, it sets *start* to 0 and *end* to *arr.length* – 1, which is 16. Thus, *middle* is assigned the value 8 for the first comparison.

The element at index 8 (45) is greater than 34, so we set *end* to 7 (*middle* – 1), and keep searching in the left subarray. The value of *middle* becomes 3 for the next comparison.

Description

The element at index 3 (8) is smaller than 34, so we search in the right subarray highlighted below. The value of *middle* is now 5.

Description

The element at index 5 (15) is smaller than 34, so we search in the right subarray. The value of *middle* is now 6.

Description

The element at index 6 (22) is smaller than 34, so we search in the right subarray. The value of *middle* is now 7.

Description

At this point, *start, end,* and *middle* all have the value 7. The element at index 7 (36) is larger than 34, so we assign *end* the value *middle* – 1, which is 6. This makes *end less* than *start* and consequently makes the while loop condition evaluate to *false*. We have not found 34, so we return –1.

8.7 Programming Activity 2: Searching and Sorting Arrays

In this activity, you will work again with a 15-element integer array, performing these activities:

1. Write a method to perform a Sequential Search of an array.
2. Write a method to implement the Bubble Sort algorithm to sort an array.

The basic approach to a Bubble Sort is to make multiple passes through the array. In each pass, we compare adjacent elements. If any two adjacent elements are out of order, we put them in order by swapping their values.

To sort an array of n elements in ascending order, Bubble Sort implements a double loop:

- The outer loop executes $n - 1$ times.
- For each iteration of the outer loop, the inner loop steps through all the unsorted elements of the array and does the following:
  - Compares the current element with the next element in the array.
  - If the next element is smaller, it swaps the two elements.

At this point, $n - 1$ elements have been moved to their correct positions. That leaves only the element at index 0, which is therefore automatically at the correct position within the array. The array is now sorted.

As the outer loop counter goes from 0 to $n - 2$, it iterates $n - 1$ times.

Outer loop counter	**Indexes of element(s) at the sorted position**
0	$n - 1$
1	$n - 2, n - 1$
2	$n - 3, n - 2, n - 1$
…	…
$n - 3$	$2, 3, 4, \ldots, n - 3, n - 2, n - 1$
$n - 2$	$1, 2, 3, 4, \ldots, n - 3, n - 2, n - 1$

Description

The pseudocode for the Bubble Sort is

```
for i = 0 to last array index - 1 by 1
  for j = 0 to ( last array index - i -1 ) by 1
    if (2 consecutive elements are in the wrong order)
      swap them
```

Description

For example, let’s walk through a Bubble Sort on the following array. At the beginning, the unsorted array is

Description

The value of the outer loop counter (*i*) is 0, and the value of the inner loop counter (*j*) is also 0. We compare elements 17 (index *j* = 0) and 26 (index *j* + 1 = 1). Since 17 is smaller than 26, we do not swap them.

The inner loop counter (*j*) is incremented, and its value is now 1.

Description

We compare elements 26 (index *j* = 1) and 5 (index *j* + 1 = 2). Since 26 is larger than 5, we swap them. The inner loop counter (*j*) is incremented, and its value is now 2.

Description

We compare elements 26 (index *j* = 2) and 2 (index *j* + 1 = 3). Since 26 is larger than 2, we swap them.

The inner loop counter (*j*) is incremented, and its value is now 3; therefore, we exit the inner loop. (We have reached the end of the unsorted subarray, which at this point is the whole array.) At the end of one execution of the inner loop, the value 26 has “bubbled up” to its correct position within the array.

We now go back to the outer loop, and the outer loop counter (*i*) is incremented; its value is now 1. We reenter the inner loop, and the value of the inner loop counter (*j*) is reinitialized to 0.

Description

We compare elements 17 (index *j* = 0) and 5 (index *j* + 1 = 1). Since 17 is larger than 5, we swap them. The inner loop counter (*j*) is incremented, and its value is now 1.

Description

We compare elements 17 (index *j* = 1) and 2 (index *j* + 1 = 2). Since 17 is larger than 2, we swap them.

The inner loop counter (*j*) is incremented, and its value is now 2; therefore, we exit the inner loop. (We have reached the end of the unsorted subarray.) At this point, the element 17 has "bubbled up" to its correct position within the array.

We go back to the outer loop, and the outer loop counter (*i*) is incremented; its value is now 2, and this will be the last iteration of the outer loop. We reenter the inner loop, and the value of the inner loop counter (*j*) is reinitialized to 0.

Description

We compare elements 5 (index *j* = 0) and 2 (index *j* + 1 = 1). Since 2 is smaller than 5, we swap them.

The inner loop counter (*j*) is incremented, and its value is now 1; therefore, we exit the inner loop. (We have reached the end of the unsorted subarray.) At this point, the element 5 has "bubbled up" to its correct position within the array.

We go back to the outer loop, and the outer loop counter (*i*) is incremented; its value is now 3, and therefore, we exit the outer loop. For the four elements in the array, we executed the outer loop three times.

Description

The array is now sorted.

The framework for this Programming Activity will animate your algorithm so that you can watch your algorithm work and check the accuracy of your code. For example, **Figure 8.26** demonstrates the Bubble Sort at work. At this point, the program has completed four passes through the array and just finished comparing the values of elements 3 and 4.

Figure 8.26 The Bubble Sort at Work

Description

Instructions

In this chapter's Programming Activity 2 folder in the supplied code files, you will find the source files needed to complete this activity. Copy all the files to a folder on your computer. Note that all files should be in the same folder.

Open the *ArrayPractice2Controller.java* source file. Searching for five asterisks (*****) in the source code will position you at the two locations where you will add your code. Your first task is to complete the *sequentialSearch* method, which searches the *arr* array, an instance variable of the *ArrayPractice2Controller* class. The array *arr* has already been instantiated for you and filled with random values. The second task is to complete the *bubbleSort* method. **Example 8.21** shows the section of the *ArrayPractice2Controller* source code where you will add your code. Note that in each method, you are asked to call the *animate* method so that your method code can be animated as it works. Note also that for the *sequentialSearch* method, we provide a dummy *return* statement (*return 0;*). We do this so that the source code will compile. In this way, you can write and test each method separately, using stepwise refinement. When you are ready to write the *sequentialSearch* method, just replace the dummy *return* statement with the appropriate *return* statement for that method.

Example 8.21 Student Section of *ArrayPractice2Controller*

```
// 1. ***** student writes this method
/**  Searches for key in integer array named arr
//     arr is an instance variable of the class and has been
//     instantiated and filled with random values.
// @param key value to search for
// @return if key is found, the index of the first element
//     in array whose value is key; if key is not found,
//     the method returns -1
*/
public int sequentialSearch( int key )
{
 // Note:  To animate the algorithm, put this method call as the
 // first statement in your for loop
 //  animate( i );
 //         where i is the index of the current array element

   return 0; // replace this statement with your return statement

} // end of sequentialSearch
//  2. *****  student writes this method
/**  Sorts arr in ascending order using the bubble sort algorithm
*/
public void bubbleSort( )
{
 // Note: To animate the algorithm, put this method call as the
 // last statement in your innermost for loop
 //  animate( i, j );
 //           where i is the value of the outer loop counter
 //           and j is the value of the inner loop counter,
 //           or the index of the current array element

} // end of bubbleSort
```

Description

When you have finished writing your code, compile *ArrayPractice2Controller*.java and run *ArrayPractice2Application*. **Figure 8.27** shows the graphics window when the application begins. To test any method, click on the appropriate button.

Figure 8.27 Opening Window of *ArrayPractice2Application*

Description

Troubleshooting

If your method implementation does not animate, consider these tips:

- Verify that your *for* loop calls the *animate* method as instructed in the method comments.
- Verify that you did not instantiate a new array. Perform all operations on the instance variable array named *arr.*

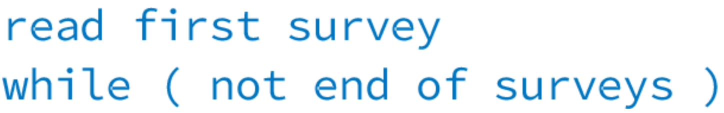
DISCUSSION QUESTIONS

1. The sequential search finds only the first occurrence of the parameter *key*. How would you modify the *sequentialSearch* method to count the occurrences of *key*?
2. It is possible that the array might be completely sorted before all the passes have been completed. How would you modify your code so that you exit the *bubbleSort* method as soon as possible?

```
Roll      Count
1         81
2         82
3         89
4         78
5         87
6         83
```

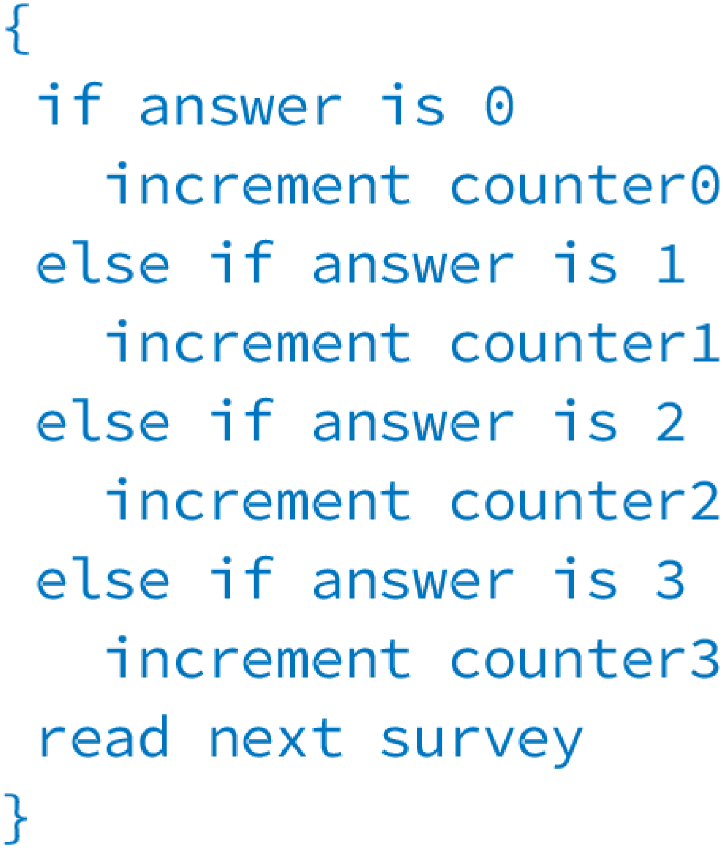
8.8 Using Arrays as Counters

In some circumstances, it is useful to use an array of integers as an ordered group of accumulators, or counters. For example, suppose we are analyzing a survey that has four possible answers, 0 through 3. We want to count how many people selected each answer. We could set up four counters and use an *if/else* statement to increment the appropriate counter. The pseudocode would be:



```
read first survey
while ( not end of surveys )
```

Description



```
{
  if answer is 0
    increment counter0
  else if answer is 1
    increment counter1
  else if answer is 2
    increment counter2
  else if answer is 3
    increment counter3
  read next survey
}
```

Description

That would work if we have only a few possible answers, but what if we had 100 or more answers? We would end up writing a very long *if/else* statement.

Instead, we could set up an array of counters and let the counter for answer 0 be *array[0]*, the counter for answer 1 be *array[1],* and so on. This approach—using an array of counters—is simpler to code and saves processing time.

As another example, suppose we want to throw a die 500 times and count the number of times each outcome occurs; that is, we want to count the number of ones, twos, threes, fours, fives, and sixes that are rolled. To do this, we set up a simple *Die* class shown in **Example 8.22**, with a method for rolling a value. Then we set up the client class, *DieCount,* shown in

Example 8.23, that has an array with six integer elements; each element will hold the number of times a particular roll occurs.

Example 8.22 The *Die* Class

```
/** Die class
*   Anderson, Franceschi
*/
import java.util.Random;

public class Die
{
    public final int SIDES = 6;
    private Random rand;

    /** default constructor
    * instantiates the Random object
    */
    public Die( )
    {
       rand = new Random( );
    }

    /** rolls the die
    * @return the value of the roll
    */
    public int roll( )
    {
       return rand.nextInt( SIDES ) + 1;
    }
}
```

Description

Example 8.23 The *DieCount* Class

```
 1 /** DieCount Class
 2 *   Anderson, Franceschi
 3 */
 4
 5 public class DieCount
 6 {
 7   public static void main( String [ ] args )
 8   {
 9      final int FACES = 6, NUMBER_OF_ROLLS = 500;
10
11      // instantiate the counter array
12      // which sets initial values to 0
13      int [ ] rollCount = new int [FACES];
14
15      // instantiate the Die
16      Die d1 = new Die( );
17
18      // roll the die 500 times
19      for ( int i = 1; i <= NUMBER_OF_ROLLS; i++ )
20      {
21         int myRoll = d1.roll( );
22         rollCount[myRoll - 1]++; // increment the counter for roll
23      }
24
25      // print count for each roll
26      System.out.println( "Roll\tCount" );
27      for ( int i = 0; i < rollCount.length; i++ )
28      {
29         System.out.println( ( i + 1 ) + "\t" + rollCount[i] );
30      }
31   }
32 }
```

Description

In the *Die* class constructor, we instantiate the *Random* object *rand,* which will be used by the *roll* method (lines 19–25), which in turn generates a random number between 1 and 6 to simulate the roll of a die.

In the *DieCount* class, we instantiate our array of six counters, *rollCount,* on line 13, which autoinitializes each element to 0—exactly what we want for counters.

To count the number of times each roll occurs, we use a *for* loop that iterates 500 times, with each iteration calling the *roll* method of the *Die* class. We then need to count each roll. That’s where our array of counters, *rollCount,* comes in.

Since the *rollCount* array has six elements, the index of the first element is 0, and the index of the last element is 5. We will use *rollCount[0]* to hold the number of times we rolled a 1, *rollCount[1]* to hold the number of times we rolled a 2, and continue that way until we use *rollCount[5]* to hold the number of times we rolled a 6. Thus, to get the index of the appropriate counter, we need to decrement the roll by 1. So our statement to increment the count for a roll (line 22) becomes

```
rollCount[myRoll - 1]++;
```

Description

After rolling the die 500 times and counting each roll, we print the total times each roll occurred (lines 25–30). Note that we increment the loop variable to convert between our counter index and the roll number. The output from a sample run of this program is shown in **Figure 8.28**. Because the program generates the rolls randomly, your output may be slightly different.

Figure 8.28 Output from *DieCount*

Description

Our algorithm is not ideal, however. We need to subtract 1 from the index in order to increment the counter, and we need to add 1 to the index to print the outcome.

A better approach would be to create the array with seven elements. Then we can use elements 1 through 6 as the counters for the rolls 1 through 6. The index and the roll number will be the same. What happens to element 0? Nothing. We just ignore it.

The revised *DieCount2* class is shown in **Example 8.24**.

Example 8.24 The *DieCount2* Class

```
 1 /** DieCount2 Class
 2 *   Anderson, Franceschi
 3 */
 4
 5 public class DieCount2
 6 {
 7   public static void main( String [ ] args )
 8   {
 9      final int FACES = 7, NUMBER_OF_ROLLS = 500;
10
11      // instantiate the counter array
12      // which sets initial values to 0
13      int [ ] rollCount = new int [FACES];
14
15      // instantiate the Die
16      Die d1 = new Die( );
17
18      // roll the die 500 times
19      for ( int i = 1; i <= NUMBER_OF_ROLLS; i++ )
20      {
21        int myRoll = d1.roll( );
22        rollCount[myRoll]++; // increment the counter for roll
23      }
24
25      // print count for each roll
26      System.out.println( "Roll\tCount" );
27      for ( int i = 1; i < rollCount.length; i++ )
28      {
29        System.out.println( i + "\t" + rollCount[i] );
30      }
31   }
32 }
```

Description

Notice the changes to the code in this example. First, we set *FACES* to 7 (line 9), so we will instantiate an array with seven elements. Then we can use the roll of the die as the index into the counter array to increment the appropriate count (line 22). One last change is that when we loop through the *rollCount* array to print the counters, we initialize our loop counter to 1 (line 27), since we are not using element 0 as a counter and we simply use *i* as the roll number.

It’s true that we’re allocating an extra integer (four bytes of memory) that is never used, but we’re eliminating 500 subtract operations and 6 addition operations! The program is more efficient, easier to write, and easier to read.

```
Mary: rating 4.0
Mary: rating 4.7
Mary: rating 4.5
Mary: rating 4.5
```

8.9 Methods Accepting a Variable Number of Arguments

Sometimes, the number of arguments to be sent to a method cannot be determined until run time. For example, we may have a method that validates inputs for other methods. The number of inputs may vary from one method call to the next.

In these cases, we can use a feature in the Java language named **varargs**. We specify in the method header that the method will accept a variable number of arguments by typing three dots immediately after the data type of the last parameter.

The syntax is the following:

```
accessModifier returnType methodName( (0 to many parameters,)
                                       dataType... lastParameter )
```

Description

Note that there is no space between the data type and the three dots.

A parameter that a method specifies using the *varargs* syntax must be the last parameter listed in the method header.

When the method starts executing, the *varargs* parameters are available to the method as if the client had passed the arguments as an array. Thus, the method treats the parameter as an array.

When calling a method that accepts a variable number of arguments, we can pass a single argument, several arguments, an array of arguments, or we can pass no arguments.

Example 8.25 shows a *Seller* class with a method that accepts a variable number of arguments, and **Example 8.26** shows a client program that calls the method. In this example, we are updating the average rating a seller receives on an auction website. Each seller could have a different number of new ratings, so we specify the new ratings as a variable number of arguments.

Example 8.25 The *Seller* Class

```java
/** Seller class
*   Anderson, Franceschi
*/
import java.text.DecimalFormat;

public class Seller
{
  private String sellerName;
  private double rating;
  private int numberOfRatings;
  private static final DecimalFormat ONE_PLACE
                        = new DecimalFormat( "0.0" );

  /** constructor
    * @param sellerName seller name
  */
  public Seller( String sellerName )
  {
    this.sellerName = sellerName;
  }

  /** calcRating method
    * @param newRatings 0 to many new ratings
    * updates rating and numberOfRatings instance variables
  */
  public void calcRating( int... newRatings )
  {
    if ( newRatings != null && newRatings.length > 0 )
    {
      int totalNewRatings = 0;
      for ( int i = 0; i < newRatings.length; i++ )
        totalNewRatings += newRatings[i];

      rating = ( ( rating * numberOfRatings ) + totalNewRatings )
              / ( newRatings.length + numberOfRatings );
      numberOfRatings += newRatings.length;
    }
    // else, no new ratings, so no change to instance variables
  }

  /** toString method
   * @return the seller name
   * and rating (formatted to 1 decimal place)
  */
  @Override
  public String toString( )
  {
    return sellerName + ": rating " + ONE_PLACE.format( rating );
  }
}
```

Description

Example 8.26 The *SellerRatings* Class

```
/** SellerRatings - client for Seller
*  Anderson, Franceschi
*/

public class SellerRatings
{
  public static void main( String [ ] args )
  {
    Seller seller = new Seller( "Mary" );

    seller.calcRating( 4 ); // one value
    System.out.println( seller );

    seller.calcRating( 5, 5 ); // two values
    System.out.println( seller );

    int [ ] arrayOfRatings = { 4, 4, 5 };
    seller.calcRating( arrayOfRatings ); // array
    System.out.println( seller );

    seller.calcRating( ); // no values
    System.out.println( seller );
  }
}
```

Description

In the *Seller* class, we define three instance variables representing the seller name, the current average rating, and the number of ratings the seller has received (lines 8–10). We also define a *static* constant *ONE_PLACE* that the *toString* method (lines 41–49) uses to format the average rating.

The *calcRating* method (lines 22–39) accepts one *varargs* parameter, *newRatings*. Note that if the method accepted other parameters, the *newRatings* parameter would need to be listed last. When the method starts executing, the arguments sent to the method by the caller have been assembled into an *int* array with the parameter's name, *newRatings*. Thus, *newRatings.length* will hold the number of arguments actually sent to the method. In the *calcRating* method we first check that the array reference is not *null* and that the array is not empty (line 28). We then use a *for* loop to calculate the total of the new ratings (lines 30–32). Finally, we calculate the new average rating and update the instance variables *rating* and *numberOfRatings*. If the *varargs* parameter is *null* or the array is empty, we do nothing.

In the client program, *SellerRatings*, we instantiate a *Seller* object (line 9), then successively call the *calcRating* method with one argument, two arguments, an array, and no arguments. After each method call, we output the new rating by implicitly calling the *toString* method in the *Seller* class (lines 11–22). **Figure 8.29** shows the output from Example 8.26.

Figure 8.29 Output from the *SellerRatings* Application

CHAPTER REVIEW

8.10 Chapter Summary

- An array is a sequence of variables of the same data type. The data type can be any Java primitive data type, such as *int, float, double, byte, short, long, boolean, or char,* or it can be a class.
- Each element in the array is accessed using the array name and an index, which refers to the element's position in the array.
- Arrays are implemented as objects. Creating an array consists of declaring an object reference for the array and instantiating the array. The size of the array is given when the array is instantiated.
- In arrays of primitive types, each element of the array contains a value of that type. In arrays of objects, each element is an object reference.
- When an array is instantiated, the elements are given initial values automatically, depending on the data type. Numeric types are set to 0; *boolean* types are set to *false; char* types are set to the Unicode null character; and object references are set to *null.*
- Instantiating an array of object references involves two steps: instantiating the array and instantiating the objects.
- Arrays can be instantiated when they are declared by

assigning initial values in a comma-separated list within curly braces. The number of values in the initialization list determines the number of elements in the array.

- Array elements are accessed using the array name and an index. The first element's index is 0 and the last element's index is the size of the array –1.
- Arrays have an integer instance variable, *length,* which holds the number of elements in the array.
- Attempting to access an element of an array using an index less than 0 or greater than *arrayName.length* – 1 will generate an *ArrayIndexOutOfBoundsException* at run time.
- Aggregate array operations, such as printing and copying arrays, are not supported *for* arrays. Using a *for* loop, we can process each array element individually.
- To change the size of an array, instantiate an array of the desired size with a temporary name, copy the appropriate elements from the original array to the new array, and assign the new array reference to the original array. Assign *null* to the temporary array name.
- Arrays can be passed as arguments to methods and can also be the return type of methods.
- When an array is an instance variable of a class, the constructor should instantiate a new array and copy the elements of the parameter array into the new array.
- A Sequential Search determines whether a particular value, the search key, is in an array by comparing the search key to each element in the array.
- A Selection Sort arranges elements in the array in order by value by reducing the array into successively smaller subarrays and placing the largest element in each subarray into the last position of the subarray.
- An Insertion Sort arranges elements of an array much like a card player arranges cards in sorted order in his or her hand. The elements are inserted one at a time in ascending order into the left side of the array.
- To sort an array of objects, we can use the class method provided to compare objects' values.

- A sorted array can be searched more efficiently using a Binary Search, which successively reduces the number of elements to search by half.
- Arrays of integers can be used as an ordered group of counters.
- Methods can accept a variable number of parameters using the *varargs* … syntax.

8.11 Exercises, Problems, and Projects

8.11.1 Multiple Choice Exercises

1. What are the valid ways to declare an integer array named *a*? (Check all that apply.)

    - `int [ ] a;`
    - `int a[ ];`
    - `array int a;`
    - `int array a;`

6. What is the index of the first element of an array?

    - –1
    - 0
    - 1

10. An array *a* has 30 elements; what is the index of its last element?

    - 29
    - 30
    - 31

14. What is the default value of the elements in an array of *ints* after declaration and instantiation of the array?

    - 0
    - *null*
    - undefined

18. How do you access the element of array *a* located at index

6?

- `a{6}`
- `a( 6 )`
- `a[6]`

22. Which of the following assertions is true?

    - An array cannot be sized dynamically.
    - An array can be sized dynamically, but cannot be resized without instantiating it again.
    - An array can be sized dynamically and can also be resized without instantiating it again.

26. How do you retrieve the number of elements in an array *a*?

    - `a.length( )`
    - `a.length`
    - `a.size( )`
    - `a.size`

31. All the elements of an array must be of the same data type.

    - true
    - false

34. Array aggregate assignment is possible in Java.

    - true
    - false

37. Aggregate comparison of arrays is possible in Java.

    - true
    - false

40. An array can be returned by a method.

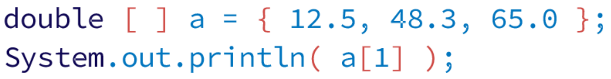
- true
- false

43. A Sequential Search on a sorted array can be written more efficiently than a Sequential Search on an unsorted array.

    - true
    - false

8.11.2 Reading and Understanding Code

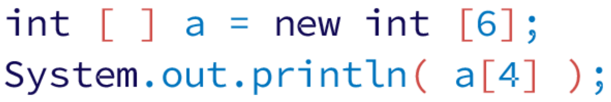
1. What is the output of this code sequence?



```
double [ ] a = { 12.5, 48.3, 65.0 };
System.out.println( a[1] );
```

Description

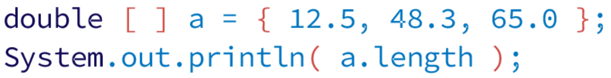
2. What is the output of this code sequence?



```
int [ ] a = new int [6];
System.out.println( a[4] );
```

Description

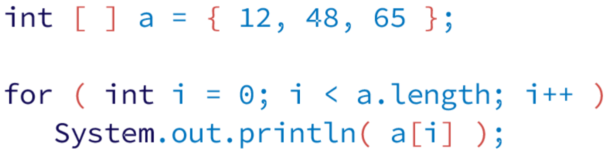
3. What is the output of this code sequence?



```
double [ ] a = { 12.5, 48.3, 65.0 };
System.out.println( a.length );
```

Description

4. What is the output of this code sequence?



```
int [ ] a = { 12, 48, 65 };

for ( int i = 0; i < a.length; i++ )
   System.out.println( a[i] );
```

Description

5. What is the output of this code sequence?

```
int [ ] a = { 12, 48, 65 };

for ( int i = 0; i < a.length; i++ )
   System.out.println( "a[" + i + "] = " + a[i] );
```

Description

6. What is the output of this code sequence?

```
int s = 0;
int [ ] a = { 12, 48, 65 };

for ( int i = 0; i < a.length; i++ )
   s += a[i];
System.out.println( "s = " + s );
```

Description

7. What is the output of this code sequence?

```
int [ ] a = new int[10];

for ( int i = 0; i < a.length; i++ )
a[i] = i + 10;

System.out.println( a[4] );
```

Description

8. What is the output of this code sequence?

```
double [ ] a = { 12.3, 99.6, 48.2, 65.8 };
double temp = a[0];

for ( int i = 1; i < a.length; i++ )
{
   if ( a[i] > temp )
      temp = a[i];
}

System.out.println( temp );
```

Description

9. What is the output of this code sequence?

```
int [ ] a = { 12, 48, 65, 23 };
int temp = a[1];
a[1] = a[3];
a[3] = temp;

for ( int i = 0; i < a.length; i++ )
  System.out.print( a[i] + " " );
```

Description

10. What does this method do?

```
public int foo( int [ ] a )
{
   int temp = 0;
   for ( int i = 0; i < a.length; i++ )
   {
         if ( a[i] == 5 )
               temp++;
   }
   return temp;
}
```

Description

11. What does this method do?

```
public int foo( int [ ] a )
{
     for ( int i = 0; i < a.length; i++ )
     {
           if ( a[i] == 10 )
                return i;
     }
     return -1;
}
```

Description

12. What does this method do?

```
public boolean foo( int [ ] a )
{
     for ( int i = 0; i < a.length; i++ )
     {
          if ( a[i] < 0 )
               return false;
     }
     return true;
}
```

Description

13. What does this method do?

```
public String [ ] foo( String [ ] a )
{
     String [ ] temp = new String[a.length];
     for ( int i = 0; i < a.length; i++ )
     {
          temp[i] = a[i].toLowerCase( );
     }
     return temp;
}
```

Description

14. What does this method do?

```
public boolean [ ] foo( String [ ] a )
{
     boolean [ ] temp = new boolean[a.length];
     for ( int i = 0; i < a.length; i++ )
     {
          if (a[i].indexOf( "@" ) != -1 )
               temp[i] = true;
          else
               temp[i] = false;
     }
     return temp;
}
```

Description

8.11.3 Fill In the Code

1. This code assigns the value 10 to all the elements of an array *a*.

   ```
   int [ ] a = new int[25];
   for ( int i = 0; i < a.length; i++ )
   {
           // your code goes here
   }
   ```

   Description

2. This code prints all the elements of array *a* that have a value greater than 20.

   ```
   double [ ] a = { 45.2, 13.1, 12.8, 87.4, 99.0, 100.1, 43.8, 2.4 };
   for ( int i = 0; i < a.length; i++ )
   {
         // your code goes here
   }
   ```

   Description

3. This code prints the average of the elements of array *a*.

   ```
   int [ ] a = { 45, 13, 12, 87, 99, 100, 43, 2 };

   double average = 0.0;
   for ( int i = 0; i < a.length; i++ )
   {
           // your code goes here
   }
   // ... and your code continues here
   ```

   Description

4. This code calculates and prints the dot product of two arrays (∑ *a*[*i*] * *b*[*i*]).

```
int [ ] a = { 3, 7, 9 };
int [ ] b = { 2, 9, 4 };
int dotProduct = 0;

for ( int i = 0; i < a.length; i++ )
{
      // your code goes here
}
```

Description

5. This code prints the following three lines:

```
a[0] = 3
a[1] = 6
a[2] = 10
```

```
int [ ] a = { 3, 6, 10 };
for ( int i = 0; i < a.length; i++ )
{
        // your code goes here
}
```

Description

6. This method returns *true* if an element in an array of *Strings* passed as a parameter contains the substring *IBM*; otherwise, it returns *false*.

```
public boolean foo( String [ ] a )
{
      // your code goes here
}
```

Description

7. This method returns the number of elements in an array passed as a parameter that are multiples of 7.

```
public int foo( int [ ] a )
{
        // your code goes here
}
```

Description

8. This method returns true if the first two elements of the array passed as a parameter have the same value; otherwise, it returns *false*.

```
public boolean foo( String [ ] a )

{
        // your code goes here
}
```

Description

9. This method takes an array of *ints* as a parameter and returns an array of *booleans*. For each element in the parameter array whose value is 0, the corresponding element of the array returned will be assigned *false*; otherwise, the element will be assigned *true*.

```
public boolean [ ] foo( int [ ] a )
{
        // your code goes here
}
```

Description

8.11.4 Identifying Errors in Code

1. Where is the error in this code sequence?

```
double [ ] a = { 3.3, 26.0, 48.4 };
a[4] = 2.5;
```

Description

2. Where is the error in this code sequence?

```
double [ ] a = { 3.3, 26.0, 48.4 };
System.out.println( a[-1] );
```

Description

3. Where is the error in this code sequence?

```
double [ ] a = { 3.3, 26.0, 48.4 };
System.out.println( a{1} );
```

Description

4. Where is the error in this code sequence?

```
double [ ] a = { 3.3, 26.0, 48.4 };
for ( int i = 0; i <= a.length; i++ )
 System.out.println( a[i] );
```

Description

5. Where is the error in this code sequence?

```
double a[3] = { 3.3, 26.0, 48.4 };
```

Description

6. Where is the error (although this code will compile and run) in this code sequence?

```
int a[ ] = { 3, 26, 48, 5 };
int b[ ] = { 3, 26, 48, 5 };

if ( a != b )
      System.out.println( "Array elements are NOT identical" );
```

Description

7. Where is the error in this code sequence?

```
int [ ] a = { 3, 26, 48, 5 };
a.length = 10;
```

Description

8. Where is the logic error in this code sequence?

```
int [ ] a = { 3, 26, 48, 5 };
System.out.println( "The array elements are " + a );
```

Description

9. Where is the error in this code sequence?

```
Integer i1 = 10;
Integer i2 = 15;
Double d1 = 3.4;
String s = new String( "Hello" );
Integer [ ] a = { i1, i2, d1, s };
```

Description

8.11.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

1. You coded the following on line 26 of the class *Test.java*:

```
int a[6] = { 2, 7, 8, 9, 11, 16 }; // line 26
```

Description

When you compile, you get the following messages:

```
Test.java:26: error: ']' expected
       int a[6] = { 2, 7, 8, 9, 11, 16}; // line 26
             ^
Test.java:26: error: not a statement
       int a[6] = { 2, 7, 8, 9, 11, 16}; // line 26
                    ^
Test.java:26: error: ';' expected
     int a[6] = { 2, 7, 8, 9, 11, 16}; // line 26
                   ^
3 errors
```

Description

Explain what the problem is and how to fix it.

2. You coded the following on lines 26, 27, and 28 of the class

Test.java:

```
int [ ] a = { 2, 7, 8, 9, 11, 16 }; // line 26 of class Test.java
for ( int i = 0; i <= a.length; i++ ) // line 27 of class Test.java
      System.out.println( a[i] ); // line 28 of class Test.java
```

Description

The code compiles properly, but when you run, you get the following output:

```
2
7
8
9
11
16
Exception in thread "main"
   java.lang.ArrayIndexOutOfBoundsException: Index 6 out of
   bounds for length 6 at Test.main(Test46.java:28)
```

Description

Explain what the problem is and how to fix it.

3. You coded the following in the class *Test.java*:

```
int [ ] a = { 1, 2, 3 };
int [ ] b = { 1, 2, 3 };
if ( a == b )
      System.out.println( "Arrays are equal" );
else
      System.out.println( "Arrays are NOT equal" );
```

Description

The code compiles properly and runs, but the result is not what you expected; the output is

```
Arrays are NOT equal
```

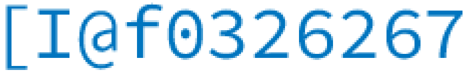
Explain what the problem is and how to fix it.

4. You coded the following in the class *Test.java*:

```
int [ ] a = { 1, 2, 3 };
System.out.println( a );
```

Description

The code compiles properly and runs, but the result is not what you expected; instead of 1 2 3, the output is similar to the following:



```
[I@f0326267
```

Description
Explain what the problem is and how to fix it.

8.11.6 Write a Short Program

1. Write a value-returning method that returns the number of elements in an integer array.
2. Write a value-returning method that returns the product of all the elements in an integer array.
3. Write a *void* method that sets to 0 all the elements of an integer array.
4. Write a *void* method that multiplies by 2 all the elements of an array of *floats*.
5. Write a method that returns the percentage of elements greater than or equal to 90 in an array of *ints*.
6. Write a method that returns the difference between the largest and smallest elements in an array of *doubles*.
7. Write a method that returns the sum of all the elements of an array of *ints* that have an odd index.
8. Write a method that returns the percentage of the number of elements that have the value *true* in an array of *booleans*.
9. Write a method that returns *true* if an array of *Strings* contains the *String “Hello”; false* otherwise.
10. Write a method that prints all the elements of an array of *chars* in reverse order.

11. Write a method that returns an array composed of all the elements in an array of *chars* in reverse order.
12. Write an array-returning method that takes a *String* as a parameter and returns the corresponding array of *chars*.
13. Code an array-returning method that takes an array of *ints* as a parameter and returns an array of *booleans*, assigning *true* for any element of the parameter array greater than or equal to 100; and *false* otherwise.

8.11.7 Programming Projects

1. Write a class encapsulating the concept of statistics for a baseball team, which has the following attributes: a number of players, a list of number of hits for each player, a list of number of at-bats for each player.
   Write the following methods:

   - A constuctor with two equal-length arrays as parameters, the number of hits per player, and the number of at-bats per player.
   - Accessors, mutators, *toString*, and *equals* methods.
   - Generate and return an array of batting averages based on the attributes given.
   - Calculate and return the total number of hits for the team.
   - Calculate and return the number of players with a batting average greater than .300.
   - A method returning an array holding the number of hits, sorted in ascending order.

   Write a client class to test all the methods in your class.
8. Write a class encapsulating the concept of student grades on a test, assuming student grades are composed of a list of integers between 0 and 100.
   Write the following methods:

- A constructor with just one parameter, the number of students; all grades can be randomly generated
- Accessor, mutator, *toString*, and *equals* methods
- A method returning an array of the grades sorted in ascending order
- A method returning the highest grade
- A method returning the average grade
- A method returning the median grade (*Hint:* The median grade will be located in the middle of the sorted array of grades.)
- A method returning the mode (the grade that occurs most often) (*Hint:* Create an array of counters; count how many times each grade occurs; then pick the maximum in the array of counters; the array index is the mode.)

Write a client class to test all the methods in your class.

16. Write a class encapsulating the concept of daily temperatures for a week.
Write the following methods:

    - A constructor accepting an array of seven temperatures as a parameter
    - Accessor, mutator, *toString*, and *equals* methods
    - A method returning how many temperatures were below freezing
    - A method returning an array of temperatures above 100 degrees
    - A method returning the largest change in temperature between any two consecutive days
    - A method returning an array of daily temperatures, sorted in descending order

    Write a client class to test all the methods in your class.

23. Write a class encapsulating the concept of a tic-tac-toe game as follows:
Two players will be playing, player 1 and player 2.

The board is represented by an array of 9 integer elements: elements at indexes 0, 1, and 2 represent the first row; elements at indexes 3, 4, and 5 represent the second row; elements at indexes 6, 7, and 8 represent the third row.

The value 0 in the array indicates that this space is available; the value 1 indicates the space is occupied by player 1; and the value 2 indicates that this space is occupied by player 2.

In the *main* method of your client class, your program will simulate a tic-tac-toe game from the command line, doing the following:

- Create a *TicTacToe* object and instantiate it.
- In a loop, prompt for plays, as *ints*, from the user. At each iteration of the loop, you will need to call methods of the *TicTacToe* class to update the *TicTacToe* object. You need to keep track of who is playing (player 1 or 2), enforce the rules, check if either player has won the game. It is clear that if anyone has won the game, it is the last player who played.
- If a player wins, you will need to exit the loop and present the result of the game. If the game ends in a tie, you should output that result.

In your *TicTacToe* class, you will need to code the following methods:

- A default constructor instantiating the array representing the board.
- A method that allows a player to make a move; it takes two arguments: the player number and the position played on the board.
- A method checking if a play is legal.
- A method checking if a player has won the game; you can break up that method into several methods if you like (for instance, check if a player has won the game by claiming an entire horizontal row).
- A method that checks whether the game is a tie (if no player has won and all squares have been played, the

game is tied).

- A method that displays the results of the game (“Player 1 won,” “Player 2 won,” or “Tie game”).

Write a client class, where the *main* method is located, to test all the methods in your class and enable the user to play.

33. When a new user logs in for the first time on a website, the user has to submit personal information, such as user_id, password, name, email address, telephone number, and so forth. Typically, there are two fields for passwords, requiring the user to enter the password twice, to ensure that the user did not make a typo in the first password field.

Write a class encapsulating the concept of processing a form with the following elements:

User_id
Password
Reenter password
Email address
Name
Street address
City
State
Zip
Telephone

In your class, write the following methods:

- A constructor with one parameter, a sequence of 10 words in an array of *Strings*, your only instance variable.
- Accessor, mutator, *toString*, and *equals* methods.
- A method checking that no *Strings* in the array are empty. (All fields are mandatory.) If at least one is empty, it returns *false*; otherwise, it returns *true*.
- A method returning the number of characters in the

user_id.

- A method checking if the two *Strings* representing the passwords (representing the password typed in twice) are identical. If they are, it returns *true*; if not, it returns *false*.
- A method checking if the *String* representing the email address actually “looks like” an email address; to simplify, we can assume that an email address contains one and only one @ character and contains one or more periods after the @ character. If it does “look like” an email address, then the method returns *true*; otherwise, it returns *false*.
- A method checking if the *String* representing the state has exactly two characters. If it does, it returns *true*; otherwise, it returns *false*.

Write a client class to test all the methods in your class.

52. We want to write a program that performs some syntax checking on HTML code; for simplicity reasons, we will assume that the HTML code is syntactically correct if the number of < characters in any word is the same as the number of > characters in that word. We will also assume that the syntax is correct if the first word is *<html>* and the last word is *</html>*.

    Write a class encapsulating that concept, including the following methods:

    - A constructor with one parameter, an array of the words in the HTML sentence, your only instance variable. Your constructor should then get user input from the console for that same number of words and store them in an array of *Strings*, your only data member.
    - Accessor, mutator, *toString*, and *equals* methods.
    - A method returning how many words are in the array.
    - A method returning *true* if the first word is *<html>* and the last word is *</html>*; false otherwise.
    - A method checking if each array element contains the same number of < characters as > characters. If that is

the case, the method returns *true*; otherwise, it returns *false*. For this, we suggest the following method to help you:

    - Write an *int*-returning method that takes a *String* and a *char* as parameters and returns how many times that *char* appears in the *String*; you can convert the *String* to an array of *chars* and loop through it, or use another strategy of your choice.

  - A method counting and returning the number of *img* tags overall.

  Write a client class to test all the methods in your class.

60. Write a class encapsulating the concept of converting integer grades to letter grades (A, B, C, D, or F), assuming grades are composed of a list of integers between 0 and 100.
    Write the following methods:

    - A constructor with just one parameter, the number of students; all grades can be randomly generated.
    - Accessor, mutator, *toString*, and *equals* methods.
    - A method returning an array of *chars* corresponding to the integer grades (90 or above should be converted to A, 80 or above to B, 70 or above to C, 60 or above to D, and 59 or less to F).
    - A method returning the number of A's.
    - A method returning an array of *ints* counting how many A's, B's, C's, D's, and F's were received.

    Write a client class to test all the methods in your class.

66. Write a class that includes a method that converts two parallel arrays of *Strings* to a *Hashtable* (look up the *Hashtable* class in the Java Class Library) such that the keys of the *Hashtable* are the elements of the first array and its corresponding values are the elements of the second array. Test your method with a client program.

67. Write a class encapsulating the concept of a team of baseball players, assuming a baseball player has the following attributes: a name, a position, and a batting percentage. In addition to that class, you will need to design and code a *Player* class to encapsulate the concept of a baseball player.

    In your class encapsulating the team, you should write the following methods:

    - A constructor taking an array of *Player* objects as its only parameter and assigning that array to the array data member of the class, its only instance variable. In your client class, when you test all your methods, you can hard-code nine baseball *Player* objects.
    - Accessor, mutator, *toString*, and *equals* methods.
    - A method checking that all positions are different, returning *true* if they are, *false* if they are not.
    - A method returning the batting percentage of the team.
    - A method checking that we have a pitcher (that is, the name of the position) on the team. If we do not have

any, it returns *false*; otherwise, it returns *true*.

- A method returning the array of *Player* objects sorted in ascending order using the batting percentage as the sorting key.
- A method checking if a certain person (a parameter of the method) is on the team, based on the name of that person. If the person is on the team, the method returns *true*; otherwise, it returns *false*.
- A method returning an array of *Player* objects, sorted in ascending order based on batting percentages.

Write a client class to test all the methods in your class.

76. Write a class encapsulating a similar concept to the one used in the die counting problem of Section 8.8. Here, we want to roll two dice; the total of the numbers rolled will be between 2 and 12. We want to keep track of how many times each possible total was rolled.
Write the following methods:

    - A constructor with no parameter; it randomly generates two numbers between 1 and 6, representing the dice.
    - Accessor, mutator, *toString*, and *equals* methods.
    - A method returning the total of the two dice.
    - A method checking if the two dice have identical values. If they do, it returns *true*; otherwise, it returns *false*.

    The number of times we roll the dice should be an input from the user at the command line (not inside the program). Your program should output the total for each possible roll (from 2 to 12), as well as the number of times the two dice had identical values.
    Write a client class to test all the methods in your class.

81. Write a graphical application that creates two *Die* objects and rolls the two dice 5,000 times. Display the results showing the frequency of each possible total in a bar chart. Pick a scale that is appropriate for the maximum height of your bar chart.

8.11.8 Technical Writing

1. What do you think are advantages and disadvantages of arrays?
2. Write the pseudocode to perform a Selection Sort on an array of *Auto* objects based on the instance variable *model*.
3. When you try to use an array index that is out of bounds, your code will compile, but you will generate a run-time exception. Discuss whether this is an advantage or a disadvantage, and why.
4. When instantiating an array, you can assign the number of elements in the array dynamically, using a variable (as opposed to using a constant). Discuss a situation where that would be useful.

8.11.9 Group Project (for a group of 1, 2, or 3 students)

1. Security is an important feature of information systems. Often, text is encrypted before being sent, and then decrypted upon receipt. We want to build a class (or several classes) encapsulating the concept of encryption. You will need to test that class with a client program where the *main* method is located.

   For this project, encrypting consists of translating each character into another character. For instance, if we consider the English alphabet, including characters *a* through *z*, each character is randomly encrypted into another, which could be the same character. (If you like, you can design your program so that no character is encrypted into itself.) To represent this concept, we can have an array of characters for the original alphabet, and another array of characters for the encrypted alphabet. For example, we could have

Original alphabet	**Encrypted alphabet**
a	u
b	p
c	h
d	a
e	s
f	x
g	z
h	b
i	j
. . .	. . .

To encrypt a word, each letter in the word is replaced by the corresponding letter in the encrypted alphabet. For example, the word *caged* would be encrypted into *huzsa*. To decrypt a word, the letters in the encrypted word are replaced by the corresponding letter in the original alphabet. For example, the encrypted word *xssa* would be decrypted as *feed*.

If we have 26 different characters in the original alphabet, then we will have 26 different characters in the encrypted alphabet. Furthermore, the encrypted alphabet should be randomly generated.

In your *main* method, you should prompt the user for a sentence. Your program should encrypt the sentence, output the encrypted sentence, then decrypt it, and output the decrypted sentence, which should be identical to the original sentence that was input by the user.

For extra credit, use an array to keep track of the number of occurrences of each character. Convert these occurrences to percentages, and then use these percentages to attempt to decrypt a large, encrypted message.

Introduction

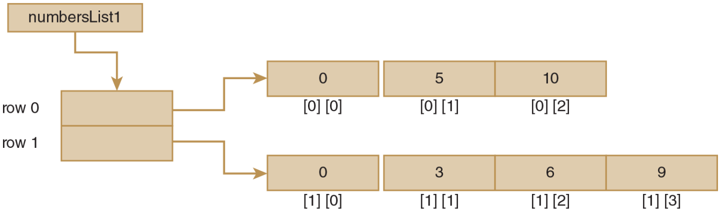
Arrays can be useful when we have a lot of data to store in memory. If we write a program to perform statistics on last year's temperatures, it is convenient to set up an array of *doubles* of size 365 to store the daily temperature data.

But what if in addition to analyzing daily temperatures, we want to analyze temperatures by the week, or by a particular day of the week? For instance, if we sail on weekends, we could want to know how many times the temperature was above 65 degrees on Saturdays and Sundays. If we are considering investing in air conditioning at home, we might be interested in knowing how many weeks had temperatures above 90 degrees. If we are avid skiers, we could be interested in the number of weeks with temperatures lower than 32 degrees.

In this situation, we would want to organize our data along two dimensions: weeks and days of the week. If we were to visualize the data as a table, we could imagine a table made up of 52 rows, each row representing a week. Each row would have seven columns, representing the days of the week. This table is shown in **Figure 9.1**. Or we could imagine a table of seven rows, each row representing a day of the week, and 52 columns, each column representing a week of the year. In either case, we can represent the rows and columns of our temperature table using a two-dimensional array. More generally, **multidimensional** arrays allow us to represent data organized along *n* dimensions with a single array.

Figure 9.1 Temperature Data for the Previous 52 Weeks

Description



9.1 Declaring and Instantiating Multidimensional Arrays

Just like single-dimensional arrays, multidimensional arrays are implemented as objects, so creating a multidimensional array takes the same two steps as creating a single-dimensional array:

1. declaring the object reference for the array
2. instantiating the array

In arrays with elements of primitive types, each element of the array contains a value of that type. For example, in an array of *doubles*, each element contains a *double* value. In arrays with a class data type, each element is an object reference, which points to the location of an object of that class.

9.1.1 Declaring Multidimensional Arrays

To declare a multidimensional array, we use the same syntax as for a single-dimensional array, except that we include an empty set of brackets for each dimension.

Here is the syntax for declaring a two-dimensional array:

```
datatype [ ][ ] arrayName;
```

Description

Here is the syntax for declaring a three-dimensional array:

```
datatype [ ][ ][ ] arrayName;
```

Description

In order to keep things simple, we will concentrate on two-dimensional arrays at this point. We will discuss three- and four-dimensional arrays later in the chapter.

The following statement declares an array that we can use to hold the daily high temperatures for the last 52 weeks:

```
double [ ][ ] dailyTemps;
```

Description

The brackets can be placed before or after the array name. So the following syntax for declaring a two-dimensional array is also valid:

```
datatype arrayName [ ][ ];
```

Description

We prefer to put the brackets right after the data type, because it’s easier to read.

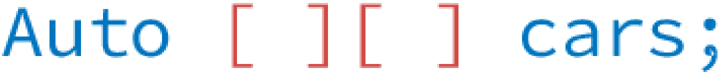
To store quiz grades for students, we could declare a two-dimensional array, where each row will store the quiz grades for a particular student and each column will store the grades for a particular quiz:

```
char [ ][ ] quizzes; // each element is a char
```

Description

The syntax is the same whether we declare arrays with basic data types or class types.

Imagine that we are interested in keeping track of a fleet of cars within a multinational corporation. The corporation operates in various countries, and in each of these countries, some employees have a company car. For this situation, we can declare a two-dimensional array where the first dimension will represent the country and the second dimension will represent the employee. Assuming we have an *Auto* class, the following statement declares this two-dimensional array to hold *Auto* objects:



```
Auto [ ][ ] cars;
```

Description

We can also declare multiple multidimensional arrays of the same data type in one statement by inserting a comma after each array name, using this syntax:

```
datatype [ ][ ] arrayName1, arrayName2;
```

Description

For example, the following statement will declare two integer arrays to hold the number of stolen bases for two baseball players for each game in their career:

```
int [ ][ ] brian, jon;
```

Description

The first dimension represents the games (per season), and the second dimension represents the season.

COMMON ERROR TRAP

Specifying the size of any of the dimensions of a multidimensional array in the declaration will generate a compiler error.

Notice that when we declare a multidimensional array, we do not specify how many elements the array will have. Declaring a multidimensional array does not allocate memory for the array; this is done in step 2, when we instantiate the array.

For example, this code:

```
double [7][52] dailyTemps;
```

Description

will generate compiler errors.

9.1.2 Instantiating Multidimensional Arrays

Just like instantiating single-dimensional arrays, we instantiate a multidimensional array using the *new* keyword. Here is the syntax for instantiating a two-dimensional array:

```
arrayName = new datatype [exp1][exp2];

  where exp1 and exp2 are expressions that evaluate to integers and specify,
  respectively, the number of rows and the number of columns in the array.
```

Description

This statement allocates memory for the array. The number of elements in a two-dimensional array is equal to the sum of the number of elements in each row. When all the rows have the same number of columns, the number of elements in the array is equal to the number of rows multiplied by the number of columns.

For example, if we instantiate the following *dailyTemps* array with 52 rows and 7 columns, the array will have 52 * 7, or 364, elements:

```
dailyTemps = new double [52][7]; // dailyTemps has 52 rows
                                 // and 7 columns,
                                 // for a total of 364 elements
```

Description

These statements will instantiate the other arrays declared above:

```
int numberOfStudents = 25;
int numberOfQuizzes = 10;
quizzes = new char [numberOfStudents][numberOfQuizzes];
// quizzes has 25 rows and 10 columns
// for a total of 250 elements

cars = new Auto [5][50];
// cars has 5 rows and 50 columns
// cars will store 250 Auto objects

brian = new int [80][20];
// brian has 80 rows and 20 columns
// there are 80 games per season
// brian played baseball for 20 seasons

jon = new int [80][10];
// jon has 80 rows and 10 columns
// jon played baseball for 10 seasons
```

Description

When a multidimensional array is instantiated, the elements are given initial values automatically. Elements of arrays with numeric types are initialized to 0, elements of *char* type are initialized to the Unicode null character, elements of *boolean* type are initialized to *false*, and elements of class types are initialized to *null*.

9.1.3 Combining the Declaration and Instantiation of Multidimensional Arrays

Multidimensional arrays, like single-dimensional arrays, can also be instantiated when they are declared. To combine the declaration and instantiation of a two-dimensional array, use this syntax:

```
datatype [ ][ ] arrayName = new datatype [exp1][exp2];

  where exp1 and exp2 are expressions that evaluate to integers and specify,
  respectively, the number of rows and columns in the array.
```

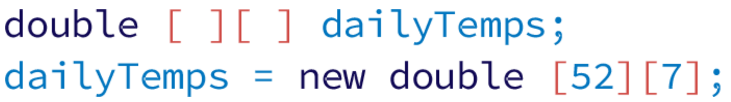
Description

Thus, this statement:

```
double [ ][ ] dailyTemps = new double [52][7];
```

Description

is equivalent to:



```
double [ ][ ] dailyTemps;
dailyTemps = new double [52][7];
```

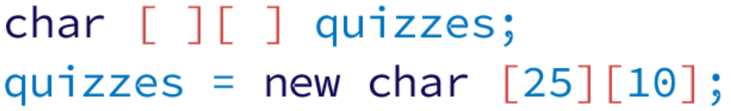
Description

Similarly, this statement:

```
char [ ][ ] quizzes = new char [25][10];
```

Description

is equivalent to:

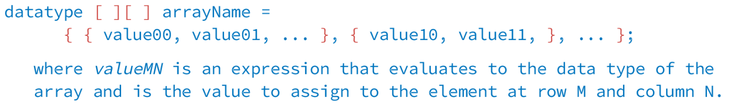


```
char [ ][ ] quizzes;
quizzes = new char [25][10];
```

Description

9.1.4 Assigning Initial Values to Multidimensional Arrays

We can instantiate a two-dimensional array by assigning initial values when the array is declared. To do this, we specify the initial values using comma-separated lists, enclosed in an outer set of curly braces:



```
datatype [ ][ ] arrayName =
      { { value00, value01, ... }, { value10, value11, }, ... };

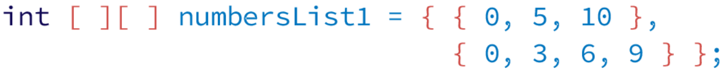
   where valueMN is an expression that evaluates to the data type of the
   array and is the value to assign to the element at row M and column N.
```

Description

The list contains a number of sublists, separated by commas. The number of these sublists determines the number of rows in the array. For each row, the number of values in the corresponding sublist determines the number of columns in the row. Thus, Java allows a two-dimensional array to have a different number of columns in each row. For example, in our *Auto* array, each country (row) could have a different number of employees (columns) with company cars.

Indeed, a two-dimensional array is an array of arrays. The first dimension of a two-dimensional array consists of an array of array references, with each reference pointing to a single-dimensional array. Thus, a two-dimensional array is composed of an array of rows, where each row is a single-dimensional array.

For example, this statement declares and instantiates a two-dimensional array of integers:



```
int [ ][ ] numbersList1 = { { 0, 5, 10 },
                            { 0, 3, 6, 9 } };
```

Description

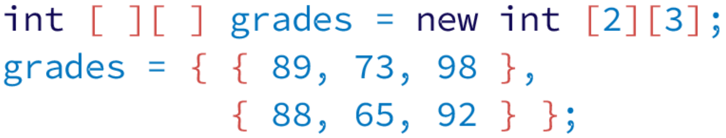
Because two sublists are given, this two-dimensional array has two rows. The first sublist specifies three values, and therefore, the first row will have three columns; the second sublist specifies four values, and therefore, the second row will have four columns.

Figure 9.2 shows the *numbersList1* array after the preceding statement is executed.

Figure 9.2 The *numbersList1* Array After Instantiation

Description

An initialization list can be given only when the array is declared. If a two-dimensional array has already been instantiated, attempting to assign values to an array using an initialization list will generate a compiler error. For example, this code:



```
int [ ][ ] grades = new int [2][3];
grades = { { 89, 73, 98 },
           { 88, 65, 92 } };
```

Description

will generate compiler errors.

We can declare and instantiate an array of objects by providing object references in the list:

```
Auto sportsCar = new Auto( "Ferrari", 0, 0.0 );
Auto sedan1 = new Auto( "BMW", 0, 0.0 );
Auto sedan2 = new Auto( "BMW", 100, 15.0 );
Auto sedan3 = new Auto( "Toyota", 0, 0.0 );
Auto rv1 = new Auto( "Jeep", 0, 0.0 );

Auto [ ][ ] cars = { { sportsCar, sedan1 },
                     { rv1, new Auto( ) },
                     { sedan2, sedan3 } };
```

Description

COMMON ERROR TRAP

An initialization list can be given only when the two-dimensional array is declared. Attempting to assign values to an array using an initialization list after the array is instantiated will generate a compiler error.

This array of *Auto* objects has three rows with two columns in each row. The elements of the array *cars* are object references to *Auto* objects.

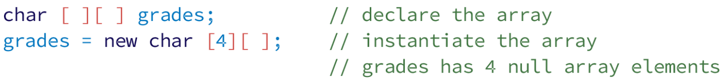
In most situations, the number of columns will be the same for each row. However, there are situations where it is useful to have a different number of columns for each row. For instance, Dr. Smith, a college professor, keeps track of grades using a two-dimensional array. The rows represent the courses she teaches and the columns represent the grades for the students in those sections. Grades are A, B, C, D, or F, so she declares the array with *char* elements. Dr. Smith teaches four courses: CS1, CS2, Database Management, and Operating Systems. Thus, she has four rows in the array. But in each course, Dr. Smith has a different number of students: There are 23 students in CS1, 16 in CS2, 12 in Database Management, and 28 in Operating Systems. So the first row will have 23 columns, the second row 16 columns, the third row 12 columns, and the fourth and last row will have 28 columns.

Using an initialization list, it is easy to instantiate a two-dimensional array with a different number of columns for every row. But sometimes the data are retrieved dynamically—read from a file, for example—and it is not possible to use an initialization list.

To instantiate a two-dimensional array with a different number of columns for each row, we can do the following:

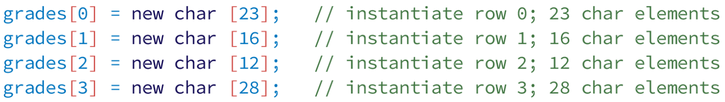
- First, instantiate the two-dimensional array.
- Second, instantiate each row as a single-dimensional array.

For the preceding example, we can use the following code:



```
char [ ][ ] grades;          // declare the array
grades = new char [4][ ];    // instantiate the array
                             // grades has 4 null array elements
```

Description



```
grades[0] = new char [23];   // instantiate row 0; 23 char elements
grades[1] = new char [16];   // instantiate row 1; 16 char elements
grades[2] = new char [12];   // instantiate row 2; 12 char elements
grades[3] = new char [28];   // instantiate row 3; 28 char elements
```

Description

The second statement:

```
grades = new char [4][ ];
```

Description

instantiates the two-dimensional array *grades* as an array having four rows, none of which has been instantiated yet. Because a two-dimensional array is an array of arrays, each element of the first dimension of the *grades* array is an array reference. Thus, before being instantiated, each element of the first dimension of the *grades* array has the value *null*.

As explained earlier, in a two-dimensional array, each row is a single-dimensional array. The last four statements instantiate each row, *grades[0]*, *grades[1]*, *grades[2]*, and *grades[3]*, each row having a different number of elements, or columns. The elements in these arrays are *chars*, initialized to the Unicode null character.

Later in this chapter, we will define a general pattern for processing two-dimensional array elements so that it applies to all situations: an identical number of columns for each row, or a different number of columns for each row.

The first monthly cell bill for the first family member is 45.24
The last monthly cell bill for the last family member is 28.16

The number of rows is 3
The number of columns in row 0 is 4
The number of columns in row 1 is 4
The number of columns in row 2 is 4
```

```
cars[1][0]'s description is:

Model: Ferrari; miles driven; 0; gallons of gas: 0.0
```

9.2 Accessing Multidimensional Array Elements

Elements of a two-dimensional array are accessed using this syntax:

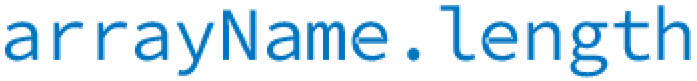
```
arrayName[exp1][exp2]
```

where *exp1* and *exp2* are expressions that evaluate to integers.

Description

Exp1 is the element's row position, or **row index**, within the two-dimensional array. *Exp2* is the element's column position, or **column index**, within the two-dimensional array. The row index of the first row is always 0; the row index of the last row is always 1 less than the number of rows. The column index of the first column is always 0. The column index of the last column is always 1 fewer than the number of columns in that row.

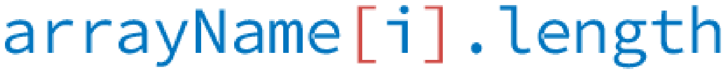
Because a two-dimensional array is an array of arrays, the length of a two-dimensional array is its number of arrays, or rows. We access the number of rows in a two-dimensional array using the following syntax:



```
arrayName.length
```

Description

Similarly, the length of each row is the number of columns (or elements) in that row's array. To access the number of columns in row *i* of a two-dimensional array named *arrayName*, we use this syntax:



```
arrayName[i].length
```

Description

Table 9.1 summarizes the syntax for accessing elements of a two-dimensional array.

Accessing Two-Dimensional Array Elements

Array Element	**Syntax**
Row 0, column *j*	`arrayName[0][j]`
Row *i*, column *j*	`arrayName[i][j]`
Last row, column *j*	`arrayName[arrayName.length - 1][j]`
Last row, last column	`arrayName[arrayName.length - 1][arrayName[arrayName.length - 1].length - 1]`
Number of rows in the array	`arrayName.length`
Number of columns in row *i*	`arrayName[i].length`

Description

Suppose we want to analyze the monthly cell phone bills for the past three months for a family of four persons. The parents, Joe and Jane, each have a cell phone, and so do the children, Mike and Sarah. We want to calculate the average monthly bill for each person, the total payments for the three months, and determine which family member had the lowest and highest bills. We could use a two-dimensional array of *doubles* with three rows and four columns. The rows will represent the months and the columns will represent the family members. For example, we could have the following mapping for the row and column indexes:

row 0 : July
row 1 : August
row 2 : September

column 0 : Joe
column 1 : Jane
column 2 : Mike
column 3 : Sarah

We could visualize our two-dimensional array as the table shown in **Table 9.2**.

Visualizing a Two-Dimensional Array

Description

We'll name the array *familyCellBills*. Each element in the array will be referenced as *familyCellBills[i][j]*, where *i* is the index of the row (the month), and *j* is the index of the column (the person). Remember that the first element in a row or column is at index 0, so the first element in the first row is at index [0][0].

In lines 13–15 of **Example 9.1**, we declare and instantiate the *familyCellBills* array. Because the elements of *familyCellBills* are *doubles*, instantiating the array also initializes each element to 0.0. Lines 18–31 store values into each element of the array. **Figure 9.3** shows how the *familyCellBills* array looks after lines 18–31 are executed.

Example 9.1 The *familyCellBills* Array

```
 1 /* Two-Dimensional Array of Cell Phone Bills
 2    Anderson, Franceschi
 3 */
 4
 5 public class FamilyCellBills
 6 {
 7  public static void main( String [ ] args )
 8  {
 9   // declare constants for the number of rows and columns
10   final int NUMBER_OF_MONTHS = 3;
11   final int NUMBER_OF_PERSONS = 4;
12
13   // declare and instantiate the array
14   double [ ][ ] familyCellBills =
15      new double [NUMBER_OF_MONTHS][NUMBER_OF_PERSONS];
16
17   // assign values to array elements
18   familyCellBills[0][0] = 45.24;  // row 0
19   familyCellBills[0][1] = 54.67;
20   familyCellBills[0][2] = 32.55;
21   familyCellBills[0][3] = 25.61;
22
23   familyCellBills[1][0] = 65.29;  // row 1
24   familyCellBills[1][1] = 49.75;
25   familyCellBills[1][2] = 32.08;
26   familyCellBills[1][3] = 26.11;
27
28   familyCellBills[2][0] = 75.24;  // row 2
29   familyCellBills[2][1] = 54.53;
30   familyCellBills[2][2] = 34.55;
31   familyCellBills[2][3] = 28.16;
32
33   System.out.println( "The first monthly cell bill for the first "
34      + "family member is\n"
35      + familyCellBills[0][0] );
36   System.out.println( "The last monthly cell bill for the last "
37      + "family member is\n"
38      + familyCellBills[NUMBER_OF_MONTHS - 1][NUMBER_OF_PERSONS - 1] );
39
40   int numRows = familyCellBills.length;
41   System.out.println( "\nThe number of rows is " + numRows );
42
43   for ( int i = 0; i < numRows; i++ )
44   {
45    System.out.print( "The number of columns in row " + i + " is " );
46    System.out.println( familyCellBills[i].length );
47   }
48  }
49 }
```

Description

Figure 9.3 The *familyCellBills* Array After Assigning Values

Description

COMMON ERROR TRAP

Attempting to access an element of a two-dimensional array using a row index less than 0 or greater than *arrayName.length – 1* will generate an *ArrayIndex-OutOfBoundsException* at run time. Similarly, attempting to access an element of row *i* of a two-dimensional array using a column index less than 0 or greater than *arrayName[i].length – 1* also will generate an *ArrayIndexOutOfBounds-Exception*.

Note that the last element is *familyCellBills[2][3]*, with a row index that is 1 less than *familyCellBills.length*, and a column index that is 1 less than *familyCellBills[2].length*, which is the number of columns in the last row. More generally, for a two-dimensional array named *arr*, the last element is:

```
arr[arr.length - 1][arr[arr.length - 1].length - 1]
```

Description

Lines 33–38 output the first and last element of the array *familyCellBills*.

Line 40 assigns the number of rows in the *familyCellBills* array to the *int* variable *numRows*. The variable *numRows* now has the value 3 and is output at line 41.

At lines 43–47, a *for* loop outputs the number of columns in each row of *familyCellBills*. **Figure 9.4** shows the output of this example.

Figure 9.4 Output of Example 9.1

Description

Row indexes of a two-dimensional array *must* be between 0 and *arrayName.length – 1*. Attempting to access an element of an array using a row index less than 0 or greater than *arrayName.length – 1* will compile without errors, but will generate an *ArrayIndexOutOfBoundsException* at run time. By default, this exception halts execution of the program.

For example, all the following expressions are invalid:

```
// invalid row indexes for the familycellBills array!!

familyCellBills[-1][2]
// the lowest valid row index is 0

familyCellBills[cellBills.length][2]
// the highest valid row index is familyCellBills.length - 1
```

Description

Similarly, column indexes of a two-dimensional array *must* be between 0 and *arrayName[i].length – 1*, where *i* is the row index. Attempting to access an element of row *i* in a two-dimensional array using a column index less than 0 or greater than *arrayName[i].length – 1* will compile without errors, but will generate an *ArrayIndexOutOfBoundsException* at run time.

For example, all the following expressions are invalid:

```
// invalid column indexes for the familyCellBills array!

familyCellBills[1][-1]
// the lowest valid column index is 0

familyCellBills[1][familyCellBills[1].length]
// the highest valid column index of row i is
// familyCellBills[i].length - 1
```

Description

Example 9.2 illustrates how to work with an array of objects. In this example, we use an *Auto* class that has three instance variables; *model*, a *String*; *milesDriven,* an *int*; and *gallonsOfGas*, a *double*. At lines 17–20, we declare and initialize *cars*, a two-dimensional array of *Auto* objects. Before using an element of *cars*, that *Auto* element has to be instantiated; failure to do so could generate a *NullPointerException* at run time.

There are three rows in *cars*: the first row has three columns, and the second and third rows have two columns each. Line 22 retrieves the array element at row 1 and column 0—here *sportsCar*—and assigns it to the *Auto* object reference *retrievedCar*, which is then printed at lines 25–26, where *toString* is called implicitly. **Figure 9.5** shows the output of this example.

Figure 9.5 Output of Example 9.2

Description

Example 9.2 Two-Dimensional Array of *Auto* Objects

```
/* Working with a Two-Dimensional Array of Objects
   Anderson, Franceschi
*/

public class TwoDimAutoArray
{
 public static void main( String [ ] args )
 {
  // instantiate several Auto object references
  Auto sedan1 = new Auto( "BMW", 0, 0.0 );
  Auto sedan2 = new Auto( "BMW", 100, 15.0 );
  Auto sedan3 = new Auto( "Toyota", 0, 0.0 );
  Auto sportsCar = new Auto( "Ferrari", 0, 0.0 );
  Auto rv1 = new Auto( "Jeep", 0, 0.0 );
  Auto rv2 = new Auto( "Ford", 200, 30.0 );

  // declare and initialize two-dimensional array of Autos
  Auto [ ][ ] cars = { { sedan1, sedan2, sedan3 },
                       { sportsCar, new Auto( ) },
                       { rv1, rv2 } };

  Auto retrievedCar = cars[1][0];
  // retrievedCar gets the sportsCar object reference

  System.out.println( "cars[1][0]'s description is:\n"
                      + retrievedCar );
 }
}
```

9.3 Aggregate Two-Dimensional Array Operations

As with single-dimensional arrays, Java does not support aggregate operations on multidimensional arrays. For example, we cannot print the contents of an array using only the array name. Instead, we need to process each element individually.

9.3.1 Processing All the Elements of a Two-Dimensional Array

To process all the elements of a two-dimensional array, we use nested *for* loops that access and process each element individually. Often, the most logical way to process all elements is in row order, and within each row, in column order. We could also process elements one column at a time if that is more logical for the problem at hand.

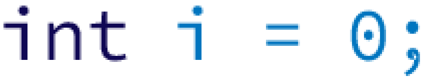
In our nested *for* loops, the outer *for* loop will process the rows and the inner *for* loop will process the columns within each row. We will use *i* for the row index and *j* for the column index.

For the outer *for* loop, we can use the same header as we use to process single-dimensional arrays:

```
for ( int i = 0; i < arrayName.length; i++ )
```

Description

Note that the initialization statement of the outer loop:

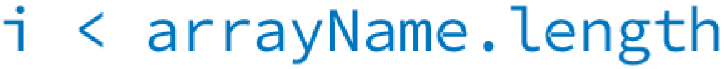


```
int i = 0;
```

Description

sets *i* to the index of the first row of the two-dimensional array. Then the outer loop update statement increments *i*, so that we process each row in order.

The outer loop condition:



```
i < arrayName.length
```

Description

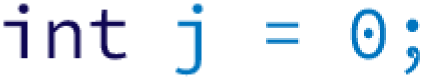
continues execution of the outer loop as long as the row index is less than the *length* of the two-dimensional array, which represents the number of rows. Note that we use the *less than* operator (<) instead of the *less than or equal to* operator (<=). Using the *less than or equal to* operator would cause us to illegally attempt to reference an element with a row index of *arrayName.length*.

The *for* loop header for the inner loop, which processes the columns of the current row, is as follows:

```
for ( int j = 0; j < arrayName[i].length; j++ )
```

Description

The initialization statement of the inner loop:



```
int j = 0;
```

Description

sets *j* to the index of the first column of the current row. Then the inner loop update statement increments *j* to the next column index, so that we process each column of the current row in order.

The inner loop condition:

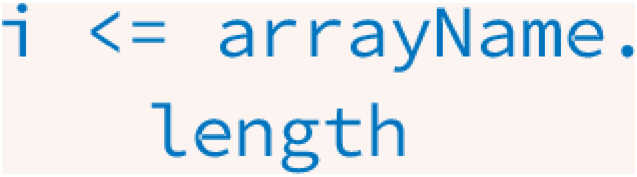
```
j < arrayName[i].length
```

Description

continues execution of the inner loop as long as the column index is less than the *length* of the current row (row *i*). Given that each row can have a different number of columns, this will ensure that we do not attempt to access an element beyond the last column index of the current row.

COMMON ERROR TRAP

In the outer *for* loop, using the following condition:

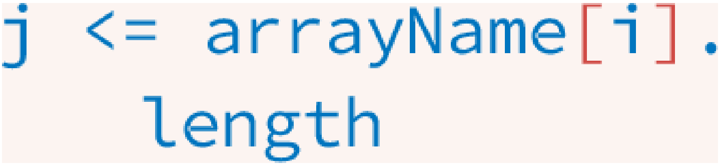


```
i <= arrayName.
    length
```

Description

will generate an *ArrayIndexOutOfBounds-Exception* because the last row of a two-dimensional array is *arrayName.length – 1*.

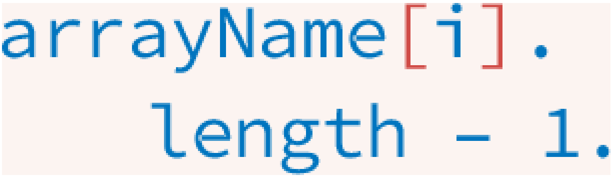
Similarly, in the inner *for* loop, using the condition:



```
j <= arrayName[i].
    length
```

Description

will generate an *ArrayIndexOutOfBounds-Exception* because the last column of row *i* in a two-dimensional array is

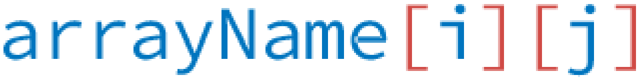


```
arrayName[i].
    length - 1.
```

Description

Note, again, that we use the *less than* operator (<), not the *less than or equal to* operator (<=), which would cause us to illegally attempt to reference an element with a column index of *arrayName[i].length*.

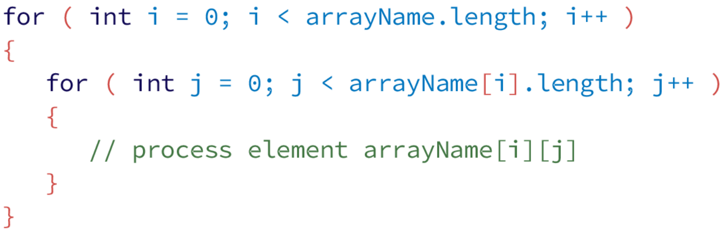
Inside the inner *for* loop, we refer to the current element being processed as:



```
arrayName[i][j]
```

Description

Thus, the general pattern for processing the elements of a two-dimensional array called *arrayName* in row-first, column-second order using nested *for* loops is:



```
for ( int i = 0; i < arrayName.length; i++ )
{
   for ( int j = 0; j < arrayName[i].length; j++ )
   {
      // process element arrayName[i][j]
   }
}
```

Description

Example 9.3 illustrates how to print all the elements of the two-dimensional array *familyCellBills* in row order. The array is declared and initialized at lines 10–12. At lines 16–23, the nested *for* loops, using the standard pattern described earlier, print all the elements of the array. Figure 9.6 shows the output of the program.

Figure 9.6 Output of Example 9.3

Description

Example 9.3 Two-Dimensional Array Processing

```java
/* Processing a Two-Dimensional Array of Cell Phone Bills
   Anderson, Franceschi
*/

public class OutputFamilyCellBills
{
 public static void main( String [ ] args )
 {
  // declare and initialize the array
  double [ ][ ] familyCellBills = { {45.24, 54.67, 32.55, 25.61},
                                    {65.29, 49.75, 32.08, 26.11},
                                    {75.24, 54.53, 34.55, 28.16} };

  System.out.println( "\tData for family cell bills" );

  for ( int i = 0; i < familyCellBills.length; i++ )
  {
    System.out.print( "\nrow " + i + ":\t" );
    for ( int j = 0; j < familyCellBills[i].length; j++ )
    {
      System.out.print( familyCellBills[i][j] + "\t" );
    }
  }
  System.out.println( );
 }
}
```

Description

9.3.2 Processing a Given Row of a Two-Dimensional Array

What if we want to process just one row of a two-dimensional array? For instance, we could be interested in calculating the sum of the cell bills for the whole family for a particular month, or identifying who had the highest cell bill in a particular month. The general pattern for processing the elements of row *i* of a two-dimensional array called *arrayName* uses a single *for* loop:

```java
for ( int j = 0; j < arrayName[i].length; j++ )
{
    // process element arrayName[i][j]
}
```

Description

Example 9.4 shows how to sum all the elements of a particular row of the two-dimensional array *familyCellBills*.

Example 9.4 Processing One Row in a Two-Dimensional Array

```
 1 /* Processing One Row of a Two-Dimensional Array
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6 import java.text.NumberFormat;
 7
 8 public class SumARowFamilyCellBills
 9 {
10  public static void main( String [ ] args )
11  {
12   // declare and initialize the array
13   double [ ][ ] familyCellBills = { {45.24, 54.67, 32.55, 25.61},
14                                     {65.29, 49.75, 32.08, 26.11},
15                                     {75.24, 54.53, 34.55, 28.16} };
16
17   String [ ] months = { "July", "August", "September" };
18   for ( int i = 0; i < months.length; i++ )
19       System.out.println( "Month " + i + " : " + months[i] );
20
21   Scanner scan = new Scanner( System.in );
22   int currentMonth;
23   do
24   {
25     System.out.print( "Enter a month number between 0 and 2 > " );
26     currentMonth = scan.nextInt( );
27   } while ( currentMonth < 0 || currentMonth > 2 );
28
29   double monthlyFamilyBills = 0.0;
30   for ( int j = 0; j < familyCellBills[currentMonth].length; j++ )
31   {
32     // add current family member bill to total
33     monthlyFamilyBills += familyCellBills[currentMonth][j];
34   }
35
36   NumberFormat priceFormat = NumberFormat.getCurrencyInstance( );
37   System.out.println( "\nThe total family cell bills during "
38                       + months[currentMonth] + " is "
39                       + priceFormat.format( monthlyFamilyBills ) );
40  }
41 }
```

Description

Since the rows correspond to the months, we declare and initialize at line 17 a single-dimensional *String* array named *months* in order to make our prompt more user-friendly. At lines

18–19, we print a menu for the user, providing month names and the corresponding indexes. At lines 23–27, we use a *do/while* loop to prompt the user for a month index until the user enters a valid value between 0 and 2.

To calculate the total of the family cell bills for the month index that the user inputs, we first initialize the variable *monthlyFamilyBills* to 0.0 at line 29. We then use a single *for* loop at lines 30–34, following the pattern described earlier, to sum all the family member bills for the month chosen by the user. We then format and output the total at lines 36–39. Figure 9.7 shows the output of the program when the user chooses 1 for the month.

Figure 9.7 Output of Example 9.4

Description

9.3.3 Processing a Given Column of a Two-Dimensional Array

If we want to determine the highest cell bill for Mike or calculate the average cell bill for Sarah, we will need to process just one column of the two-dimensional array.

The general pattern for processing the elements of column *j* of a two-dimensional array called *arrayName* uses a single *for* loop:

```
for ( int i = 0; i < arrayName.length; i++ )
{
    if ( j < arrayName[i].length )
       // process element arrayName[i][j]
}
```

Description

Because rows may have a different number of columns, a given row *i* may not have a column *j*. Thus, we need to check that the current column number is less than *arrayName[i].length* before we attempt to access *arrayName[i][j]*.

SOFTWARE ENGINEERING TIP

Before processing an element in a column, check whether the current row contains an element in that column. Doing so will avoid an *ArrayIndexOutOfBounds-Exception*.

Because our two-dimensional array *familyCellBills* has the same number of columns (4) in every row, no extra precaution is necessary here. It is a good software engineering practice, however, to verify that the column index is valid before attempting to process the array element.

Example 9.5 shows how to find the maximum value of all the elements of a particular column.

Example 9.5 Processing a Column in a Two-Dimensional Array

```
1 /* Processing One Column of a Two-Dimensional Array
2    Anderson, Franceschi
3 */
4
5 import java.util.Scanner;
6 import java.text.NumberFormat;
7
8 public class MaxMemberBill
9 {
10  public static void main( String [ ] args )
11  {
12   // declare and initialize the array
13   double [ ][ ] familyCellBills = { {45.24, 54.67, 32.55, 25.61},
14                                     {65.29, 49.75, 32.08, 26.11},
15                                     {75.24, 54.53, 34.55, 28.16} };
16
17   String [ ] familyMembers = { "Joe", "Jane", "Mike", "Sarah" };
18   for ( int i = 0; i < familyMembers.length; i++ )
19          System.out.println( "Family member " + i + " : "
20                              + familyMembers[i] );
21
22   Scanner scan = new Scanner( System.in );
23   int currentMember;
24   do
25   {
26    System.out.print( "Enter a family member between 0 and 3 > " );
27    currentMember = scan.nextInt( );
28   } while ( currentMember < 0 || currentMember > 3 );
29
30   double memberMaxBill = familyCellBills[0][currentMember];
31   for ( int i = 1; i < familyCellBills.length; i++ )
32   {
33    if ( currentMember < familyCellBills[i].length )
34    {
35      // update memberMaxBill if necessary
36      if ( familyCellBills[i][currentMember] > memberMaxBill )
37        memberMaxBill = familyCellBills[i][currentMember];
38    }
39   }
40
41   NumberFormat priceFormat = NumberFormat.getCurrencyInstance( );
42   System.out.println ( "\nThe max cell bill for "
43                        + familyMembers[currentMember] + " is "
44                        + priceFormat.format( memberMaxBill ) );
45  }
46 }
```

Description

At line 17, we declare and initialize a single-dimensional *String* array named *familyMembers* to make our prompt more user-friendly. At lines 24–28, we again use a *do/while* loop to prompt the user for a valid family member index.

To calculate the maximum value of the family member cell bills, we first initialize the variable *memberMaxBill* to the first element in the column (*familyCellBills[0][currentMember]*) at line

30. We then use a standard *for* loop at lines 31–39, following the pattern described earlier to update the value of *memberMaxBill* as necessary. There is one minor difference; we do not need to start the row at index 0 because we initialized *memberMaxBill* to the value of the element in row 0 of the column *currentMember*. Note that we assume that there is an element at column 0 of each row; that is, each row has been instantiated. The value of the variable *memberMaxBill* is then formatted and printed at lines 41–44. Figure 9.8 shows the output of the program.

Figure 9.8 Output of Example 9.5

Description

9.3.4 Processing a Two-Dimensional Array One Row at a Time

Earlier, we calculated the sum of the elements of a given row of a two-dimensional array. But what if we are interested in calculating that sum for each row? In this case, we need to initialize our total variable before we process each row and print the results after we process each row.

The general pattern for processing each row of a two-dimensional array called *arrayName* using nested *for* loops is

```
   for ( int i = 0; i < arrayName.length; i++ )
   {
      // initialize processing variables for row i
   for ( int j = 0; j < arrayName[i].length; j++ )
   {
       // process element arrayName[i][j]
   }
   // finish the processing of row i
}
```

Description

There are two important additions to the general pattern for processing all elements of the array:

- Before processing each row, that is, before the inner loop, we need to initialize the processing variables for the current row. If we are summing elements, we initialize the total variable to 0. If we are calculating a minimum or maximum value, we initialize the current minimum or maximum to the value of the first element of the current row.
- When we reach the end of each row, that is, after each completion of the inner loop, we finish processing the current row. For instance, we may want to print the sum or maximum value for that row.

Example 9.6 shows how to sum the elements of each row of the two-dimensional array *familyCellBills*.

Example 9.6 Processing Each Row in a Two-Dimensional Array

```
/* Processing Each Row of a Two-Dimensional Array
   Anderson, Franceschi
*/

import java.util.Scanner;
import java.text.NumberFormat;

public class SumEachRowFamilyCellBills
{
 public static void main( String [ ] args )
 {
  // declare and initialize the array
  double [ ][ ] familyCellBills = { {45.24, 54.67, 32.55, 25.61
                                    {65.29, 49.75, 32.08, 26.11
                                    {75.24, 54.53, 34.55, 28.16

  String [ ] months = { "July", "August", "September" };

  NumberFormat priceFormat = NumberFormat.getCurrencyInstance(
  double currentMonthTotal;
  for ( int i = 0; i < familyCellBills.length; i++ )
  {
   currentMonthTotal = 0.0;  // initialize total for row
   for ( int j = 0; j < familyCellBills[i].length; j++ )
   {
    // add current family member bill to current monthly total
    currentMonthTotal += familyCellBills[i][j];
   }
   // print total for row
   System.out.println( "The total for " + months[i] + " is "
                        + priceFormat.format( currentMonthTotal
  }
 }
}
```

Description

Again, the rows correspond to the months, and we declare and initialize at line 17 a *String* array named *months* in order to make the output user-friendly.

To calculate the total of the family cell bills for each month, we use nested *for* loops at lines 21–32, following the pattern described earlier.

Inside the outer *for* loop, we initialize the *currentMonthTotal* at line 23 before processing each row. Without this statement, the variable *currentMonthTotal* would continue to accumulate, as if we were summing all the elements of the array instead of calculating a separate sum for each row.

After the inner loop finishes, we complete the processing of row *i* by printing the value of *currentMonthTotal* at lines 29–31. **Figure 9.9** shows the output of the program.

Figure 9.9 Output of Example 9.6

Description

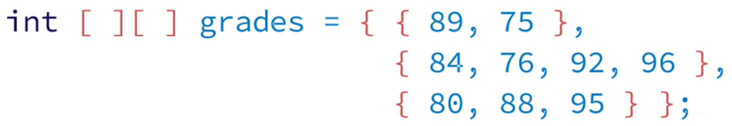
COMMON ERROR TRAP

Failing to initialize the row processing variables before each row is a logic error and will generate incorrect results.

9.3.5 Processing a Two-Dimensional Array One Column at a Time

Processing each column of a two-dimensional array requires a little extra checking. If the number of columns in each row differs, we must be careful not to attempt to access an element with an out-of-bounds column index. Generally, we will need to determine the number of columns in the largest row in the array before coding the outer loop header.

For example, suppose we are keeping track of our test grades in three classes: Intro to Java, Database Management, and English Composition. We have two test grades in Intro to Java, four in Database Management, and three in English Composition. We can use a two-dimensional array to store these test grades as follows:

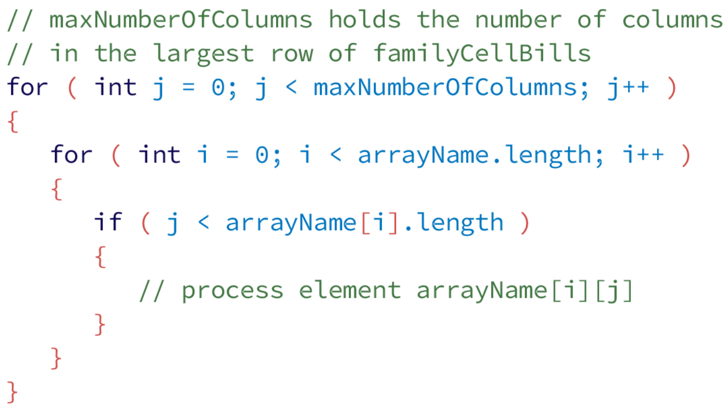


```
int [ ][ ] grades = { { 89, 75 },
                      { 84, 76, 92, 96 },
                      { 80, 88, 95 } };
```

Description

There are three rows in the array *grades*. The maximum number of columns in any row is four; therefore, in order to process all the columns, our outer loop should loop from column index 0 to column index 3. Our inner loop should check that the current column number exists in the row before attempting to process the element.

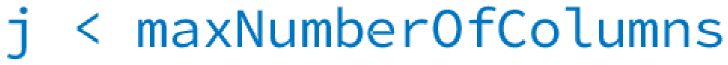
Let’s assume, at this point, that we stored the maximum number of columns in an *int* variable called *maxNumberOfColumns*. The general pattern for processing elements of a two-dimensional array, *arrayName*, one column at a time is:



```
// maxNumberOfColumns holds the number of columns
// in the largest row of familyCellBills
for ( int j = 0; j < maxNumberOfColumns; j++ )
{
   for ( int i = 0; i < arrayName.length; i++ )
   {
      if ( j < arrayName[i].length )
      {
         // process element arrayName[i][j]
      }
   }
}
```

Description

The outer loop condition:

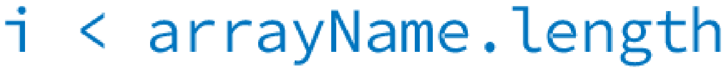


```
j < maxNumberOfColumns
```

Description

continues execution of the outer loop as long as the column index is less than the maximum number of columns of the two-dimensional array, which has been computed and assigned to the variable *maxNumberOfColumns*.

The inner loop condition:



```
i < arrayName.length
```

Description

continues execution of the inner loop as long as the row index is less than the number of rows.

Again, because each row may have a different number of columns, a given row *i* may not have a column *j*. Thus, using the following *if* condition, we check that an element in column *j* exists—*j* is less than *arrayName[i].length*—before we attempt to access *arrayName[i][j]*:

```
if ( j < arrayName[i].length )
```

Description

Example 9.7 shows how this pattern can be implemented in a program.

Example 9.7 Processing a Two-Dimensional Array in Column Order

```
 1 /* Processing Each Column in a Two-Dimensional Array
 2    Anderson, Franceschi
 3 */
 4
 5 public class GradesProcessing
 6 {
 7  public static void main( String [ ] args )
 8  {
 9   int [ ][ ] grades = { { 89, 75 },
10                         { 84, 76, 92, 96 },
11                         { 80, 88, 95 } };
12
13   // compute the maximum number of columns
14   int maxNumberOfColumns = grades[0].length;
15   for ( int i = 1; i < grades.length; i++ )
16   {
17    if ( grades[i].length > maxNumberOfColumns )
18       maxNumberOfColumns = grades[i].length;
19   }
20   System.out.println( "The maximum number of columns in grades is "
21                       + maxNumberOfColumns );
22
23   for ( int j = 0; j < maxNumberOfColumns; j++ )
24   {
25    System.out.print( "\nColumn " + j + ": " );
26    for ( int i = 0; i < grades.length; i++ )
27    {
28     if ( j < grades[i].length )
29          System.out.print( grades[i][j] );
30     System.out.print( "\t" );
31    }
32   }
33   System.out.println( );
34  }
35 }
```

Description

The array *grades* is declared and initialized at lines 9–11. Lines 13–19 compute the maximum number of columns in a row and store the value in the *int* variable *maxNumberOfColumns*. First, we initialize *maxNumberOfColumns* to the number of columns of row 0 at line 14. At lines 15 to 19, we loop through each remaining row in *grades* and update *maxNumberOfColumns* if we find that the current row has more columns than *maxNumberOfColumns*.

At lines 23–32, we use nested loops to print all the elements of *grades* in column order, following the general pattern described earlier. The output of the program is shown in **Figure 9.10**.

Figure 9.10 The Output of Example 9.7

Description

9.3.6 Displaying Two-Dimensional Array Data as a Bar Chart

Another way to display two-dimensional array data is graphically, by drawing a bar chart. For example, the bar chart in **Figure 9.11** displays the data in the *familyCellBills* array.

Figure 9.11 The *familyCellBills* Array as a Bar Chart

Description

Each bar is a rectangle. In order to draw a rectangle, we need to provide four arguments to the *fillRect* method of the *GraphicsContext* class: the *x* and *y* coordinate of the upper-left corner of the rectangle and the width and height of the rectangle. We use the variables *xStart* and *yStartBar*, adjusted by the value of the array element, for the *x* and *y* coordinates of the rectangle. We use a constant, *BAR_WIDTH*, for the width of each rectangle, and the value of the array element for its height.

So to create a bar chart, we use our standard nested *for* loops, and call the *fillRect* method of the *GraphicsContext* class to draw a rectangle for each element. We use the *fillText* method to display the value of each element. To change colors for each row, we set up an array of *Color* objects, and loop through the array to set the current color for each row iteration. Furthermore, each time we process a row, we must reset the (*x*, *y*) coordinates of the first bar for the next row.

Example 9.8 shows the code that displays the bar chart shown in Figure 9.11.

Example 9.8 Displaying a Two-Dimensional Array as a Bar Chart

```
/* A two-dimensional bar chart application
   Anderson, Franceschi
*/

import javafx.application.Application;
import javafx.stage.Stage;
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;

public class FamilyBarChartApplication extends Application
{
  final int LEFT_MARGIN = 80;         // starting x coordinate
  final int BASE_Y_BAR  = 100;        // bottom of the bars
  final int BASE_Y_VALUE = 125;       // bottom of the values
  final int BAR_WIDTH = 30;           // width of each bar
  final int SPACE_BETWEEN_BARS = 10;  // pixels between bars
  final int ROW_HEIGHT = 110;         // pixels between rows

  double [ ][ ] familyCellBills = { {45.24, 54.67, 32.55, 25.61},
                                    {65.29, 49.75, 32.08, 26.11},
                                    {75.24, 54.53, 34.55, 28.16} };

  String [ ] months = { "July", "August", "September" };
  Color [ ] colors = { Color.RED, Color.BLUE, Color.MAGENTA };

  @Override
  public void start( Stage stage )
  {
    // set up window title and size
    GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
                  stage, "Family Bar Chart", 275, 375 );

    int xStart = LEFT_MARGIN;   // x value for 1st column (bars)
    int yStart = BASE_Y_VALUE;  // y value for 1st row (data)
    int yStartBar = BASE_Y_BAR; // y value for 1st row (bars)

    for ( int i = 0; i < familyCellBills.length; i++ )
    {
      gc.setFill( colors[i] ); // set color for current row
      gc.fillText( months[i], xStart - LEFT_MARGIN + 10,
                              yStart - .3 * ROW_HEIGHT );

      for ( int j = 0; j < familyCellBills[i].length; j++ )
      {
        gc.fillRect( xStart, yStartBar - familyCellBills[i][j],
                     BAR_WIDTH, familyCellBills[i][j] );

        gc.fillText( Double.toString( familyCellBills[i][j] ),
                   xStart, yStart );

        // move to starting x value for next bar
        xStart += BAR_WIDTH + SPACE_BETWEEN_BARS;
      }

      // new row: increase yStart and yStartBar
      yStart += ROW_HEIGHT;
      yStartBar += ROW_HEIGHT;
      xStart = LEFT_MARGIN;
    }
  }

  public static void main( String [ ] args )
  {
    launch( args );
  }
}
```

Description

The *Color* single-dimensional array *colors* that we use to determine the color of each row of bars is declared and initialized at line 24. The first row of bars will be displayed in red, the second row in blue, and the third row in magenta. We use a *String* single-dimensional array, *months*, to label each row. Both arrays have the same number of rows as *familyCellBills*.

In the *start* method, at the beginning of the outer loop and before the inner loop, we set the color for the current row (line 39) by using the row number as an index into the *colors* array. At lines 40–41, we display the month.

In the body of the inner loop (lines 45–52), we draw the rectangle for the element value at row *i* and column *j* of *familyCellBills*, then display a *String* representing the same value. We then increment *xStart* to the location of the next bar to draw.

After the inner loop and before restarting the outer loop, we update the values of *yStart*, *yStartBar*, and *xStart* (lines 55–58) so that they are properly set for processing the next row. Earlier, we said that initializing variable values for the next row is usually done at the beginning of the outer loop body before entering the inner loop, but it also can be done after the inner loop and before re-entering the outer loop, as shown here.

CODE IN ACTION

To see a step-by-step illustration showing how to use two-dimensional arrays, look for the movie within the online resources. Click on the link to this chapter to start the movie.

9.4 Two-Dimensional Arrays Passed to and Returned from Methods

Writing methods that take two-dimensional arrays as parameters and/or return two-dimensional arrays is similar to working with single-dimensional arrays.

The syntax for a method that accepts a two-dimensional array as a parameter is the following:

```
returnType methodName( arrayType [ ][ ] arrayParameterName )
```

Description

The syntax for a method that returns a two-dimensional array is the following:

```
returnArrayType [ ][ ] methodName( parameterList )
```

Description

The caller of the method passes the argument list and assigns the return value to a reference to a two-dimensional array of the appropriate data type.

Combining both possibilities, the syntax for a method that accepts a two-dimensional array as a parameter and whose return value is a two-dimensional array is the following:

```
returnArrayType [ ][ ] methodName( arrayType [ ][ ] arrayParameterName )
```

Description

The caller of the method simply passes the name of the array without any brackets and assigns the return value to a reference to a two-dimensional array of the appropriate data type.

For example, suppose we want to tally votes in an election. We have four candidates running in six districts. We want to know how many votes each candidate received and how many votes were cast in each district. Thus, we can set up a two-dimensional array with each row representing a district and each column representing a candidate, with the values in each element representing the votes a candidate received in that district. We need to compute the sum of each row to find the number of votes per district and the sum of each column to find the number of votes per candidate.

To do this, we create a class, *Tally*, that has a two-dimensional array instance variable, *voteData*, storing the votes. The *Tally* class also has a method, *arrayTally*, that will compute the sums for each column and row of *voteData*. The sums will be returned from the method as a two-dimensional array with two rows. The first row will hold the totals for each column of *voteData*, and the second row will hold the totals for each row of *voteData*.

Example 9.9 shows the *Tally* class.

Example 9.9 The *Tally* Class

```
 1 /** Two-Dimensional Arrays as Method Parameters
 2 *   and Return Values: the Tally class
 3 *   Anderson, Franceschi
 4 */
 5
 6 public class Tally
 7 {
 8   int [ ][ ] voteData;
 9
10   /** constructor
11   * @param     voteData a 2-D array of vote counts
12   */
13   public Tally( int [ ][ ] voteData )
14   {
15     this.voteData = new int [voteData.length][ ];
16     for ( int i = 0; i < voteData.length; i++ )
17         this.voteData[i] = new int [voteData[i].length];
18
19      for ( int i = 0; i < voteData.length; i++ )
20      {
21        for ( int j = 0; j < voteData[i].length; j++ )
22        {
23          this.voteData[i][j] = voteData[i][j];
24        }
25      }
26   }
27
28   /** arrayTally method
29   *   @return a two-dimensional array of votes
30   */
31   public int [ ][ ] arrayTally( )
32   {
33     // create array of tallies, all elements are 0
34     int [ ][ ] returnTally = new int [2][ ];
35     returnTally[0] = new int [voteData[0].length];
36     returnTally[1] = new int [voteData.length];
37
38     for ( int i = 0; i < voteData.length; i++ )
39     {
40       for ( int j = 0; j < voteData[i].length; j++ )
41       {
42         returnTally[0][j] += voteData[i][j]; // add to column sum
43         returnTally[1][i] += voteData[i][j]; // add to row sum
44       }
45     }
46     return returnTally;
47   }
48 }
```

Description

The constructor, coded at lines 10–26, receives the two-dimensional array argument *voteData*. After instantiating the instance variable *voteData* at line 15, we copy the parameter *voteData* into the instance variable *voteData* one element at a time at lines 19–25.

We coded the *arrayTally* method at lines 28–47. Our first job is to instantiate the *returnArray*, which is the array the method will return to the caller. We know that the array will have two rows, one holding the sums of the columns and one holding the sums of the rows. Because each row in the *returnArray* will have a different number of columns, we instantiate the array with two rows, but do not give a value for the number of columns (line 34). We then instantiate each row with the appropriate number of columns (lines 35–36). Row 0, the sums of the columns, will have the same number of columns as the *voteData* array. In the interest of keeping this example simple, we have assumed that *voteData* has the same number of columns in every row, that is, each candidate was on the ballot in each district. Thus, that number is therefore equal to the number of columns in the first row, *voteData[0].length* (line 35). Row 1, the sum of the rows, will have the same number of columns as the number of rows in the *voteData* array.

In lines 38–45, we loop through the *voteData* array, computing the sums. We add each element's value to the sum for its column (line 42) and the sum for its row (line 43). When we finish, we return the *returnTally* array to the caller (line 46).

Example 9.10 shows a client program that instantiates a *Tally* object reference and calls the *arrayTally* method.

Example 9.10 The *VoteTally* Class

```
/** Tally votes: the VoteTally class
*   Anderson, Franceschi
*/

public class VoteTally
{
  public static void main( String [ ] args )
  {
    // votes are for 4 candidates in 6 districts.
    int [ ][ ] votes = { { 150, 253, 125, 345 },
                         { 250, 750, 234, 721 },
                         { 243, 600, 212, 101 },
                         { 234, 243, 143, 276 },
                         { 555, 343, 297, 990 },
                         { 111, 426, 834, 101 } };
    // candidate names
    String [ ] candidates = { "Smith", "Jones",
                              "Berry", "Chase" };

    // instantiate a Tally object reference
    Tally tally = new Tally( votes );

    // call arrayTally method to count the votes
    int [ ][ ] voteCounts = tally.arrayTally( );

    // print totals for candidates
    System.out.println( "Total votes per candidate" );
    for ( int i = 0; i < candidates.length; i++ )
      System.out.print( candidates[i] + "\t" );
    System.out.println( );
    for ( int j = 0; j < voteCounts[0].length; j++ )
      System.out.print( voteCounts[0][j] + "\t" );
    System.out.println( );

    // print totals for districts
    System.out.println("\nTotal votes per district" );
    for ( int i = 0; i < voteCounts[1].length; i++ )
       System.out.print( ( i + 1 ) + "\t\t" );
    System.out.println( );
    for ( int i = 0; i < voteCounts[1].length; i++ )
       System.out.print( voteCounts[1][i] + "\t" );
    System.out.println( );
  }
}
```

Description

We start by defining our two-dimensional array, *votes*, which holds the votes for each candidate for each district (lines 9–15). Most likely, we would read these values from a file, but for simplicity, we hard-coded the values in the initialization list. We also define a single-dimensional array of *Strings*, *candidates*, which holds the candidates' names (lines 16–18). Each name in the *candidates* array corresponds to the column in the *votes* array that holds that candidate's votes.

On lines 20–21, we instantiate the *Tally* object *tally*, passing the two-dimensional array *votes* to the *Tally* constructor. Notice that for the argument, we use only the array name, *votes*, without brackets.

On line 24, we call the *arrayTally* method, assigning the return value to a two-dimensional array reference named *voteCounts*.

Lines 26–33 print the totals per candidate by printing the elements in row 0 of the returned array, and lines 35–42 print the totals per district by printing the elements in row 1 of the returned array. The output is shown in Figure 9.12.

9.5 Programming Activity 1: Working with Two-Dimensional Arrays

In this activity, you will work with a 4-row, 20-column, two-dimensional array of integers. Specifically, you will write methods to perform the following operations:

1. Fill the array with random numbers between 50 and 80.
2. Print the array.
3. Set every array element of a given row to a specified value. The value is a parameter of a method.
4. Find the minimum value in a given column of the array. The column is a parameter of a method.

5. Count the number of elements of the array having a specified value. The value is a parameter of a method.

The framework for this Programming Activity will animate your algorithm so that you can check the accuracy of your code. For example, Figure 9.13 shows the application counting the elements having the value 61.

Figure 9.13 Animation of the Programming Activity

Description

At this point, the application has found the value 61 in four array elements.

Instructions

In this chapter's Programming Activity 1 folder in the supplied code files, you will find the source files needed to complete this activity. Copy all the files to a folder on your computer. Note that all files should be in the same folder.

Open the *TwoDimArrayPracticeController.java* source file. Searching for five asterisks (*****) in the source code will position you at the sample method and the four other locations where you will add your code. We have provided the sample code for task number 1, which you can use as a model for completing the other tasks. In every task, you will fill in the code for a method that will manipulate an existing array of 4 rows and 20 columns. You should not instantiate the array; we have done that for you. Example 9.11 shows the section of the *TwoDimArrayPracticeController* source code where you will add your code.

Example 9.11 Location of Student Code in *TwoDimArrayPracticeController*

```
// ***** 1.  This method has been coded as an example
/** Fills the array with random numbers between 50 and 80
*  The instance variable named intArray is the integer array to be
*  filled with values
*/
public void fillValues( )
{
 Random rand = new Random( );
 for ( int row = 0; row < intArray.length; row++ )
 {
     System.out.print( row + "\t" );
     for ( int column = 0; j < intArray[row].length; column++ )
     {
      intArray[row][column] = rand.nextInt( 31 ) + 50;
      animate( row, column, -1 );  // needed for visual feedback
     }
     System.out.println( );
 }
}  // end of fillValues method

// ***** 2.  Student writes this method
/** Prints array to the console, elements are separated by a space
*  The instance variable named intArray is the integer array to be
*  printed
*/
public void printArray( )
{
  // Note:  To animate the algorithm, put this method call as the
  // last statement in your inner for loop
  //            animate( row, column, -1 );
  //      where row is the index of the array's current row
  //  and column is the index of the array's current column
  // Write your code here:

} // end of printArray method

// ***** 3.  Student writes this method
/** Sets all the elements in the specified row to the specified value
*  The instance variable named intArray is the integer array
*  @param value      the value to assign to the element of the row
*  @param row        the row in which to set the elements to value
*/
public void setValues( int value, int row )
{
   // Note:  To animate the algorithm, put this method call as the
   // last statement in your for loop
   //            animate( row, column, -1);
   //      where row is the index of the array's current row
   //      where column is the index of the array's current column
   // Write your code here:

}  // end of setValues method

// ***** 4.  Student writes this method
/** Finds minimum value in the specified column
*  The instance variable named intArray is the integer array
*  @param column     the column to search
*  @return           the minimum value found in the column
*/
public int findMinimum( int column )
{
  // Note:  To animate the algorithm, put this method call as the
  // last statement in your for loop
  //            animate( row, column, minimum );
  //  where row is the index of the array's current row
  //        column is the index of the array's current column
  //        minimum is the variable storing the current minimum
  // Write your code here:

  return 0; // replace this line with your return statement

}  // end of findMinimumn method

// ***** 5.  Student writes this method
/** Finds the number of times value is found in the array
*  The instance variable named intArray is the integer array
*  @param value     the value to count
*  @return          the number of times value was found
*/
public int countFound( int value )
{
   // Note:  To animate the algorithm, put this method call as the
   // last statement in your inner for loop
   //            animate( row, column, num );
   // where row is the index of the array's current row
   //       column is the index of the array's current column
   //       num is the local variable storing the current frequency
   //        count
   // Write your code here:

   return 0;  // replace this line with your return statement

}
// end of countFound method
```

Description

Note that for the *countFound* and *findMinimum* methods, we provide a dummy *return* statement: (*return 0;*). We do this so that the source code will compile. In this way, you can write and test each method separately, using step-wise refinement. When you are ready to write the *countFound* and *findMinimum* methods, just replace the dummy *return* statements with the appropriate *return* statement for that method.

The framework will animate your algorithm so that you can watch your code work. For this to happen, be sure that your single or nested *for* loops call the method *animate*. The arguments that you send to *animate* are not always the same and the location of the call to *animate* will differ depending on the task you are coding. Detailed instructions for each task are included in the code.

To test your code, compile *TwoDimArrayPracticeController.java* and run the *TwoDimArrayPracticeApplication* source code. Figure 9.14 shows the graphics window when the program begins. Because the values of the array are randomly generated, the values will be different each time the program runs. To test any method, click on the appropriate button.

Figure 9.14 The Graphics Window When the Application Begins

Description

Troubleshooting

If your method implementation does not animate, check these tips:

- Verify that the last statement in your single *for* loop or inner *for* loop is a call to the *animate* method and that you passed the appropriate arguments. For example:

  ```
  animate( row, column );
  ```

  Description

- Verify that your exit conditions for your *for* loops are correct. Sometimes the exit condition depends on the length of the array (i.e., the number of rows in the array), and sometimes it depends on the number of columns in the current row of the array.

DISCUSSION QUESTIONS

1. With a two-dimensional array, for which operations would you use nested *for* loops and for which operations would you use a single *for* loop?
2. When performing an operation on a given row, which index is fixed and which index is used as the looping variable? When performing an operation on a given column, which index is fixed and which index is used as the looping variable?

9.6 Other Multidimensional Arrays

Sometimes we might need an array with more than two dimensions. For example, we might be interested in keeping track of sales on a per-year, per-week, and per-day basis. In this case, we would use a three-dimensional array as follows:

1st dimension: year
2nd dimension: week
3rd dimension: day of the week

Earlier in this chapter, we explained that a two-dimensional array is an array of single-dimensional arrays. Similarly, a three-dimensional array is an array of two-dimensional arrays. And a four-dimensional array is an array of three-dimensional arrays. More generally, an *n*-dimensional array is an array of (*n* – 1)-dimensional arrays.

Table 9.3 shows how an *n*-dimensional array is structured dimension by dimension; i_1, i_2, ..., i_n are used as generic indexes for the first dimension, second dimension, ..., and nth dimensions.

Structure of an *n*-Dimensional Array

Dimension	**Array Element**
first	arrayName[i$_1$] is an (n – 1)-dimensional array
second	arrayName[i$_1$][i$_2$] is an (n – 2)-dimensional array
*k*th	arrayName[i$_1$][i$_2$][i$_3$][..][i$_k$] is an (n – k) multi-dimensional array

$(n-2)$th	arrayName[i_1][i_2][i_3][..][i_{n-2}] is a two-dimensional array
$(n-1)$th	arrayName[i_1][i_2][i_3][..][i_{n-1}] is a single-dimensional array
nth	arrayName[i_1][i_2][i_3][..][i_{n-1}][i_n] is an array element

Description

If we keep track of sales over a period of 10 years, then we would have a 10-by-52-by-7 array. The principles discussed for a two-dimensional array still apply; we just have three dimensions instead of two. The following code sequence illustrates how to declare, instantiate, and access elements of this three-dimensional array:

```
double [ ][ ][ ] Sales;            // declare a four-dimensional array
Sales = new double [10][52][7];    // instantiate the array
Sales[0][0][0] = 638.50;           // access the first element
sales[4][22][3] = 928.30;          // access another element
sales[9][51][6] = 1234.90;         // access the last element
```

Description

To process elements of a single-dimensional array, we use a simple *for* loop; for a two-dimensional array, we use a double *for* loop. For a three-dimensional array, we use a triple *for* loop.

The general pattern for processing elements in a three-dimensional array is

```
for ( int i = 0; i < arrayName.length; i++ )
{
    for ( int j = 0; j < arrayName[i].length; j++ )
    {
       for ( int k = 0; k < arrayName[i][j].length; k++ )
       {
          // access and process the element arrayName[i][j][k]
       }
    }
}
```

Description

The following code sequence will print the elements of the three-dimensional array *sales*:

```
for ( int i = 0; i < sales.length; i++ )
{
   for ( int j = 0; j < sales[i].length; j++ )
   {
      for ( int k = 0; k < sales[i][j].length; k++ )
      {
       // access the element at sales[i][j][k]
       System.out.println( sales[i][j][k] + "\t" );
      }
       // skip a line when second dimension index changes
       System.out.println( );
   }
   // skip a line when first dimension index changes
   System.out.println( );
}
```

Description

If we are interested in keeping track of sales on a state-by-state basis, we can use a four-dimensional array as follows:

1st dimension: state
2nd dimension: year
3rd dimension: week
4th dimension: day of the week

The following code sequence illustrates how to declare, instantiate, and access the elements of such a four-dimensional array:

```
double [ ][ ][ ][ ] stateSales;           // declare a four-dimensional
                                          // array
stateSales = new double [50][10][52][7];  // instantiate the array
stateSales[0][0][0][0] = 58.50;           // access the first element
sales[34][4][22][3] = 98.30;              // access another element
sales[49][9][51][6] = 137.70;             // access the last element
```

Description

To process elements of a four-dimensional array, we use a quadruple *for* loop. That quadruple *for* loop pattern parallels the ones for the two-dimensional and three-dimensional arrays. For a four-dimensional array called *arrayName*, it is:

```
for ( int i = 0; i < arrayName.length; i++ )
{
    for ( int j = 0; j < arrayName[i].length; j++ )
    {
       for ( int k = 0; k < arrayName[i][j].length; k++ )
       {
          for ( int l = 0; l < arrayName[i][j][k].length; l++ )
          {
             // process element arrayName[i][j][k][l]
          }
       }
    }
}
```

Description

```
Using the traditional for loop:
34     89     65

Using the enhanced for loop:
34     89     65

Using unboxing and enhanced for loop:
34     89     65

After calling set( 1, 100 ):
34     100      65

At index 0, 34 was removed

After removing the element at index 0:
100     65
```

9.7 The *ArrayList* Class

As we have seen, single-dimensional and multidimensional arrays are useful in many situations. However, they have limitations.

Let's say we are designing a search engine for a large website, for example, an online bookstore. The user will type a word in a text field box, our code will access a database, retrieve all the books with titles that contain this word, and return them to the user.

We could store the book information in an array of books. One problem, however, is that we don't know how many books we will have. There could be 3, 32, 500, or 5,000 books, or maybe even more. Without knowing the number of books, we do not know what size to make the array. The safest bet would be to create the array with the maximum possible number of elements, that is, the maximum number of books that we anticipate. If we actually have fewer books than we anticipated, however, we will waste space.

And if we end up with more books than we anticipated, we would need to increase the size of the array. Because the size of an array is fixed when it is instantiated, changing the size of an array is a tedious process. We have to instantiate a new array and copy the elements of the original array to the new array.

The *ArrayList* class, in the *java.util* package, solves these problems. An *ArrayList* object automatically expands its capacity as needed. The *ArrayList* class uses **generics**. Generics are **parameterized types**, meaning that the data type will be defined at the time a client class declares and instantiates an object of the class. Generics allow programmers to design and code classes that use objects without specifying the class—or data type—of the object.

Thus, for example, we could have an *ArrayList* of *Book* objects, an *ArrayList* of *Auto* objects, or an *ArrayList* of *Strings*. The specified type must be a class, not a primitive type. If we want to store primitive data types in an *ArrayList*, then we need to use one of the wrapper classes such as *Integer*, *Double*, or *Character*.

The *ArrayList* class, and more generally a class using generics, can be used for many purposes. This is another facet of object-oriented programming that allows programmers to reuse code.

Because the *ArrayList* class is in the *java.util* package, programs using an *ArrayList* object will need to provide the following *import* statement:

```
import java.util.ArrayList;
```

Description

9.7.1 Declaring and Instantiating *ArrayList* Objects

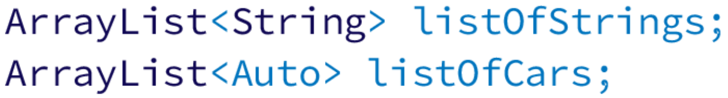
Here is the syntax for declaring an *ArrayList* of objects:

```
ArrayList<ClassName> arrayListName;
```

Description

Inside the brackets, we declare the class type of the objects that will be stored in the *ArrayList*. A space is optional between the *ArrayList* class name and the opening bracket.

For example, these two statements declare an *ArrayList* of *Strings* and an *ArrayList* of *Auto* objects:



```
ArrayList<String> listOfStrings;
ArrayList<Auto> listOfCars;
```

Description

If we try to declare an *ArrayList* object reference using a primitive data type instead of a class type, as in

```
ArrayList<int> listOfInts;
```

Description

we will get this compiler error:

```
Test.java:7: error: unexpected type
  ArrayList<int> listOfInts;
            ^
required: reference
found:    int
1 error
```

Description

Two constructors of the *ArrayList* class are shown in Table 9.4.

ArrayList Constructors

ArrayList Constructors Summary

Constructor name and argument list
`ArrayList<ClassName>( )` constructs an *ArrayList* object of *ClassName* type with an initial capacity of 10
`ArrayList<ClassName>( int initialCapacity )` constructs an *ArrayList* object of *ClassName* type with the specified initial capacity

Description

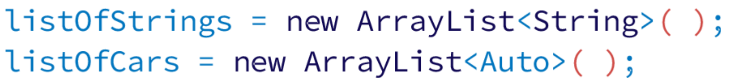
If we know how many elements we will store in the *ArrayList* object, we can use the overloaded constructor to specify the initial capacity; otherwise, we can simply use the default constructor. As we add elements to the *ArrayList* object, its capacity will increase automatically, as needed.

Here is the syntax for instantiating an *ArrayList* using the default constructor:

```
arrayListName = new ArrayList<ClassName>( );
  where ClassName is the class type of the objects that will be stored
  in the ArrayList and arrayListName has been declared previously as an
  ArrayList reference for that class.
```

Description

These statements will instantiate the *ArrayList* objects declared earlier, with an initial capacity of 10:



```
listOfStrings = new ArrayList<String>( );
listOfCars = new ArrayList<Auto>( );
```

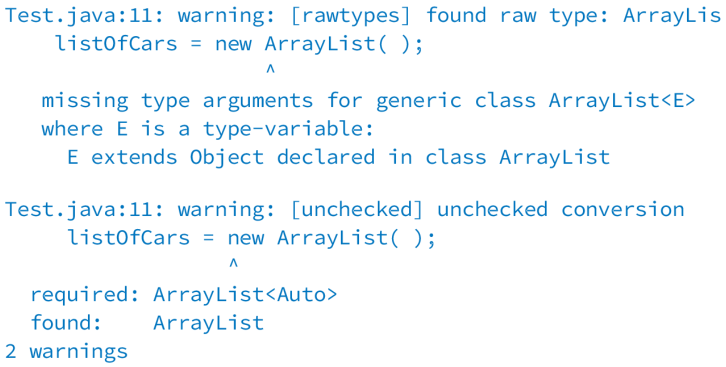
Description

If we try to instantiate an *ArrayList* object without specifying the object type, as in

```
listOfCars = new ArrayList( );
```

Description

we get the following warnings from the compiler (using Xlint):



```
Test.java:11: warning: [rawtypes] found raw type: ArrayLis
    listOfCars = new ArrayList( );
                                 ^
   missing type arguments for generic class ArrayList<E>
   where E is a type-variable:
     E extends Object declared in class ArrayList

Test.java:11: warning: [unchecked] unchecked conversion
     listOfCars = new ArrayList( );
                              ^
  required: ArrayList<Auto>
  found:    ArrayList
2 warnings
```

Description

In *ArrayLists*, there is a distinction between capacity and size. The **capacity** of an *ArrayList* is the number of elements allocated to the list. The **size** is the number of those elements that are filled with objects. Thus, when we instantiate an *ArrayList* using the default constructor, its capacity is 10, but its size is 0. In other words, the *ArrayList* has room for 10 objects, but no objects are currently stored in the list.

These statements will declare, then instantiate, an *ArrayList* of *String* objects with an initial capacity of 5, using the overloaded constructor:

```
ArrayList<String> listOfStrings1;
listOfStrings1 = new ArrayList<String>( 5 );
```

Description

In this case, the capacity of *listOf Strings1* is 5 and its size is 0.

We can also combine the declaration and instantiation of an *ArrayList* object into one statement. Here is the syntax using the default constructor:

```
ArrayList<ClassName> arrayListName = new ArrayList<ClassName>( );
```

Description

These statements will declare and instantiate two *ArrayList* objects of *Integers* and *Strings*, respectively:

```
ArrayList<Integer> listOfInts = new ArrayList<Integer>( );
ArrayList<String> listOfStrings2 = new ArrayList<String>( );
```

Description

9.7.2 Methods of the *ArrayList* Class

Like arrays, the *ArrayList* class uses indexes to refer to elements. Among others, it provides methods that provide the following functions:

- add an item at the end of the list
- replace an item at a given index
- remove an item at a given index
- remove all the items in the list
- search the list for a specific item
- retrieve an item at a given index
- retrieve the index of a given item
- check to see if the list is empty

- return the number of items in the list, that is, its size
- optimize the capacity of the list by setting its capacity to the number of items in the list

Some of the most useful methods are shown in Table 9.5. Note that some of the method headers include *E* as their return type or parameter data type (as opposed to a class name or simply the *Object* class). *E* represents the data type of the *ArrayList*. Thus, for an *ArrayList* of *Integer* objects, *E* is an *Integer*; and the *get* method, for example, returns an *Integer* object. Similarly, for an *ArrayList* of *Auto* objects, *E* is an *Auto* object. In this case, the *get* method returns an *Auto* object.

ArrayList Methods

Useful Methods of the *ArrayList* Class

Return value	Method name and argument list
`boolean`	`add( E element )` appends the specified *element* to the end of the list
`E`	`remove( int index )` removes and returns the element at the specified *index* position in the list
`void`	`clear( )` removes all the elements from this list
`E`	`get( int index )` returns the element at the specified *index* position in the list; the element is not removed from the list
`E`	`set( int index, E element )` replaces the element at the specified *index* position in this list with the specified *element*
`int`	`size( )`

	returns the number of elements in this list
`void`	`trimToSize( )` sets the capacity to the list's current size

Description

9.7.3 Looping Through an *ArrayList* Using an Enhanced *for* Loop

The general pattern for processing elements of an *ArrayList* of *ClassName* objects called *arrayListName* using a *for* loop is

```
ClassName currentObject;
for ( int i = 0; i < arrayListName.size( ); i++ )
{
      currentObject = arrayListName.get( i );
      // process currentObject
}
```

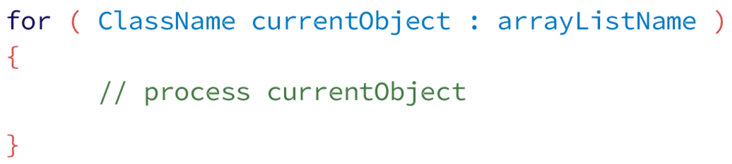
Description

For instance, to process elements of an *ArrayList* of *String* object references called *listOfStrings* using a standard *for* loop, the general pattern is:

```
String currentString;
for ( int i = 0; i < listOfStrings.size( ); i++ )
{
      currentString = listOfStrings.get( i );
      // process currentString
}
```

Description

Java provides a simplified way to process the elements of an *ArrayList*, called the **enhanced *for* loop.** The general pattern for processing elements of an *ArrayList* of *ClassName* objects called *arrayListName* using the enhanced *for* loop is:



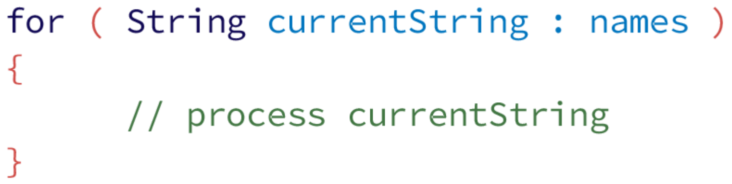
```
for ( ClassName currentObject : arrayListName )
{
      // process currentObject

}
```

Description

A variable of the class type of the objects stored in the *ArrayList* is declared in the enhanced *for* loop header, followed by a colon and name of the *ArrayList*. The enhanced *for* loop enables looping through the *ArrayList* objects automatically. Your code does not call the *get* method; inside the body of the loop, *currentObject* is directly available for processing.

For example, to process elements of an *ArrayList* of *Strings* called *names* using the enhanced *for* loop, the general pattern is:



```
for ( String currentString : names )
{
      // process currentString
}
```

Description

Example 9.12 shows how to create and use an *ArrayList* of *Integers*. Line 11 declares and instantiates the *ArrayList* object reference *list* using the default constructor. Three elements are added to *list* using the *add* method at lines 12–14. As the arguments to the *add* method, we use *ints.* The autoboxing feature of Java automatically converts an *int* to an *Integer* object when an *int* variable is used where an *Integer* object is expected.

Example 9.12 Using *ArrayList* Methods

```
 1 /* A Simple ArrayList of Integers
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.ArrayList;
 6
 7 public class ArrayListOfIntegers
 8 {
 9  public static void main( String [ ] args )
10  {
11   ArrayList<Integer> list = new ArrayList<Integer>( );
12   list.add( 34 ); // autoboxing
13   list.add( 89 ); // autoboxing
14   list.add( 65 ); // autoboxing
15
16   System.out.println( "Using the traditional for loop:" );
17   for ( int i = 0; i < list.size( ); i++ )
18      System.out.print( list.get( i ) + "\t" );
19   System.out.println( );
20
21   System.out.println( "\nUsing the enhanced for loop:" );
22   for ( Integer currentInteger : list )
23      System.out.print( currentInteger + "\t" );
24   System.out.println( );
25
26   System.out.println( "\nUsing unboxing and enhanced for loop:" );
27   for ( int currentInt : list ) // unboxing
28      System.out.print( currentInt + "\t" );
29   System.out.println( );
30
31   list.set( 1, 100 );
32   System.out.println( "\nAfter calling set( 1, 100 ):" );
33   for ( int currentInt : list ) // unboxing
34      System.out.print( currentInt + "\t" );
35   System.out.println( );
36
37   int removed = list.remove( 0 );
38   System.out.println( "\nAt index 0, " + removed + " was removed" );
39   System.out.println( "\nAfter removing the element at index 0:" );
40   for ( int currentInt : list ) // unboxing
41      System.out.print( currentInt + "\t" );
42   System.out.println( );
43  }
44 }
```

Description

After an *ArrayList* object has been declared and instantiated as being of a certain class type, you cannot add an object of a different class type. For example, you could not add a *Double* value to an *ArrayList* of *Integers*.

At lines 17–18, we print the elements of *list* using a traditional *for* loop, using the *get* method to retrieve the element at the current index. At lines 22–23, we use the enhanced *for* loop to print the elements. At lines 27–28, we also use the enhanced *for* loop to print the elements; but this time, we use an *int* as the looping variable, using the unboxing feature of Java, which converts *Integer* objects to *int* values, as needed. At line 31, we use the *set* method to change the value of the element at index 1 to 100, also using autoboxing. At line 37, we use the *remove* method to delete the element at index 0 and assign it to the variable *removed*, using unboxing again.

The output of this example is shown in **Figure 9.15**.

Figure 9.15 Output of Example 9.12

Description

9.7.4 Using the *ArrayList* Class in a Program

Now let's see how we can use the *ArrayList* class in a Java program. Going back to our example of a bookstore and a search engine, we want to design and code a simple program that enables users to search for books.

We will have three classes in this program:

- a *Book* class, encapsulating the concept of a book
- a *BookStore* class, encapsulating the concept of a bookstore
- a *BookSearchEngine* class, including the *main* method, which provides the user interface

In the interest of keeping things simple, our *Book* class will contain only three instance variables: the book title, which is a *String*; the book's author, which is also a *String*; and the book price, which is a *double*.

Example 9.13 shows a simplified *Book* class with constructors, accessor methods, and a *toString* method.

Example 9.13 The *Book* Class

```java
/* Book class
   Anderson, Franceschi
*/

public class Book
{
 private String title;
 private String author;
 private double price;

 /** default constructor
 */
 public Book( )
 {
  title = "";
  author = "";
  price = 0.0;
 }

 /** overloaded constructor
 * @param title    the value to assign to title
 * @param author   the value to assign to author
 * @param price    the value to assign to price
 */
 public Book( String title, String author, double price
 {
  this.title = title;
  this.author = author;
  this.price = price;
 }

 /** getTitle method
 *   @return the title
 */
 public String getTitle( )
 {
  return title;
 }

 /** getAuthor method
 *   @return the author
 */
 public String getAuthor( )
 {
  return author;
 }

 /** getPrice method
 *   @return the price
 */
 public double getPrice( )
 {
  return price;
 }

 /** toString
 * @return title, author, and price
 */
 @Override
 public String toString( )
 {
  return ( "title: " + title + "\t"
           + "author: " + author + "\t"
           + "price: " + price );
 }
}
```

Description

Our *BookStore* class, shown in **Example 9.14**, will simply have one instance variable: an *ArrayList* of *Book* objects, representing the collection of books in the bookstore, which we name *library*.

Example 9.14 The *BookStore* Class

```java
/*  BookStore class
    Anderson, Franceschi
*/

import java.util.ArrayList;

public class BookStore
{
 private ArrayList<Book> library;

 /** default constructor
 *   instantiates ArrayList of Books
 */
 public BookStore( )
 {
  library = new ArrayList<Book>( );
  library.add( new Book( "Intro to Java", "James", 56.99 ) );
  library.add( new Book( "Advanced Java", "Green", 65.99 ) );
  library.add( new Book( "Java Servlets", "Brown", 75.99 ) );
  library.add( new Book( "Intro to HTML", "James", 29.49 ) );
  library.add( new Book( "Intro to Flash", "James", 34.99 ) );
  library.add( new Book( "Advanced HTML", "Green", 56.99 ) );
  library.trimToSize( );
 }

 /** toString
 *  @return  each book in library, one per line
 */
 @Override
 public String toString( )
 {
  String result = "";
  for ( Book tempBook : library )
  {
    result += tempBook.toString( ) + "\n";
  }
  return result;
 }

 /** Generates list of books containing searchString
 * @param searchString       the keyword to search for
 * @return       the ArrayList of books containing the keyword
 */
 public ArrayList<Book> searchForTitle( String searchString )
 {
  ArrayList<Book> searchResult = new ArrayList<Book>( );
  for ( Book currentBook : library )
  {
   if ( currentBook.getTitle( ).indexOf( searchString ) != -1 )
        searchResult.add( currentBook );
  }
  searchResult.trimToSize( );
  return searchResult;
 }
}
```

Description

In most cases, when an *ArrayList* is filled with data, that data will come from a database or a file. In the interest of focusing on the *ArrayList* class and its methods, we have hard-coded the objects for the *ArrayList library* in the *BookStore* class, rather than reading them from a database or a file.

In the default constructor (lines 11 to 24), we instantiate the *library* instance variable, then add six *Book* objects to *library* using the *add* method from the *ArrayList* class. At line 23, we call the *trimToSize* method to set the capacity of *library* to its current size, which is 6, in order to minimize the memory resources used.

The *toString* method is coded from lines 26 to 38. It generates and returns a *String* representing all the books in *library*, one book per line. In order to do that, we use an enhanced *for* loop from lines 33 to 36. The header of that loop, at line 33, follows the general pattern of the enhanced *for* loop header by declaring a *Book* variable named *tempBook*, followed by a colon, followed by *library*, the *ArrayList* object to loop through.

The *searchForTitle* method, coded from lines 40 to 54, performs the task of searching for a keyword within the title of each *Book* object stored in *library*. The keyword, a *String*, is the parameter of the method and is named *searchString*. This method returns an *ArrayList* containing the *Book* objects that have the keyword in their title. We create that *ArrayList* of *Books*, which we name *searchResult* at line 46 and loop through *library* using an enhanced *for* loop from lines 47 to 51. Inside the body of the loop, we use the *indexOf* method of the *String* class to test if the current *Book* object contains the keyword *searchString* in its *title*. If it does, we add that *Book* object to *searchResult*. Finally, we call the method *trimToSize* to set the capacity of *searchResult* to the current number of elements, then return the *ArrayList* to the caller.

Our *BookSearchEngine* class, shown in Example 9.15, contains the *main* method: it creates a *BookStore* object, asks the user for a keyword, and searches for partial matches in our *BookStore* object.

Example 9.15 A Search Engine for Books

```
/* BookSearchEngine class
   Anderson, Franceschi
*/
```

```
 1 /* BookSearchEngine class
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.*;
 6
 7 public class BookSearchEngine
 8 {
 9  public static void main( String [ ] args )
10  {
11   BookStore bs = new BookStore( );
12
13   System.out.println( "Our book collection is:" );
14   System.out.println( bs.toString( ) );
15   Scanner scan = new Scanner( System.in );
16   System.out.print( "Enter a keyword > " );
17   String keyword = scan.next( );
18
19   ArrayList<Book> results = bs.searchForTitle( keyword );
20
21   System.out.println( "The search results for " + keyword
22                       + " are:" );
23   for ( Book tempBook : results )
24         System.out.println( tempBook.toString( ) );
25  }
26 }
```

Description

A *BookStore* object, *bs*, is declared and instantiated at line 11. Lines 13 and 14 simply output the collection of *Books* in the *BookStore* object *bs*; later, when the search results are output, we can compare that output to the original list of *Books* to check our results. At lines 15–17, the user is then prompted for a keyword that will be used to search for books whose title contains that keyword. At line 19, we call the *searchForTitle* method with *keyword* as its argument; the *ArrayList* of *Book* objects returned is assigned to the variable *results*. At lines 23–24, we loop through *results* and output its contents, again using the enhanced *for* loop. Figure 9.16 shows a run of the program with the user searching for books containing the word “Java.”

Figure 9.16 Results of a Search for the Keyword “Java”

Description

CODE IN ACTION

To see a step-by-step illustration showing how to use the *ArrayList* class, look for the movie within the online resources. Click on the link to start the movie.

ArrayList Practice
Fill Cars
Print Auto List
Set Model
Count Model Frequency
Find Maximum Miles
BMW

Miles = 4000

Gallons = 200.0

Student’s current count is 2

Correct current count is 2

ArrayList Practice
Fill Cars
Print Auto List
Set Model
Count Model Frequency
Find Maximum Miles

9.8 Programming Activity 2: Working with the *ArrayList* Class

In this activity, you will work with an *ArrayList* object. Specifically, you will write the code to perform the following operations:

1. Fill the *ArrayList* object with *Auto* elements.
2. Print the *Auto* elements contained in the *ArrayList* object.
3. Set the *model* instance variable of every *Auto* element in the *ArrayList* object to a specified model.

4. Find the maximum number of miles of all *Auto* elements contained in the *ArrayList* object.
5. Count the number of *Auto* elements in the *ArrayList* with a specified model.

Table 9.6 provides the API for the *Auto* class.

Constructors and Some Methods of the *Auto* Class

***Auto* Class Constructor Summary**
`Auto( )` creates an *Auto* object with initial default values of "unknown," 0, and 0.0.
`Auto( String model, int milesDriven, double gallonsOfGas )` creates an *Auto* object with the initial values of *model, milesDriven,* and *gallonsOfGas.*

***Auto*Class Method Summary**

Return value	**Method name and argument list**
`String`	`getModel( )` returns the value of *model*
`int`	`getMilesDriven( )` returns the value of *milesDriven*
`double`	`getGallonsOfGas( )` returns the value of *gallonsOfGas*
`Auto`	`setModel( String model )` mutator for *model*
`Auto`	`setMilesDriven( int milesDriven )` mutator for *milesDriven*
`Auto`	`setGallonsOfGas(`

	`double gallonsOfGas )` mutator for *gallonsOfGas*
`double`	`milesPerGallon( )` returns the gas mileage for this *Auto* object
`String`	`toString( )` returns a *String* representation of this object
`boolean`	`equals( Object obj )` compares this *Auto* object to another object

Description

The framework for this Programming Activity will animate your algorithm so that you can check the accuracy of your code. For example, **Figure 9.17** shows the application counting the number of *Auto* elements in the *ArrayList* object having a *model* value equal to “Ferrari.” The application accesses each element in the *ArrayList* in order, checking the *model* for the desired value, “Ferrari.” At this point, the current element being accessed is a *BMW* and the application has found two *Auto* elements with the *model* value, “Ferrari.”

Figure 9.17 Animation of the Programming Activity

Description

Instructions

In this chapter’s Programming Activity 2 folder in the supplied code files, you will find the source files needed to complete this activity. Copy all the files to a folder on your computer. Note that all files should be in the same folder.

Open the *ArrayListController.java* source file. Searching for five asterisks (*****) will position you at the sample method and the four other locations where you will add your code. We have provided the sample code for task number 1. In every task, you will fill in the code for a method that will manipulate an existing *ArrayList* of *Auto* elements. You should not instantiate the *ArrayList* object; we have done that for you. Example 9.16

shows the section of the *ArrayListController* source code where you will add your code.

Note that for the *countFound* and *findMaximumMilesDriven* methods, we provide a dummy *return* statement (*return* 0;). We do this so that the source code will compile. In this way, you can write and test each method separately, using step-wise refinement. When you are ready to write the *countFound* and *findMaximumMilesDriven* methods, just replace the dummy *return* statements with the appropriate *return* statement for that method.

Example 9.16 Location of Student Code in *ArrayListController*

```java
// ***** 1.  This method has been coded as an example
/** Fills the carList with hard-coded Auto objects
*    The instance variable carList is the ArrayList
*        to be filled with Auto objects
*/
public void fillWithCars( )
{
  // clear carList before adding cars
  carList.clear( );
  // Reset the number of Autos to 0
  // This is needed so that the animation feedback works correctly
  Auto.clearNumberAutos( );

  Auto car1 = new Auto( "BMW", 0, 0.0 );
  Auto car2 = new Auto( "Ferrari", 100, 500.0 );
  Auto car3 = new Auto( "Jeep", 1000, 90.0 );
  Auto car4 = new Auto( "Ferrari", 10, 3.0 );
  Auto car5 = new Auto( "BMW", 4000, 200.0 );
  Auto car6 = new Auto( "Ferrari", 1000, 50.0 );

  carList.add( car1 );
  animate( car1 );
  carList.add( car2 );
  animate( car2 );
  carList.add( car3 );
  animate( car3 );
  carList.add( car4 );
  animate( car4 );
  carList.add( car5 );
  animate( car5 );
  carList.add( car6 );
  animate( car6 );
}
// end of fillWithCars method

// ***** 2.  Student writes this method
/**  Prints carList to console, elements are separated by a space
*    The instance variable carList is the ArrayList to be printed
*/
public void printAutoList( )
{
 // Note:  To animate the algorithm, put this method call as the
 // last statement in your for loop
 //              animate( car );
 //  where car is the variable name for the current Auto object
 //  as you loop through the ArrayList object
 // Write your code here:

}
// end of printAutoList method

// ***** 3.  Student writes this method
/** Sets the model of all the elements in carList to parameter value
* The instance variable carList is the ArrayList to be modified
*  @param model the model to assign to all Auto objects in carList
*/
public void setModelValues( String model )
{
 // Note:  To animate the algorithm, put this method call as the
 // last statement in your for loop
 //            animate( car );
 //  where car is the variable name for the current Auto object
 //  as you loop through the ArrayList object
 // Write your code here:

}
// end of setModelValues method

// ***** 4.  Student writes this method
/** Finds maximum number of miles driven
*   Instance variable carList is the ArrayList to search
*  @return     the maximum miles driven by all the Auto objects
*/
public int findMaximumMilesDriven( )
{
 // Note:  To animate the algorithm, put this method call as the
 // last statement in your for loop
 //           animate( car, maximum );
 //  where car is the variable name for the current Auto object
 //  and maximum is the int variable storing the current maximum
 //  number of miles for all Auto elements you have already tested
 //  as you loop through the ArrayList object
 // Write your code here:

 return 0; // replace this statement with your return statement

}
// end of findMaximumMilesDriven method

// ***** 5.  Student writes this method
/** Finds number of times parameter model is found in the carList
*   Instance variable carList is the ArrayList in which we search
*  @param model       the model to count
*  @return            the number of times model was found
*/
public int countFound( String model )
{
 // Note:  To animate the algorithm, put this method call as the
 // last statement in your for loop
 //             animate( car, num );
 //  where car is the variable name for the current Auto object
 //  and num is the int variable storing the current number of
 //  Auto elements whose model is equal to the method's parameter
 //  as you loop through the ArrayList object
 // Write your code here:

 return 0; // replace this statement with your return statement

}
// end of countFound method
```

Description

The framework will animate your code so that you can watch it work. For this to happen, be sure that your *for* loops call the *animate* method. The arguments that you send to *animate* are not always the same, but the location of the call to *animate* is always the same, that is, the last statement of your *for* loop. Detailed instructions for each task are included in the code.

To test your code, compile *ArrayListController.java* and run the *ArrayListApplication* source code. Figure 9.18 shows the graphics window when the program begins. Because the *Auto* elements of the *ArrayList* object are hard-coded, the values will be the same each time the program runs. Click on the “Fill Cars” button first. To test any method, click on the appropriate button.

Figure 9.18 The Graphics Window When the Application Begins

Description

Troubleshooting

If your method implementation does not animate, check these tips:

- Verify that the last statement in your *for* loop is a call to the *animate* method and that you passed the loop variable(s) as the argument(s), as in the following:

```
animate( car ); // or
animate( car, maximum ); // or
animate( car, num );
```

  Description

- Verify that the headers of your *for* loops are correct. They should all be the same.
- Verify that you updated the variables *maximum* and *num* correctly.

DISCUSSION QUESTIONS

1. Change the code in the *fillWithCars* method so that there are more or fewer *Auto* objects in the *ArrayList*. How does the number of *Auto* objects impact how the other methods are coded? Explain.
2. **Explain how looping through an** *ArrayList* **is different from looping through an array.**

```
states: {MD=Maine, NY=New York, NJ=New Jersey, CA=California}
NY is New York

states: {MD=Maryland, NY=New York, NJ=New Jersey, CA=California}
Maryland was removed

states: {NY=New York, NJ=New Jersey, CA=California}

NY: New York
NJ: New Jersey
CA: California

New York
New Jersey
California
```

9.9 The *HashMap* Class

Sometimes data comes in the form of (key, value) pairs. A data set can be made up of (key, value pairs) where each value is associated with a key and can be accessed via its key. For example, the keys could be U.S. states' abbreviated names (e.g., MD, CA, NY, ..) and their associated values could be the state's full name (Maryland, California, New York, ..). Or, the keys could be SUN, MON TUES, .. and the values could be Sunday, Monday, Tuesday, … Such data structures are called hash tables, or hash maps, or associative arrays. Other programming languages, like Python, call them dictionaries.

The *HashMap* class, part of the *java.util* package, implements such data structure. Like the *ArrayList* class, the *HashMap* class uses generics. Note that there is no concept of order in a *HashMap*. The only way to access a value is via its key; there is no index.

9.9.1 Declaring and Instantiating *HashMap* Objects

Here is the syntax for declaring a *HashMap* of objects:

```
HashMap<ClassName1, ClassName2> hashMapName;
```

Description

ClassName1 is the data type of the keys, and ClassName2 is the data type of the values. As with the *ArrayList* class, we cannot declare a *HashMap* using primitive data types. For example, these two statements declare two *HashMaps*:

```
HashMap<String, String> countries;
HashMap<Integer, Auto> cars;
```

Description

The first one stores a hash map whose keys are *Strings* and values are *String* objects.

The second one stores a hash map whose keys are *Integers* and values are *Auto* objects. Note that we cannot use a primitive data type, so we use *Integer*, the wrapper class for *int*.

Two constructors of the *HashMap* class are listed in **Table 9.7**.

HashMap Constructors

HashMap Constructors Summary

Constructor name and argument list

`HashMap<ClassName1, ClassName2>( )`

Constructs a *HashMap* object whose keys are *ClassName1* objects and values are *ClassName2* objects

`HashMap<ClassName1, ClassName2>( int initialCapacity )`

Constructs a *HashMap* object whose keys are *ClassName1* objects and values are *ClassName2* objects. The resulting *HashMap* object has the specified initial capacity and a default load factor of 0.75. A load factor of 0.75 means that if the capacity of the HashMap is 75% full, the capacity will be automatically increased.

Description

Here is the syntax for instantiating a *HashMap* of objects:

```
hashMapName = new HashMap <ClassName1, ClassName2>( argumentList );
```

Description

These two statements will instantiate the two *HashMap* objects declared earlier:

```
countries = new HashMap <String, String>( );
cars = new HashMap <String, Auto>( 10 );
```

Description

Countries is instantiated using the default constructor, and *cars* is instantiated with an initial capacity of 10. Instantiating a *HashMap* without specifying the object types will result in a compiler warning.

9.9.2 Methods of the *HashMap* Class

Among others, the *HashMap* class provides methods to do the following operations:

- add a (key, value) pair
- remove a (key, value) pair
- replace an existing value with a new value based on its key
- check if the *HashMap* is empty
- check if a key is present in the *HashMap*
- check if a value is present in the *HashMap*
- return the number of (key, value) pairs
- return all the values of the *HashMap* as a list

Some methods of the *HashMap* class are listed in **Table 9.8.**

Useful Methods of the *HashMap* Class

Useful Methods of the *HashMap* Class

Return value	**Method name and argument list**
`V`	`put( K key, V value )` Adds the (*key*, *value*) pair

	specified to this *HashMap*. If this *HashMap* previously contained *key*, the old value is replaced and returned. Returns *null* if there was no previous mapping for *key*. *K* and *V* are the data types for the keys and the values of this *HashMap*, respectively.
`V`	`get( K key )` Returns the value mapped to *key*, *null* if there is no value mapped to *key*.
`boolean`	`isEmpty( )` Returns *true* if this *HashMap* contains no mapping, *false* otherwise.
`V`	`remove( K key )` Removes the (*key*, value) pair if *key* is found and returns the value mapped to *key*. Returns *null* if no mapping exists for *key*.
`boolean`	`replace( K key, V oldValue, V newValue )` Changes *oldValue* to *newValue* if *oldValue* is mapped to *key* in this *HashMap*; if it is, it returns *true*, *false* otherwise.
`int`	`size( )` Returns the number of (key, value) pairs in this *HashMap*.
`boolean`	`contains( K key )` Returns *true* if *key* is a key in this *HashMap*, *false* otherwise.
`boolean`	`contains( V value )` Returns *true* if *value* is mapped to one or more keys in this *HashMap*, *false* otherwise.
`Set<K>`	`keySet( )` Returns a *Set* of keys contained in this *HashMap*.
`Collection<V>`	`values( )`

	Returns a *Collection* of values contained in this *HashMap*.

Description

9.9.3 Using the *HashMap* in a Program

Example 9.17 shows how we can use the *HashMap* class to store states.

Example 9.17 Using *HashMap* Methods

```
 1 /* A simple HashMap of ( String, String ) pairs
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.HashMap;
 6 import java.util.Set;
 7
 8 public class HashMapStates
 9 {
10   public static void main( String [ ] args )
11   {
12     HashMap<String,String> states = new HashMap<String,String>( );
13     states.put( "CA", "California" );
14     states.put( "MD", "Maine" ); // We correct this later
15     states.put( "NY", "New York" );
16     states.put( "NJ", "New Jersey" );
17
18     // Output all (key, value) pairs
19     System.out.println( "states: " + states );
20
21     // Retrieve value whose key is NY
22     String nyState = states.get( "NY" );
23     System.out.println( "NY is " + nyState );
24
25     // Change value whose key is MD to Maryland
26     states.replace( "MD", "Maryland" );
27     System.out.println( "states: " + states + "\n" );
28
29     // Remove state whose key is MD
30     String mdState = states.remove( "MD" );
31     System.out.println( mdState + " was removed" );
32     System.out.println( "states: " + states + "\n" );
33
34     // Loop through all the values using the keys
35     Set<String> keys = states.keySet( );
36     for( String abbr: keys )
37       System.out.println( abbr + ": " + states.get( abbr ) );
38     System.out.println( );
39
40     // Loop through all the values directly
41     for( String state: states.values( ) )
42       System.out.println( state );
43   }
44 }
```

Description

At line 12, we declare and instantiate the *HashMap states*. At lines 13–16, we place four (key, value) pairs of states in *states*. We output *states* at lines 18–19 by implicitly calling *toString*. Note that the *toString* method of *HashMap* returns a nice representation of the *HashMap*. We retrieve and output the value associated with the key *NY* at lines 21–23. At lines 25–26, we replace *Maine*, the old value for the key *MD*, with *Maryland*.

We then output *states* at line 27 to verify that the change has taken place. At lines 29–30, we remove the (key, value) pair associated with the key *MD* and capture the returned value. We output the returned value (*Maryland*) and the states again at lines 31–32, showing that (*MD*, *Maryland*) is no longer in *states*.

At lines 34–37, we loop through all the keys in states and output each key and its corresponding value. We first call the *keySet* method at line 35 to retrieve the keys as a *Set* of *Strings*. At lines 36–37, we loop through them using the enhanced *for* loop and output all the (key, value) pairs.

At lines 40–42, we call the *values* method and loop through the *Collection* of values returned by it in order to output them all. **Figure 9.19** shows the output in Example 9.17.

Figure 9.19 Output of Example 9.17

CHAPTER REVIEW

9.10 Chapter Summary

- Arrays can be single-dimensional, two-dimensional, three-dimensional, or more generally, *n*-dimensional.
- In a two-dimensional array, each row is an array.
- Each element in a two-dimensional array is accessed using the array name with a row index and column index that refer to the element’s position in the array.
- Concepts such as declaration, instantiation, initial values, indexing, and aggregate operations from single-dimensional arrays also apply to two-dimensional arrays.
- Two-dimensional arrays can be instantiated by assigning initial values in a comma-separated list of comma-separated lists at the declaration.
- Each row in a two-dimensional array can have a different number of columns.
- A two-dimensional array has an instance variable, *length*, which holds the number of rows in the array.
- Each row of a two-dimensional array has an instance variable, *length*, which holds the number of elements in that row.
- The *ArrayList* and *HashMap* classes implement generics and are part of the *java.util* package.
- An *ArrayList* can be thought of as an expandable single-

dimensional array of objects.

- To define an *ArrayList* to hold elements of primitive data types, use the wrapper classes.
- An *ArrayList* object expands automatically as objects are added.
- We access an element of an *ArrayList* via its index.
- We can process each element in an *ArrayList* using the enhanced *for* loop.
- A *HashMap* can be thought of as a set of (key, value) pairs.
- We can access a value in a *HashMap* via its key.
- We can retrieve all the keys or all the values in a *HashMap* using the *keySet* and *values* methods. We can then loop through them using an enhanced *for* loop.

9.11 Exercises, Problems, and Projects

9.11.1 Multiple Choice Exercises

1. What is/are the valid way(s) to declare a two-dimensional integer array named *a*? (Check all that apply.)

   - `int [ ][ ] a;`
   - `int a[ ][ ];`
   - `array[ ]` int `a;`
   - `int array[] a;`

6. A two-dimensional array is an array of arrays.

   - true
   - false

9. In a two-dimensional array, every row must have the same number of columns.

   - true
   - false

12. What is the default value of the elements of a two-dimensional array of *booleans* after declaration and instantiation of the array?

   - *true*
   - *false*
   - undefined

16. How do you access the element of array *a* located at row 2 and column 4?

   - `a{2}{4}`
   - `a( 2,4 )`

- `a[2][4]`
- `a[4][2]`

21. How do you retrieve the number of rows in a two-dimensional array *a*?

    - `a.rows`
    - `a.length`
    - `a.rows()`
    - `a.size`

26. How do you retrieve the number of columns in row 2 in a two-dimensional array *a*?

    - `a.length`
    - `a[2].length`
    - `a.size`
    - `a[2].size`

31. All the elements of a two-dimensional array must be of the same type.

    - true
    - false

34. An *ArrayList* can be returned by a method.

    - true
    - false

37. It is possible to declare and instantiate an *ArrayList* of a user-defined class type.

    - true
    - false

40. As we add objects to an *ArrayList*, how can we be sure it has enough capacity?

- Use the *setCapacity* method.
- Use the *trimToSize* method.
- We don’t need to do anything; capacity expands automatically as needed.

44. Where does the *add* method of the *ArrayList* class add an object?

    - at the beginning of the list
    - at the end of the list

47. To what package does the class *HashMap* belong?

    - *java.io*
    - *java.util*
    - *java.array*
    - *java.list*

9.11.2 Reading and Understanding Code

For Questions 14 to 24, consider the following two-dimensional array declaration and initialization:

```
String [ ][ ] cities = { { "New York", "LA", "San Francisco", "Chicago" },
                         { "Munich", "Stuttgart", "Berlin", "Bonn" },
                         { "Paris", "Ajaccio", "Lyon" },
                         { "Montreal", "Ottawa", "Vancouver" } };
```

Description

1. How many rows are in the array *cities*?
2. What is the value of the expression *cities[2][1]*?
3. What is the index of the last row in the array *cities*?
4. What are the row and column indexes of *Chicago* in the array *cities*?
5. What is the output of this code sequence?

```
System.out.println( cities[3][2] );
```

Description

6. What is the output of this code sequence?

```
for ( int j = 0; j < cities[1].length; j++ )
   System.out.println( cities[1][j] );
```

Description

7. What is the output of this code sequence?

```
for ( int i = 0; i < cities.length; i++ )
   System.out.println( cities[i][1] );
```

Description

8. What is the output of this code sequence?

```
for ( int i = 0; i < cities.length; i++ )
{
    for ( int j = 0; j < cities[i].length; j++ )
        System.out.print( cities[i][j] + "\t" );
    System.out.println( );
}
```

Description

9. What is the output of this code sequence?

```
for ( int i = 0; i < cities.length; i++ )
{
   for ( int j = 0; j < cities[i].length; j++ )
   {
         if ( cities[i][j].length( ) == 6 )
             System.out.println( cities[i][j] );
   }
}
```

Description

10. What is the output of this code sequence?

```
int count = 0;
for ( int i = 0; i < cities.length; i++ )
{
   for ( int j = 0; j < cities[i].length; j++ )
   {
         if ( cities[i][j].length( ) == 7 )
               count++;
   }
}
System.out.println( "count is " + count );
```

Description

11. What is the output of this code sequence?

```
for ( int i = 0; i < cities.length; i++ )
{
   for ( int j = 0; j < cities[i].length; j++ )
   {
        if ( cities[i][j].charAt( 0 ) == 'S' )
              System.out.println( cities[i][j] );
   }
}
```

Description

12. What does this method do?

```
public static int foo( double [ ][ ] a )
{
   int b = 0;
   for ( int i = 0; i < a.length; i++ )
   {
      for ( int j = 0; j < a[i].length; j++ )
            b++;
   }
   return b;
}
```

Description

13. What does this method do?

```
public static boolean foo( char [ ][ ] a )
{
   int b = a[0].length;
   for ( int i = 1; i < a.length; i++ )
   {
         if ( a[i].length != b )
            return false;
   }
   return true;
}
```

Description

14. What does this method do?

```
public static int foo( String [ ][ ] a )
{
      int b = 0;
      for ( int i = 0; i < a.length; i++ )
            b++;
      return b;
}
```

Description

15. What does this method do?

```
public static int [ ] foo( float [ ][ ] a )
{
      int [ ] temp = new int [a.length];
      for ( int i = 0; i < a.length; i++ )
            temp[i] = a[i].length;
      return temp;
}
```

Description

16. What does this method do?

```
public static int foo( ArrayList<Integer> a )
{
      int b = 0;
      for ( Integer i : a )
          b++;
      return b;
}
```

Description

17. After the following code sequence is executed, what are the contents and index of each element of *a*?

```
ArrayList<Integer> a = new ArrayList<Integer>( );
a.add( 7 );
a.add( 4 );
a.add( 21 );
```

Description

18. After the following code sequence is executed, what are the contents and index of each element of *a*?

```
ArrayList<Integer> a = new ArrayList<Integer>( );
a.add( 7 );
a.add( 4 );
a.add( 21 );
a.set( 1, 45 );
```

Description

19. After the following code is executed, what are the (key, value) pairs in *days*?

```
HashMap<String, String> days = new HashMap<String, String>( );

days.put( "SUN", "Sunday" );
days.put( "MON", "Monday" );
days.put( "TUES", "Tuesday" );
```

Description

9.11.3 Fill In the Code

For Questions 33 to 37, consider the following statement:

```
String [ ][ ] geo = { { "MD", "NY", "NJ", "MA", "ME", "CA", "MI", "OR" },
                      { "Detroit", "Newark", "Boston", "Seattle" } };
```

Description

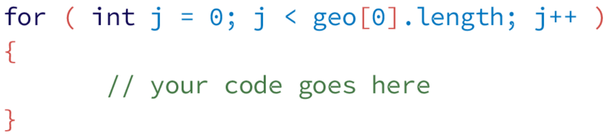
1. This code prints the element at row index 1 and column index 2 of the two-dimensional array *geo*.

```
// your code goes here
```

2. This code prints the element of the array *geo* whose value is “CA.”

```
// your code goes here
```

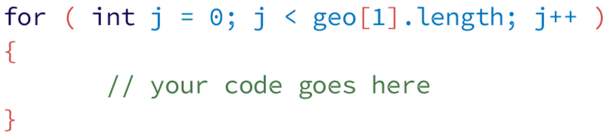
3. This code prints all the states (i.e., the first row) that start with an *M* in the array *geo*.



```
for ( int j = 0; j < geo[0].length; j++ )
{
        // your code goes here
}
```

Description

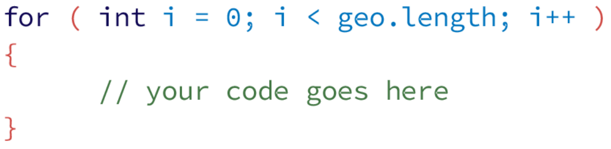
4. This code prints all the cities (i.e., the second row) in the array *geo*.



```
for ( int j = 0; j < geo[1].length; j++ )
{
        // your code goes here
}
```

Description

5. This code prints all the elements of the array *geo*.



```
for ( int i = 0; i < geo.length; i++ )
{
        // your code goes here
}
```

Description

For Questions 38 to 41, consider the following statement:

```
int [ ][ ] a = { { 9, 6, 8, 10, 5 },
                 { 7, 6, 8, 9, 6 },
                 { 4, 8, 10, 6, 6 } };
```

Description

1. This code calculates and prints the sum of all the elements in the array *a*.

   ```
   int sum = 0;
   for ( int i = 0; i < a.length; i++ )
   {
         // your code goes here
   }
   System.out.println( "sum is " + sum );
   ```

   Description

2. This code counts and prints the number of times the value 8 appears in the array *a*.

   ```
   int count = 0;
   for ( int i = 0; i < a.length; i++ )
   {
         // your code goes here
   }
   System.out.println( "# of 8s in a: " + count );
   ```

   Description

3. This code counts and prints the number of times the value 6 appears in the second row (i.e., the row whose index is 1) of array *a*.

   ```
   int count = 0;

   // your code for the for loop header goes here
   {
          if ( a[1][j] == 6 )
               count++;
   }
   System.out.println( "# of 6s in the 2nd row: " + count );
   ```

Description

4. This code calculates the sum of the elements in the second column (i.e, the column with index 1) of array *a*.

```
int sum  = 0;
for ( int i = 0; i < a.length; i++ )
{
   // your code goes here

}
System.out.println( "sum is " + sum );
```

Description

5. This method returns *true* if an element in an array of *Strings* is equal to “Java”; otherwise, it returns *false*.

```
public static boolean foo( String [ ][ ] a )
{
   // your code goes here
}
```

Description

6. This method returns the product of all the elements in an array.

```
public static int foo( int [ ][ ] a )
{
   // your code goes here
}
```

Description

7. This method returns *true* if there is at least one row in the array that has exactly five columns; otherwise, it returns *false*.

```
public static boolean foo( char [ ][ ] a )
{
   // your code goes here
}
```

Description

8. This method takes a *HashMap* parameter of *Integer* keys and *String* values and returns an *ArrayList* made up of all the values in that *HashMap* parameter.

```
public static ArrayList<String> foo( HashMap<String, String> )
{
   // your code goes here

}
```

Description

For Questions 46 to 49, consider the following statements:

```
ArrayList<String> languages = new ArrayList<String>( );
languages.add( "SQL" );
languages.add( "Java" );
languages.add( "HTML" );
languages.add( "PHP" );
languages.add( "Perl" );
```

Description

1. This code prints the number of elements in *languages*.

```
// your code goes here
```

2. This code retrieves the *String* “HTML” from *languages* (without deleting it) and assigns it to the *String* variable *webLanguage*.

```
// your code goes here
```

3. This code replaces “HTML” *with* “C++” in *languages*.

```
// your code goes here
```

4. This code prints all the elements of *languages* that start with the letter *P*.

   ```
   for ( String s : languages )
   {
     // your code goes here
   }
   ```

   Description

9.11.4 Identifying Errors in Code

1. Where is the error in this code sequence?

   ```
   double [ ][ ] a = { 3.3, 26.0, 48.4 };
   ```

   Description

2. Where is the error in this code sequence?

   ```
   int [ ][ ] a = { { 3, 26, 4 }, { 14, 87 } };
   System.out.println( a[1][2] );
   ```

   Description

3. Where is the error in this code sequence?

   ```
   double [ ][ ] a = new double [ ][10];
   ```

   Description

4. Where is the error in this code sequence?

   ```
   int [ ][ ] a = { { 1, 2 },
                    { 10.1, 10.2 } };
   ```

   Description

5. Where is the error in this code sequence? (This code compiles and runs, but does not output the array values.)

```
int [ ][ ] a = { { 3, 26, 48 }, { 5, 2, 9 } };
System.out.println( "The array elements are " + a );
```

Description

6. Where is the error in this code sequence?

```
ArrayList<double> al;
```

Description

7. Where is the error in this code sequence?

```
ArrayList<Float> a1 = new ArrayList( )<Float>;
```

Description

8. Where is the error in this code sequence?

```
ArrayList<Double> a;
a = new ArrayList<Float>( );
```

Description

9. Where is the error in this code sequence?

```
// a is an ArrayList of Strings
// a has already been declared and instantiated
a.size( ) = 10;
```

Description

9.11.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

1. You coded the following on line 14 of the *Test.java* class:

```
int a[2][ ] = { { 2, 7 }, { 9, 2 } }; // line 14
```

Description

When you compile, you get the following message:

```
Test.java:14: error: ']' expected
     int a[2][ ] = { { 2, 7 }, { 9, 2 } }; // line 14
           ^
Test.java:14: error: not a statement
     int a[2][ ] = { { 2, 7 }, { 9, 2 } }; // line 14
                       ^
Test.java:14: error: ';' expected
     int a[2][ ] = { { 2, 7 }, { 9, 2 } }; // line 14
                        ^
Test.java:14: error: illegal start of expression
     int a[2][ ] = { { 2, 7 }, { 9, 2 } }; // line 14
                             ^
Test.java:14: error: not a statement
     int a[2][ ] = { { 2, 7 }, { 9, 2 } }; // line 14
                                 ^
Test.java:14: error: ';' expected
     int a[2][ ] = { { 2, 7 }, { 9, 2 } }; // line 14
                                  ^
6 errors
```

Description

Explain what the problem is and how to fix it.

2. You coded the following in the *Test.java* class:

```
int [ ][ ] a = { { 1, 2, 3, 4 },
                 { 10, 20, 30 } };
for ( int i = 0; i < a.length; i++ )
{
      for ( int j = 0; j < a[0].length; j++ )
      {
            System.out.println( a[i][j] ); // line 14
      }
}
```

Description

The code compiles properly but when you run, you get the following output:

```
 1
 2
 3
 4
10
20
30
Exception in thread "main" java.lang.ArrayIndexOutOfBoundsException:
       Index 3 out of bounds for length 3
       at Test.main(Test.java: 14)
```

Description

Explain what the problem is and how to fix it.

3. You coded the following in the *Test.java* class in order to output the smallest element in the array *a*:

```
int [ ][ ] a = { { 9, 8, 7, 6 },
                 { 10, 20, 30, 40 } };
int min = a[0][0];
for ( int i = 1; i < a.length; i++ )
{
      for ( int j = 0; j < a[i].length; j++ )
      {
            if ( a[i][j] < min )
                 min = a[i][j];
      }
}
System.out.println( "The minimum is " + min );
```

Description

The code compiles properly, but when you run, you get the following output:

```
The minimum is 9
```

Description

You expected the value of *min* to be 6. Explain what the problem is and how to fix it.

4. You coded the following in file *Test.java*:

```
int [ ][ ] a = { { 9, 8, 7, 6 },
                 { 10, 20, 30, 40 } };
for ( int j = 0; j <= a[1].length; j++ )
{
  if ( a[1][j] == 20 ) // line 14
  {
     System.out.println( "Found 20 at column index " + j
                         + " of second row" );
  }
}
```

Description

The code compiles properly, but when you run, you get the following output:

```
Found 20 at column index 1 of second row
Exception in thread "main" java.lang.ArrayIndexOutOfBoundsException:
        Index 4 out of bounds for length 4
        at Test.main(Test.java:14)
```

Description

Explain what the problem is and how to fix it.

5. You coded the following in the *Test.java* class:

```
// cars is an ArrayList of Auto objects
// cars has already been declared and instantiated
for ( Auto a ; cars )     // line 12
{
    System.out.println( a.toString( ) );
}   // line 15
```

Description

When you compile, you get the following message :

```
Test.java:12: error: ';' expected
  for ( Auto a ; cars ) // line 12
                     ^

1 error
```

Description

Explain what the problems are and how to fix them.

6. You coded the following in the *Test.java* class:

```
ArrayList<String> a = new ArrayList<String>( );
a.add( "Cloudy" );
a.add( "Snowy" );
a.add( "Cloudy" );
System.out.println( "Weather is " + a.get( 3 ) ); // line 14
```

Description

The code compiles properly, but when you run, you get the following output:

```
Exception in thread "main" java.lang.IndexOutOfBoundsException:
Index 3 out of bounds for length 3
...
```

Description

Explain what the problem is and how to fix it.

7. You coded the following in the file *Test.java*:

```
ArrayList<Integer> a = new ArrayList( );
```

Description

When you compile (using Xlint), you get the following warning message:

```
Test.java:10: warning: [rawtypes] found raw type: ArrayList
    ArrayList<Integer> a = new ArrayList( );
                               ^
    missing type arguments for generic class ArrayList<E>
    where E is a type-variable:
    E extends Object declared in class ArrayList

Test.java:10: warning: [unchecked] unchecked conversion
    ArrayList<Integer> a = new ArrayList( );
                           ^
  required: ArrayList<Integer>
  found:    ArrayList
2 warnings
```

Description

Explain what the problem is and how to fix it.

8. You coded the following in the file *Test.java*:

```
a.add( 2.3 );
a.add( 8.4 );
a.add( 5 ); // line 11
```

Description

When you compile, you get the following message:

```
Test.java:11: error: incompatible types: int cannot be converted to Double
    a.add( 5 ); // line 11
           ^
Note: Some messages have been simplified; recompile with -Xdiags:verbose
    to get full output
1 error
```

Description

Explain what the problem is and how to fix it.

9. You coded the following in the file *Test.java*:

```
ArrayList<Character> a = new ArrayList<Character>( );
a.add( 'X' );
a.add( 'A' );
a.add( 'V' );
a.add( 'A' );
a.set( 1, 'J' );
for ( Character c : a )
  System.out.print( c + " " );
```

Description

The code compiles properly, but when you run, you get the following output:

```
X J V A
```

when you expected:

```
J A V A
```

Explain what the problem is and how to fix it.

9.11.6 Write a Short Program

1. Write a value-returning method that returns the number of rows in a two-dimensional array of *doubles*. Include code to test your method.
2. Write a value-returning method that returns the number of elements in a two-dimensional array of *floats*. Include code to test your method.
3. Write a value-returning method that returns the number of columns that have two elements in a two-dimensional array of *booleans*. Include code to test your method.
4. Write a value-returning method that returns the number of columns with *n* elements in a two-dimensional array of *chars*, where *n* is a parameter of the method. Include code to test your method.
5. Write a value-returning method that returns the sum of all the elements in a two-dimensional array of *floats*. Include code to test your method.
6. Write a method with a *void* return value that sets to 0 all the elements of the even-numbered rows and sets to 1 all the elements of odd-numbered rows of a two-dimensional array

of *ints*. Include code to test your method.

7. Write a value-returning method that returns the sum of the elements in the last column of each row in a two-dimensional array of *ints*. Include code to test your method.
8. Write a method with a *void* return value that inverts all the elements of a two-dimensional array of *booleans* (*true* becomes *false* and *false* becomes *true*). Include code to test your method.
9. Write a method that returns the number of elements having the value *true* in a two-dimensional array of *booleans*. Include code to test your method.
10. Write a method that returns the percentage of elements having the value *false* in a two-dimensional array of *booleans*. Include code to test your method.
11. Write a method that returns the average of all elements in a two-dimensional array of *ints*. Include code to test your method.
12. Write a method that returns the *String* “regular” if all the rows of a two-dimensional array of *floats* have the same number of columns; otherwise, it returns “irregular.” Include code to test your method.
13. Write a method that returns the concatenation of all elements in a two-dimensional array of *Strings*. Include code to test your method.
14. Write an array-returning method that takes a two-dimensional array of *chars* as a parameter and returns a single-dimensional array of *Strings* as follows: The array returned should have a number of elements equal to the number of rows in the parameter array; every element of the array returned should be the concatenation of all the column elements of the corresponding row in the

parameter array. Include code to test your method.

15. Write a method that takes as parameters two *ArrayLists* of *Strings* of the same size. The method returns a *Hashtable* (look up the *Hashtable* class in the Java Class Library) such that the *Hashtable*'s keys are the elements of the first *ArrayList*, and the *Hashtable*'s values are the elements of the second *ArrayList*. Test your method in a program using an *ArrayList* of state codes and an *ArrayList* of state names.
16. Write a method that returns the sum of all the elements of an *ArrayList* of *Integer* objects. Include code to test your method.
17. Write a method that returns the *String* “odd” or “even” if the number of elements of an *ArrayList* of *Strings* is odd or even. Include code to test your method.
18. Write a method that takes an *ArrayList* of *Integer* objects and returns an *ArrayList* of *Character* objects of the same size. The returned elements of the *ArrayList* are assigned a letter grade corresponding to the integer grade of the same index element of the *ArrayList* parameter (A if 90 or above, ..., F if less than 60). Include code to test your method.

9.11.7 Programming Projects

1. Write a class (and a client class to test it) that encapsulates statistics for summer job salaries for a group of people over several years. Your only instance variable should be a two-dimensional array of values representing salaries. Dimension 1 represents the people and dimension 2 represents the year of the summer job. Your constructor can simply take two integers representing the number of people and the number of years, then randomly generate

the salaries and fill the array. You should include the following methods:

- a method returning the index of the person having made the most money over the years
- a method returning the year when the highest salary was earned
- a method returning the total amount of money made by all the people over the years

5. Write a class (and a client class to test it) that encapsulates the evolution of the passwords of three students over four months. Your only instance variable should be a two-dimensional array of values representing the passwords. Dimension 1 represents the student and dimension 2 represents the month. (Since we are concerned about security, we are assuming that people change their password once a month; we only care about the value of the password at the end of a given month.) Your constructor can simply take a single-dimensional array of words representing the 12 passwords; they can be assigned to the two-dimensional array elements one at a time, starting with the first row. You should include the following methods:

   - a method returning the index of the person who changed his or her password the most times
   - a method returning the longest password
   - a method changing all the passwords to “unlock”
   - a method returning *true* if at least one person had a given word—the method’s parameter—as his/her password in at least one month; *false* otherwise

10. Write a class (and a client class to test it) that encapsulates the evolution of the sales tax rates in the 50 U.S. states over the last 10 years. Your only instance variable should be a two-dimensional array of values representing the sales tax rates. Dimension 1 represents the state and dimension 2 represents the year. Your constructor can simply be a default constructor, randomly generating the sales tax rates, which should be between 0 and 0.06. You should include the following methods:

    - a method returning the index of the state that has the biggest average tax rate over the years
    - a method returning an array of indexes of the states that have had at least one year with a tax rate less than 0.001
    - a method returning the highest sales tax rate over the years for a given state (which will be a parameter)

14. Write a class (and a client class to test it) that encapsulates the evolution of the quality ratings of various hotels over the years. Hotel ratings are represented by a number of stars, which can vary from one star (lowest quality) to five stars (highest quality). Your only instance variable should be a two-dimensional array of values representing the quality ratings. Dimension 1 represents the hotel and dimension 2 represents the year. Your constructor can take two parameters representing the number of hotels and the number of years. The ratings can simply be generated randomly. You should include the following methods:

    - a method returning an array of indexes of the hotels that have earned five stars at least once over the years

- a method returning the average rating of all the hotels over the years
- a method printing the indexes of the hotels that have earned five stars every year
- a method returning *true* if at least one hotel earned five stars for at least one year; *false* otherwise

19. Write a class (and a client class to test it) that encapsulates the value of the 26 letters of the English alphabet in the game of Scrabble in 10 countries. You should have three instance variables:

    - a two-dimensional array of integers representing the point values of the letters in the various countries
    - a single-dimensional array representing the alphabet from a to z
    - another single-dimensional array representing 10 countries

    For the two-dimensional array, dimension 1 represents the letter and dimension 2 represents the country. Your constructor can simply be a default constructor, randomly generating the values between 1 and 10. You should include the following methods:

    - a method returning an array of letters with their highest point value in any country
    - a method printing the names of the countries that have at least one letter with a point value of 10
    - a method taking a *String* as a parameter and printing the score of the word represented by that *String* in every country

26. Write a class (and a client class to test it) that encapsulates

the numbers of the various chessboard pieces in a chess game. You should have two instance variables:

- a two-dimensional array of integers; each array element represents how many of a particular chess piece of a particular color are on the board. In order to set it up, consider the following:
  - The first dimension represents the color of the pieces. On a chessboard, there are white and black pieces.
  - The second dimension represents the pieces themselves. On a chessboard, we have on each side: one king, one queen, two bishops, two knights, two rooks, and eight pawns.
- a single-dimensional array describing the pieces (king, queen, etc.)

Your constructor can simply be a default constructor, declaring and instantiating the two arrays to match the preceding information. You should include the following methods:

- a method with a *void* return value, called *playerATakesPlayerB*, updating the array based on a piece being taken by the opponent. It takes two parameters:
  - a *boolean* parameter representing whether “white takes black” or “black takes white”
  - an *int* parameter representing which piece gets taken
- a method returning how many of a particular piece are on the board (this method takes a parameter representing the piece)

- a method taking a *boolean* as a parameter, representing a color and returning the value of the board for that particular color. You can consider that a king is worth 0 points, a queen is worth 6 points, a rook is worth 4 points, a knight and a bishop are each worth 3 points, and a pawn is worth 1 point

36. Write a class (and a client class to test it) that encapsulates a deck of cards. A deck of cards is made up of 52 cards. You should have three instance variables:

    - a two-dimensional array of values representing the cards
    - a single-dimensional array describing the suit: spades, hearts, diamonds, and clubs
    - an instance variable representing the trump suit

    For the two-dimensional array, dimension 1 represents the suit and dimension 2 represents the type of card (ace, two, three, ..., jack, queen, king). Your constructor should take one parameter, which will represent the suit of the trump. Based on that, the cards should be given the following values:

    - Non-trump from 2 to 10: 1 point
    - Non-trump jack = 2
    - Non-trump queen = 3
    - Non-trump king = 4
    - Non-trump ace = 5
    - Any trump card = Non-trump value + 1

    You should include the following methods:

    - a method returning the trump suit, by name

- a method printing the whole deck of cards, suit by suit, with the value for each card
- a method taking a *String* as a parameter representing a suit, and returning the total value of the cards of that suit

49. Write a class (and a client class to test it) that encapsulates a tic-tac-toe board. A tic-tac-toe board looks like a table of three rows and three columns partially or completely filled with the characters X and O. At any point, a cell of that table could be empty or could contain an X or an O. You should have one instance variable, a two-dimensional array of values representing the tic-tac-toe board.
    Your default constructor should instantiate the array so that it represents an empty board.
    You should include the following methods:

    - a method, returning a *boolean*, simulating a play with three parameters as follows: If the first parameter is *true*, then X is playing; otherwise, O is playing. The other two parameters represent what cell on the board is being played. If the play is legal, that is, the cell is a legal cell on the board and is empty, then the method should update the array and return *true*; otherwise, the array should not be updated and the method should return *false*
    - a method returning how many valid plays have been made so far
    - a method checking if a player has won based on the contents of the board; this method takes no parameter. It returns X if the “X player” has won, O if the “O player” has won, T if the game was a tie. A player wins if he or she has placed an X (or an O) in all cells in a

row, all cells in a column, or all cells in one of the two diagonals

53. Code a class and a client class to test it that includes the following:

    - a *HashMap* instance variable of *Character* keys and *String* values.
    - a default constructor that initializes all the *HashMap* keys to the hexadecimal characters in the alphabet (from 0 to F) and the values to their corresponding binary representations. For example, 'C' should be the key for the value "1100".
    - a method that accepts a *String* representing a hexadecimal number and returns its binary representation as a *String*; for example, if the argument passed to that method is "C3", the returned value should be "11000011". You should use the *HashMap* instance variable to perform the conversion.
    - a method that returns a *HashMap* that is the inverse of the *HashMap* instance variable; that is, it maps a 4-binary-digit *String* key to a *Character* value. For example, "1110" will be the key for the value 'E'. Do not hard code the *HashMap* returned by this method. Instead, derive it from the *HashMap* instance variable without knowing the (key, value) pairs that are in it.
    - a method that accepts two parameters: a *String* representing a binary number and a *HashMap* that can be used to convert the *String* parameter representing the binary number to a hexadecimal number; it returns a *String* representing the hexadecimal equivalent of the parameter. For example, if the arguments passed to that method are "11000011" and an appropriate *HashMap* (like the one returned by the method above), the returned value should be "C3".

    Inside the main method, test all the methods above.

Description

59. Write a *Garage* class (and a client class to test it) with one instance variable: an *ArrayList* of *Autos* (you can use the *Auto* class from this chapter).

    You should include the following methods:

    - a method returning the average number of miles of all cars in the garage
    - a method returning “full” if the garage has 100 cars or more, “below minimum” if the garage has fewer than 25 cars, and “normal load” if the garage has between 25 and 100 cars in it
    - a method returning the total number of gallons of gas used by all cars in the garage

63. Write a *ComputerPart* class and a *ComputerKit* class (and a client class to test them).

The *ComputerPart* class has two instance variables: a *String* representing an item (for instance, “cpu” or “disk drive”), and a *double* representing the price of that item. The *ComputerKit* class has just one instance variable: an *ArrayList* of *ComputerPart* objects (they make up a computer) representing the list of parts for the computer kit. You should include the following methods:

- a method returning “expensive” if the total of the prices of the *ComputerPart* objects is greater than 1,000, “cheap” if it is less than 250, “normal” if it is between 250 and 1,000
- a method returning *true* if a certain item is included in the list of parts; *false* otherwise
- a method returning how many times a particular item (for instance, “cpu,” or “memory”) is found in the list of parts

9.11.8 Technical Writing

1. A two-dimensional array can have a different number of columns in every row. Do you see that as an advantage or a disadvantage? Discuss.
2. Discuss the pros and cons of using an array vs. using an *ArrayList*.

9.11.9 Group Project (for a group of 1, 2, or 3 students)

1. Design and code a program including the following classes, as well as a client class to test all the methods coded:

   A *Passenger* class, encapsulating a passenger. A passenger has two attributes: a name, and a class of service, which will be 1 or 2.

   A *Train* class, encapsulating a train of passengers. A train of passengers has one attribute: a list of passengers, which must be represented with an *ArrayList*. Your constructor will build the list of passengers by reading data from a file called *passengers.txt*. You can assume that *passengers.txt* has the following format:

<name1> <class1>
<name2> <class2>
...

For instance, the file could contain:

James	1
Ben	2
Suri	1
Sarah	1
Jane	2

...

You should include the following methods in your *Train* class:

- a method returning the percentage of passengers traveling in first class
- a method taking two parameters representing the price of traveling in first and second class and returning the total revenue for the train
- a method checking if a certain person is on the train; if he/she is, the method returns *true*; otherwise, it returns *false*

Introduction

One of the most common ways to reuse a class is through inheritance. Inheritance helps us to organize related classes into **hierarchies**, or ordered levels of functionality. To set up a hierarchy, we begin by defining a class that contains methods and fields (instance variables and class variables) that are common to all classes in the hierarchy. Then we define new classes at the next lower level of the hierarchy, which inherit the behavior and fields of the original class. In the new classes, we define additional fields and more specific methods. The original class is called the **superclass**, and the new classes that inherit from the superclass are called **subclasses**. Some OOP developers call a superclass the **base class** and call a subclass the **derived class**.

As in life, a superclass (parent) can have multiple subclasses (children), and each subclass can be a superclass (parent) of other subclasses (children) and so on. Thus, a class can be both a subclass (child) and a superclass (parent). In contrast to life, however, Java subclasses inherit directly from only one superclass.

A subclass can add fields and methods, some of which may **override**, or hide, a field or method inherited from a superclass.

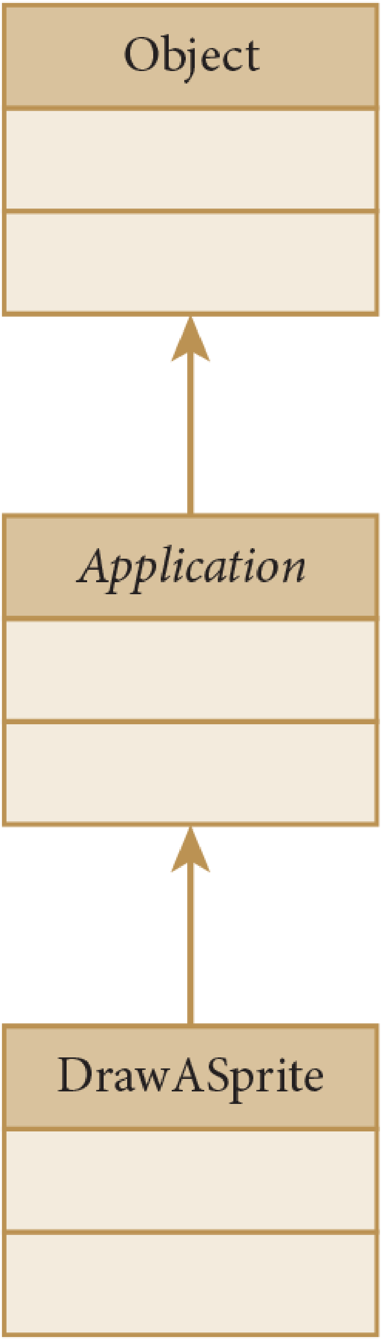
Let's look at an example. To represent a hierarchy of vehicle types, we define a *Vehicle* class as a superclass. We then define an *Automobile* class that inherits from *Vehicle*. We also define a *Truck* class, which also inherits from *Vehicle*. We further refine our classes by defining a *Pickup* class and a *TractorTrailer* class, both of which inherit from the *Truck* class. **Figure 10.1** depicts our hierarchy using a UML (Unified Modeling Language) diagram. Arrows pointing from a subclass to a superclass indicate that the subclass refers to the superclass for some of its methods and fields. The boxes below the class name are available for specifying instance variables and methods for each class. For simplicity, we leave those boxes blank. Later in the chapter, we will illustrate UML diagrams complete with fields and methods.

Figure 10.1 *Vehicle* Class Hierarchy

Description

The Java Class Library contains many class hierarchies. At the root of all Java class hierarchies is the *Object* class, the superclass for all classes. Thus, all classes inherit from the *Object* class.

The most important advantage to inheritance is that in a hierarchy of classes, we write the common code only once. After the common code has been tested, we can reuse it with confidence by inheriting it into the subclasses. And when that common code needs revision, we need to revise the code in only one place.



Object
Application
DrawASprite

10.1 Inheritance

The syntax for defining a subclass class that inherits from another class is to add an *extends* clause in the class header:

```
accessModifier class SubclassName extends SuperclassName
{
     // class definition
}
```

Description

The *extends* keyword specifies that the subclass inherits members of the superclass. That means that the subclass begins with a set of predefined methods and fields inherited from its hierarchy of superclasses.

For example, if we want to code a class named *DrawASprite*, we extend the *Application* class, and we use the following header:

```
public class DrawASprite extends Application
```

Description

This means that the *DrawASprite* class inherits from the *Application* class.

The *DrawASprite* class hierarchy is shown in **Figure 10.2**. At the top of the hierarchy is the *Object* class. It defines 11 methods. The *Application* class extends the *Object* class, so it inherits those 11 methods. In turn, the *Application* class defines two fields and 10 additional methods. So when our *DrawASprite* class extends *Application*, the *DrawASprite* class inherits 21 methods and two fields. All along the hierarchy, subclasses inherit methods and fields. True, not every class has a use for all the inherited methods and fields, but they are available if needed, and the benefit is that we don’t need to write these methods or define these fields in our classes. Thus, we can build classes with a minimum of effort.

Figure 10.2 The *DrawASprite* Class Hierarchy

Description

As we can see from Figure 10.2, our *DrawASprite* class has two superclasses. The class that a subclass refers to in the *extends* clause of the class definition is called its **direct superclass**. Thus, *Application* is the direct superclass of *DrawASprite*. Similarly, the class that *extends* the superclass is called the **direct subclass** of the superclass, so *DrawASprite* is a direct subclass of the *Application* class. A class can have multiple direct subclasses, but only one direct superclass.

In BankAccount overloaded constructor
In CheckingAccount overloaded constructor
New checking account: balance is $100.00
```

```
New checking account:
balance is $100.00; monthly fee is 7.5

After charging monthly fee:
balance is $92.50; monthly fee is 7.5
```

```
New checking account:
balance is $100.00; monthly fee is $7.50
```

10.2 Inheritance Design

We say that an “is a” relationship exists between a subclass and a superclass; that is, a subclass object “is a” superclass object. For example, we could define a student class hierarchy with a *Student* superclass and derive a *GraduateStudent* subclass. A graduate student “is a” student, but actually a special type of student. We could also define an employee class hierarchy with an *Employee* superclass and derive *Faculty* and *Staff* subclasses, because faculty and staff are both special types of employees.

To design classes for inheritance, our superclass should define fields and methods that will be common to all classes in the hierarchy. Each subclass will provide specialization by adding methods and fields. Where appropriate, subclasses can also provide new versions of inherited methods, which is called **overriding methods**.

SOFTWARE ENGINEERING TIP

The superclasses in a class hierarchy should contain fields and methods common to all subclasses. The subclasses should add specialized fields and methods.

Let’s build a bank account class hierarchy. We start by defining a generic *BankAccount* superclass. The *BankAccount* class will contain the fields and methods that are common to all bank accounts. Then we will define a *CheckingAccount* class that inherits from the *BankAccount* class. The *CheckingAccount* class will add instance variables and methods that specifically support checking accounts. Our class hierarchy is shown in the UML diagram in **Figure 10.3**. In this diagram, we display the instance variables in the box immediately below the class name and the methods in the next lower box. A “+” preceding a class member indicates that the member is *public*, while a “–” indicates that the member is *private*. Each method’s signature is given with each parameter’s type within parentheses and the return type following a colon. The *Object* class has more methods than we indicate on the UML diagram. However, the *toString* method is the only method of *Object* that we will deal with in this hierarchy, so we have omitted the other methods of *Object* on the diagram and indicate that other methods exist (+ . . . ( )).

Figure 10.3 The *BankAccount* Class Hierarchy

Description

10.2.1 Inherited Members of a Class

As shown in **Example 10.1**, our *BankAccount* class has two instance variables, the *balance*, which is a *double* (line 11), and a constant *DecimalFormat* object that we will use for formatting the *balance* as money (lines 9–10). We provide two constructors. The default constructor (lines 13–19) sets the *balance* instance variable to 0.0. The overloaded constructor (lines 21–27) takes a starting balance and passes that parameter to the *deposit* method (lines 37–48), which adds any non-negative amount to the *balance*. Otherwise, it leaves *balance* unchanged.

The *withdraw* method (lines 50–62) validates that the *amount* parameter is not less than 0.0 and is not greater than the *balance*. If *amount* is valid, the *withdraw* method subtracts *amount* from *balance*; otherwise, it leaves *balance* unchanged.

Example 10.1 *BankAccount* Class, Version 1

```java
/**   BankAccount class, version 1
*     Anderson, Franceschi
*     Represents a generic bank account
*/
import java.text.DecimalFormat;

public class BankAccount
{
  public final DecimalFormat MONEY
                  = new DecimalFormat( "$#,##0.00" );
  private double balance;

  /** default constructor
  *   sets balance to 0.0
  */
  public BankAccount( )
  {
    balance = 0.0;
  }

  /** overloaded constructor
  *   @param balance beginning balance
  */
  public BankAccount( double balance )
  {
    deposit( balance );
  }

  /** accessor for balance
  *   @return  current account balance
  */
  public double getBalance( )
  {
    return balance;
  }

  /** deposit amount to account
  *   @param amount  amount to deposit;
  *                  amount must be >= 0.0
  *   @return  a reference to this object
  */
  public BankAccount deposit( double amount )
  {
    if ( amount >= 0.0 )
      balance += amount;

    return this;
  }

  /** withdraw amount from account
  *    @param amount   amount to withdraw;
  *                    amount must be >= 0.0
  *                    amount must be <= balance
  *    @return a reference to this object
  */
  public BankAccount withdraw( double amount )
  {
    if ( amount >= 0.0 && amount <= balance )
      balance -= amount;

    return this;
  }

  /** toString
  *  @return  the balance formatted as money
  */
  @Override
  public String toString( )
  {
    return "balance is " + MONEY.format( balance );
  }
}
```

Description

Other methods of the *BankAccount* class include the *balance* accessor (lines 29–35) and the *toString* method (lines 64–71), which uses the *DecimalFormat* object, *MONEY*, to return the balance formatted as money. Note that we write *@Override* before the header of the *toString* method. We are replacing the version of *toString* that is in the *Object* class, that is, we are overriding the *Object* version of the *toString* method. To replace a method, we must write our method header exactly the same as the method we are overriding. By using the *@Override* annotation, we signal to the compiler that our intention is to override the method. If our method header is not coded correctly, the compiler will generate an error. Thus, it is a way to check our work.

Now we can derive our *CheckingAccount* subclass. **Example 10.2** shows Version 1 of our *CheckingAccount* class. For this initial version, we simply define the *CheckingAccount* class as extending *BankAccount* (line 5). The body of our class is empty for now, so we can demonstrate the fields and methods that a subclass inherits from its superclass.

Example 10.2 *CheckingAccount* Class, Version 1

```
1 /* CheckingAccount class, Version 1
2    Anderson, Franceschi
3 */
4
5 public class CheckingAccount extends BankAccount
6 { }
```

Description

When a class *extends* a superclass, all the *public* fields and methods of the superclass (excluding constructors) are inherited. That means that the *CheckingAccount* class inherits the *MONEY* instance variable and the *getBalance*, *deposit*, *withdraw*, and *toString* methods from the *BankAccount* class. An inherited field is directly accessible from the subclass, and an inherited method can be called by the other methods of the subclass. In addition, *public* inherited methods can be called by a client application using a subclass object reference.

Any fields and methods that are declared *private* are not inherited, and therefore are not directly accessible by the subclass. Nevertheless, the *private* fields are still part of the subclass object. Remember that a *CheckingAccount* object “is a” *BankAccount* object, so a *CheckingAccount* object has a *balance* instance variable. However, the *balance* is declared to be *private* in the *BankAccount* class, so the *CheckingAccount* methods cannot directly access the *balance*. The *CheckingAccount* methods must call the accessor and mutator methods of the *BankAccount* class to access or change the value of *balance*.

Calling methods to retrieve and change values of an instance variable may seem a little tedious, but it enforces encapsulation. Allowing the *CheckingAccount* class to set the value of *balance* directly would complicate the maintenance of the program. The *CheckingAccount* class would need to be responsible for maintaining a valid value for *balance*, which means that the *CheckingAccount* class would need to know all the validation rules for *balance* that the *BankAccount* class enforces. If these rules change, then the *CheckingAccount* class would also need to change. As long as the *BankAccount* class ensures the validity of *balance*, there is no reason for the *CheckingAccount* class to duplicate that code.

Java provides the ***protected*** access modifier so that fields and methods can be inherited by subclasses (like *public* fields and methods), while still being hidden from client classes (like *private* fields and methods). In addition, any class in the same package as the superclass can directly access a *protected* field, even if that class is not a subclass. Because more than one class can directly access a *protected* field, *protected* access compromises encapsulation and complicates the maintenance of a program. For that reason, we prefer to use *private*, rather than *protected*, for our instance variables. We will discuss the difference between *private* and *protected* in greater detail later in the chapter.

Table 10.1 summarizes the fields and methods that are inherited by a subclass. We will add to this table as we explain more about inheritance.

Inheritance Rules

Superclass Members	**Inherited by Subclass?**	**Directly Accessible by Subclass?**	**Directly Accessible by Client of Subclass?**
public fields	yes	yes, by using field name	yes
public methods	yes	yes, by calling method from other subclass methods	yes
protected fields	yes	yes, by using field name	no, must use accessors and mutators
protected methods	yes	yes, by calling method from subclass methods	no
private fields	no	no, must use accessors and mutators	no, must use accessors and mutators
private methods	no	no	no

Description

Example 10.3 shows a client for the *CheckingAccount* class. In line 9, we instantiate an object of the *CheckingAccount* class. After instantiation, the *c1* object has two fields (*balance* and *MONEY*), and it has inherited four methods (*getBalance*, *deposit*, *withdraw*, and *toString*) from *BankAccount*.

We illustrate this by using the *c1* object reference to call the *deposit* method in line 12 and the *withdraw* method in line 15, and to call the *toString* method implicitly in lines 13 and 16. **Figure 10.4** shows the output from this program.

Figure 10.4 Output from *CheckingAccountClient*, Version 1

Description

Example 10.3 *CheckingAccountClient*, Version 1

```
/* CheckingAccount Client, Version 1
   Anderson, Franceschi
*/

public class CheckingAccountClient
{
 public static void main( String [ ] args )
   {
   CheckingAccount c1 = new CheckingAccount( );
   System.out.println( "New checking account: " + c1 );

   c1.deposit( 350.75 );
   System.out.println( "\nAfter depositing $350.75: " + c1 );

   c1.withdraw( 200.25 );
   System.out.println( "\nAfter withdrawing $200.25: " + c1 );
 }
}
```

Description

10.2.2 Subclass Constructors

Although constructors are *public*, they are not inherited by subclasses. However, to initialize the *private* instance variables of the superclass, a subclass constructor can call a superclass constructor either implicitly or explicitly.

When a class extends another class, the default constructor of the subclass automatically calls the default constructor of the superclass. This is called **implicit** invocation. Athough we did not code any constructors in our *CheckingAccount* class in Example 10.2, we were able to instantiate a *CheckingAccount* object (with a 0.0 *balance*) because the Java compiler provided a default constructor for the *CheckingAccount* class, which implicitly called the default constructor of the *BankAccount* class.

To **explicitly** call the constructor of the direct superclass, the subclass constructor uses the following syntax:

```
super( argument list );
```

Description

Thus, if we want to instantiate a *CheckingAccount* object with a starting balance other than 0.0, we need to provide an overloaded constructor for the *CheckingAccount* class. That constructor will take the starting balance as a parameter and pass that starting balance to the overloaded constructor in the *BankAccount* class.

COMMON ERROR TRAP

In a constructor, the call to the direct superclass constructor, if used, must be the first statement.

This call to the direct superclass constructor, if used, must be the first statement in the subclass constructor. Otherwise, the following compiler error is generated:

```
call to super must be first statement in constructor
```

Description

Example 10.4 shows Version 2 of the *BankAccount* class, which, for simplicity and to help us focus on constructors, has only a default and overloaded constructor and the *toString* method. To illustrate the order in which the constructors execute, we print a message in each constructor (lines 21 and 33), indicating that it has been called.

Example 10.4 *BankAccount* Class, Version 2

```
/**   BankAccount class, Version 2
*     Constructors and toString method only
*     Anderson, Franceschi
*     Represents a generic bank account
*/

import java.text.DecimalFormat;

public class BankAccount
{
   public final DecimalFormat MONEY
                  = new DecimalFormat( "$#,##0.00" );
   private double balance;

   /** default constructor
   *   sets balance to 0.0
   */
   public BankAccount( )
   {
     balance = 0.0;
     System.out.println( "In BankAccount default constructor" );
   }

   /** overloaded constructor
   *   @param balance beginning balance
   */
   public BankAccount( double balance )
   {
     if ( balance >= 0.0 )
         this.balance = balance;
     else
         this.balance = 0.0;
     System.out.println( "In BankAccount overloaded constructor" );
   }

   /** toString
   *  @return the balance formatted as money
   */
   @Override
   public String toString( )
   {
     return "balance is " + MONEY.format( balance );
   }
}
```

Description

Example 10.5 shows Version 2 of the *CheckingAccount* class, which has both a default constructor and an overloaded constructor. Again, we have inserted messages (lines 13–14 and 24–25) to indicate when a constructor is called.

Example 10.5 *CheckingAccount* Class, Version 2

```
 1 /*  CheckingAccount class, Version 2
 2     Anderson, Franceschi
 3 */
 4
 5 public class CheckingAccount extends BankAccount
 6 {
 7    /** default constructor
 8    *   explicitly calls the BankAccount default constructor
 9    */
10    public CheckingAccount( )
11    {
12        super( ); // optional, call BankAccount constructor
13        System.out.println( "In CheckingAccount "
14                             + "default constructor" );
15    }
16
17    /** overloaded constructor
18    *   calls BankAccount overloaded constructor
19    *   @param balance starting balance
20    */
21    public CheckingAccount( double balance )
22    {
23        super( balance ); // call BankAccount constructor
24        System.out.println( "In CheckingAccount "
25                            + "overloaded constructor" );
26    }
27 }
```

Description

In the *CheckingAccount* default constructor, we explicitly call the default constructor of the *BankAccount* class (line 12). This statement is optional; without it, the *BankAccount* default constructor is still called implicitly.

COMMON ERROR TRAP

An attempt by a subclass to directly access a *private* field or call a *private* method defined in a superclass will generate a compiler error. To set initial values for *private* variables, call the appropriate constructor of the direct superclass.

In the *CheckingAccount* overloaded constructor, we pass the *balance* parameter to the *BankAccount* constructor (line 23) to initialize the *balance* instance variable. Because the *balance* instance variable has *private* access in the *BankAccount* class, our *CheckingAccount* class cannot access the *balance* instance variable directly. If we attempted to initialize the *balance* directly using the following statement:

```
this.balance = balance;
```

Description

the compiler would generate the following error:

```
balance has private access in BankAccount
```

Description

We might be tempted to call the *deposit* method instead of *super* to initialize the balance. Although this would work in this case, we don't always know what operations a constructor is performing. Perhaps the constructor also assigns an account number, in which case, calling the *deposit* method would cause us to skip that step. Thus, it is always a good practice to call the constructor of the superclass so that the superclass data will be correctly initialized.

SOFTWARE ENGINEERING TIP

Overloaded constructors in a subclass should explicitly call the direct superclass constructor to initialize the fields in its superclasses.

Example 10.6 shows Version 2 of our *CheckingAccount* client. On line 10, we instantiate a *CheckingAccount* object using the default constructor and print the balance by implicitly calling the *toString* method on line 11. Then on line 14, we instantiate a second *CheckingAccount* object with a starting balance of $100.00. Again we verify the result by printing the balance (line 15).

Example 10.6 *CheckingAccountClient*, Version 2

```
/* CheckingAccount Client, Version 2
   Anderson, Franceschi
*/

public class CheckingAccountClient
{
   public static void main( String [ ] args )
   {
     // use default constructor
     CheckingAccount c1 = new CheckingAccount( );
     System.out.println( "New checking account: " + c1 + "\n" );

     // use overloaded constructor
     CheckingAccount c2 = new CheckingAccount( 100.00 );
     System.out.println( "New checking account: " + c2 );
   }
}
```

Description

Figure 10.5 shows the output from this program. As we can see, when we construct the *c1* object, the *BankAccount* default constructor runs. When it finishes, the *CheckingAccount* default constructor runs. Similarly, when we construct the *c2* object, the *BankAccount* overloaded constructor runs, then the *CheckingAccount* overloaded constructor runs.

Figure 10.5 Output from Example 10.6

Description

Table 10.2 summarizes the inheritance rules for constructors.

Inheritance Rules for Constructors

Superclass Members	Inherited by Subclass?	Directly Accessible by Subclass?	Directly Accessible by Client of Subclass Using a Subclass Reference?
constructors	no	yes, using `super( arg list )` in a subclass constructor	no

Description

10.2.3 Adding Specialization to the Subclass

At this point, our *CheckingAccount* class provides no more functionality than the *BankAccount* class. But our purpose for defining a *CheckingAccount* class was to provide support for a specialized type of bank account. To add specialization to our *CheckingAccount* subclass, we define new fields and methods. For example, we can define a *monthlyFee* instance variable, as well as an accessor and mutator method for the monthly fee and a method to charge the monthly fee to the account.

Example 10.7 shows Version 3 of the *CheckingAccount* class with the specialization added. This version *extends* the complete *BankAccount* class shown in Example 10.1. We added the *monthlyFee* instance variable on line 8, as well as a constant default value for the monthly fee (line 7). Our default constructor (lines 10–18) still calls the default constructor of the *BankAccount* class to initialize the *balance*, but it also initializes the *monthlyFee* to the default value.

Similarly, the overloaded constructor (lines 20–30) passes the *balance* parameter to the overloaded constructor of the *BankAccount* class and adds a *monthlyFee* parameter to accept an initial value for the *monthlyFee*, which it passes to the *setMonthlyFee* mutator method (lines 50–60).

The *applyMonthlyFee* method (lines 32–40), which charges the monthly fee to the checking account, calls the *withdraw* method inherited from the *BankAccount* class to access the *balance* instance variable, which is declared *private* in the *BankAccount* class.

Example 10.7 *CheckingAccount*, Version 3

```
/* CheckingAccount class, version 3
   Anderson, Franceschi
*/

public class CheckingAccount extends BankAccount
{
   public final double DEFAULT_FEE = 5.00;
   private double monthlyFee;

   /** default constructor
   *   explicitly calls the BankAccount default constructor
   *   sets monthlyFee to default value
   */
   public CheckingAccount( )
   {
       super( ); // optional
       monthlyFee = DEFAULT_FEE;
   }

   /** overloaded constructor
   *  calls BankAccount overloaded constructor
   *  @param  balance  starting balance
   *  @param  monthlyFee starting monthly fee
   */
   public CheckingAccount( double balance,
                           double monthlyFee )
   {
      super( balance ); // call BankAccount constructor
      setMonthlyFee( monthlyFee );
   }

   /** applyMonthlyFee method
   * charges the monthly fee to the account
   * @return a reference to this object
   */
   public CheckingAccount applyMonthlyFee( )
   {
     withdraw( monthlyFee );
     return this;
   }

   /** accessor method for monthlyFee
   *  @return  monthlyFee
   */
   public double getMonthlyFee( )
   {
     return monthlyFee;
   }

   /** mutator method for monthlyFee
   *  @param monthlyFee new value for monthlyFee
   *  @return a reference to this object
   */
   public CheckingAccount setMonthlyFee( double monthlyFee )
   {
     if ( monthlyFee >= 0.0 )
        this.monthlyFee = monthlyFee;

     return this;
   }
}
```

Description

Example 10.8 shows Version 3 of our client program, which instantiates a *CheckingAccount* object and charges the monthly fee. The output is shown in Figure 10.6.

Figure 10.6 Output from *CheckingAccountClient*, Version 3

Description

Example 10.8 *CheckingAccountClient*, Version 3

```java
/* CheckingAccount Client, Version 3
   Anderson, Franceschi
*/

public class CheckingAccountClient
{
   public static void main( String [ ] args )
   {
     CheckingAccount c3 = new CheckingAccount( 100.00, 7.50 );
     System.out.println( "New checking account:\n"
                          + c3.toString( )
                          + "; monthly fee is "
                          + c3.getMonthlyFee( ) );

     c3.applyMonthlyFee( ); // charge the fee to the account
     System.out.println( "\nAfter charging monthly fee:\n"
                          + c3.toString( )
                          + "; monthly fee is "
                          + c3.getMonthlyFee( ) );
   }
}
```

Description

10.2.4 Overriding Inherited Methods

When the methods our subclass inherits do not fulfill the functions we need, we can **override** the inherited methods by providing new versions of those methods.

To override an inherited method, we provide a new method with the same header as the inherited method; that is, the new method must have the same name, the same number and type of parameters, and the same return type. Overriding a method makes the inherited version of the method invisible to the client of the subclass. We say that the overridden method is hidden from the client. When the client calls the method using a subclass object reference, the subclass version of the method is invoked.

Methods in a subclass can still access the inherited version of the method by preceding the method call with the *super* object reference as in the following syntax:

```
super.methodName( argument list )
```

Description

In our *CheckingAccount* class, we inherited the *toString* method from the *BankAccount* class. But this method returns only the *balance*. In Example 10.8, we needed to call the *CheckingAccount* method *getMonthlyFee* to print the value of *monthlyFee*. Furthermore, as Figure 10.6 shows, the *balance* value is formatted and the *monthlyFee* value is not. Instead, the *toString* method in the *CheckingAccount* class should return formatted versions of both the *balance* and the *monthlyFee*. We can accomplish this by overriding the inherited *toString* method.

Example 10.9 shows Version 4 of the *CheckingAccount* class with the new *toString* method (lines 62–71). To format the *balance*, we call the *toString* method of the *BankAccount* class (line 69), then add the formatted value of *monthlyFee* to the *String* being returned. Again, we used the *@Override* annotation so that the compiler will alert us if we do not correctly code the header of the method. Notice that we didn’t need to instantiate a new *DecimalFormat* object in order to format the *monthlyFee* instance variable. Because the *MONEY* object is declared to be *public* in the *BankAccount* class, we inherited the *MONEY* object, so we can simply call the *format* method using the *MONEY* object reference. An advantage to making the *MONEY* object *public* is that both the balance and the monthly fee will be printed using the same formatting rules. Another advantage is that if we want to change the formatting for printing the data, we need to make only one change: We redefine the value of the *MONEY* constant in the *BankAccount* class.

Example 10.9 *CheckingAccount* Class, Version 4

```
/* CheckingAccount class, version 4
   Anderson, Franceschi
*/

public class CheckingAccount extends BankAccount
{
   public final double DEFAULT_FEE = 5.00;
   private double monthlyFee;

   /** default constructor
   *   explicitly calls the BankAccount default constructor
   *   sets monthlyFee to default value
   */
   public CheckingAccount( )
   {
       super( ); // call BankAccount constructor
       monthlyFee = DEFAULT_FEE;
   }

   /** overloaded constructor
   *  calls BankAccount overloaded constructor
   *  @param  balance  starting balance
   *  @param  monthlyFee starting monthly fee
   */
   public CheckingAccount( double balance,
                           double monthlyFee )
   {
      super( balance ); // call BankAccount constructor
      setMonthlyFee( monthlyFee );
   }

   /** applyMonthlyFee method
   * charges the monthly fee to the account
   * @return a reference to this object
   */
   public CheckingAccount applyMonthlyFee( )
   {
     withdraw( monthlyFee );
     return this;
   }

   /** accessor method for monthlyFee
   *  @return  monthlyFee
   */
   public double getMonthlyFee( )
   {
     return monthlyFee;
   }

   /** mutator method for monthlyFee
   *  @param monthlyFee new value for monthlyFee
   *  @return a reference to this object
   */
   public CheckingAccount setMonthlyFee( double monthlyFee )
   {
     if ( monthlyFee >= 0.0 )
        this.monthlyFee = monthlyFee;

     return this;
   }

   /* toString method
   *  @return String containing formatted balance and monthlyFee
   *    invokes superclass toString to format balance
   */
   @Override
   public String toString( )
   {
     return super.toString( )
            + "; monthly fee is " + MONEY.format( monthlyFee );
   }
}
```

Description

COMMON ERROR TRAP

Do not confuse overriding a method with overloading a method. A subclass overriding a method provides a new version of that method, which hides the superclass version. A class overloading a method adds a version of that method, which varies in the number and/or type of parameters.

Example 10.10 shows Version 4 of the *CheckingAccountClient* class. In this class, we again instantiate a *CheckingAccount* object with an initial balance of $100.00 and a monthly fee of $7.50 (line 9), then implicitly invoke the *toString* method to print the data of the object (line 10). This time, we invoke the *toString* method of the *CheckingAccount* class, which returns both the *balance* and *monthlyFee* values, formatted as money, as shown in **Figure 10.7**.

Figure 10.7 Output from *CheckingAccountClient*, Version 4

Description

Example 10.10 *CheckingAccountClient*, Version 4

```
 1 /* CheckingAccount Client, Version 4
 2    Anderson, Franceschi
 3 */
 4
 5 public class CheckingAccountClient
 6 {
 7    public static void main( String [ ] args )
 8    {
 9      CheckingAccount c4 = new CheckingAccount( 100.00, 7.50 );
10      System.out.println( "New checking account:\n" + c4 );
11    }
12 }
```

Description

Table 10.3 summarizes the inheritance rules for inherited methods that have been overridden.

Inheritance Rules for Overridden Methods

Superclass Members	Inherited by Subclass?	Directly Accessible by Subclass?	Directly Accessible by Client of Subclass Using a Subclass Reference?
public or *protected* inherited methods that have been overridden in the subclass	no	yes, using `super.methodName ( arg list )`	no

Description

When we override a method, the method signature must be identical to the inherited method. However, wherever the overridden method specifies a class as a parameter or return type, we can substitute a subclass for that parameter or return type.

This is possible because a subclass object is a superclass object, so a subclass object reference can be substituted for any superclass object reference. If two methods of a class have the same name but different signatures (that is, if the number, order, or type of parameters is different), then the method is *overloaded*, not *overridden*.

For example, if we were to write the *toString* method in the *CheckingAccount* class with the following header that specifies an *int* parameter:

```
public String toString( int a )
```

then our *toString* method would have a different signature from the *toString* method we inherited from the *BankAccount* class, which does not take any parameters. In this case, we are overloading the *toString* method, not overriding it. In other words, we are providing an additional version of the *toString* method. The inherited version is still visible and available to be called.

SOFTWARE ENGINEERING TIP

Methods that override inherited methods should explicitly call the direct superclass method whenever appropriate.

Table 10.4 illustrates the differences between overriding *public* methods and overloading *public* methods.

Overriding vs. Overloading Methods

	Method Names	**Argument Lists**	**Return Types**	**Directly Accessible by Subclass Client Using a Subclass Object Reference?**
Overriding a *public* Method	identical	identical	identical	only the subclass version can be called
Overloading a *public* Method	identical	different in number or type of parameters	identical	all versions of the overloaded method can be called

```
New checking account:
balance is $100.00; monthly fee is $7.50

After withdrawing $95:
balance is $5.00; monthly fee is $7.50

Applying the monthly fee:
Warning: account is overdrawn!
balance is -$2.50; monthly fee is $7.50
```

10.3 The *protected* Access Modifier

We have seen that the subclass does not inherit constructors or *private* members of the superclass. However, the superclass constructors are still available to be called from the subclass and the *private* fields of the superclass are implemented as fields of the subclass.

Although *private* fields preserve encapsulation, there is additional processing overhead involved with calling methods. Whenever a method is called, the JVM saves the return address and makes copies of the arguments. Then when a value-returning method completes, the JVM makes a copy of the return value available to the caller. The *protected* access modifier was designed to avoid this processing overhead and to facilitate coding by allowing the subclass to access any *protected* field without calling its accessor or mutator method.

Be aware, however, that *protected* fields and methods also can be accessed directly by other classes in the same package, even if the classes are not within the same inheritance hierarchy.

To classes outside the package, a *protected* member of a class has the same restrictions as a *private* member. In other words, a class outside the package in which the *protected* member is declared may not call any *protected* methods and must access any *protected* fields through *public* accessor or mutator methods.

The *protected* access modifier has tradeoffs. As we mentioned, any fields declared as *protected* can be accessed directly by subclasses. Doing so, however, compromises encapsulation because multiple classes can set the value of a *protected* instance variable defined in another class.

SOFTWARE ENGINEERING TIP

Unless high performance is a critical requirement, avoid using the *protected* access modifier because doing so compromises encapsulation and complicates the maintenance of a program. Where possible, call superclass methods to change the values of *protected* instance variables.

Thus, maintaining classes that define or use *protected* members becomes more difficult. For example, we need to verify that any class that has access to the *protected* instance variable either does not set the variable's value, or if the class does change the value, that the new value is valid. Because of this added maintenance complexity, we recommend that *protected* access be used only when high performance is essential.

We also recommend that subclass methods avoid directly setting the value of a *protected* instance variable. Instead, wherever possible, call superclass methods when values of *protected* variables need to be changed.

To illustrate how *protected* access can be used in class hierarchies, let's look closely at our *CheckingAccount* class. We have been calling the *withdraw* method inherited from the *BankAccount* class to apply the monthly fee. However, the *withdraw* method leaves the *balance* unchanged if the withdrawal amount is greater than the balance. Thus, if the account does not have sufficient funds, the monthly fee is not charged. We would like the *CheckingAccount* class to be able to charge the monthly fee to the account and let the balance become negative.

To accomplish this, we declare the *balance* instance variable to be *protected* instead of *private*. This allows us to directly access *balance* inside the *applyMonthlyFee* method of the *CheckingAccount* class, because *balance* is now inherited by *CheckingAccount*.

Example 10.11 shows the *BankAccount* class, Version 3. The only change, compared to Version 1 (Example 10.1), is that the *balance* instance variable is declared as *protected*, rather than *private* (line 11).

Example 10.11 *BankAccount* Class, Version 3

```java
/**   BankAccount class, version 1
*     Anderson, Franceschi
*     Represents a generic bank account
*/
import java.text.DecimalFormat;

public class BankAccount
{
  public final DecimalFormat MONEY
                  = new DecimalFormat( "$#,##0.00" );
  protected double balance;

  /** default constructor
  *   sets balance to 0.0
  */
  public BankAccount( )
  {
    balance = 0.0;
  }

  /** overloaded constructor
  *   @param balance  beginning balance
  */
  public BankAccount( double balance )
  {
    deposit( balance );
  }

  /** accessor for balance
  *   @return  current account balance
  */
  public double getBalance( )
  {
    return balance;
  }

  /** deposit amount to account
  *   @param amount  amount to deposit;
  *                  amount must be >= 0.0
  *   @return  a reference to this object
  */
  public BankAccount deposit( double amount )
  {
    if ( amount >= 0.0 )
      balance += amount;

    return this;
  }

  /** withdraw amount from account
  *    @param amount   amount to withdraw;
  *                    amount must be >= 0.0
  *                    amount must be <= balance
  *    @return a reference to this object
  */
  public BankAccount withdraw( double amount )
  {
    if ( amount >= 0.0 && amount <= balance )
      balance -= amount;

    return this;
  }

  /** toString
  *  @return  the balance formatted as money
  */
  @Override
  public String toString( )
  {
    return "balance is " + MONEY.format( balance );
  }
}
```

Description

Example 10.12 shows Version 5 of the *CheckingAccount* class, which inherits from the *BankAccount* class in Example 10.11 that declares the *balance* as *protected*. The *CheckingAccount* class now inherits *balance*, and our *CheckingAccount* methods can access the *balance* variable directly. Nevertheless, in the default and overloaded constructors, we still call the superclass constructor to set the value of *balance* (lines 16 and 28). Otherwise, to avoid setting *balance* to an invalid initial value, we would need to know the validation rules for *balance* in *BankAccount* and unnecessarily duplicate that code.

Also, in the *toString* method (lines 63–72), we call the *toString* method of the *BankAccount* class. Again, we do this to be consistent with the superclass functionality, which formats the balance, and to avoid duplicating code.

In the *applyMonthlyFee* method (lines 32–41), however, we access *balance* directly. For this checking account, our bank will charge the monthly fee even if it results in a negative balance for the account, so we subtract *monthlyFee* from *balance*, which allows the balance to be negative. Notice that we change the value of *balance* directly instead of calling the *withdraw* method, which does not allow the balance to become negative.

Example 10.12 *CheckingAccount* Class, Version 5

```
/* CheckingAccount class, version 5
   Anderson, Franceschi
*/

public class CheckingAccount extends BankAccount
{
   public final double DEFAULT_FEE = 5.00;
   private double monthlyFee;

   /** default constructor
   *   explicitly calls the BankAccount default constructor
   *   set monthlyFee to default value
   */
   public CheckingAccount( )
   {
     super( );   // call BankAccount constructor
     monthlyFee = DEFAULT_FEE;
   }

   /** overloaded constructor
   *  calls BankAccount overloaded constructor
   *  @param  balance    starting balance
   *  @param  monthlyFee starting monthly fee
   */
   public CheckingAccount( double balance,
                           double monthlyFee )
   {
     super( balance );   // call BankAccount constructor
     setMonthlyFee( monthlyFee );
   }

   /** applyMonthlyFee method
   *   charges the monthly fee to the account
   *   @return a reference to this object
   */
   public CheckingAccount applyMonthlyFee( )
   {
     balance -= monthlyFee;

     return this;
   }

   /** accessor method for monthlyFee
   *  @return  monthlyFee
   */
   public double getMonthlyFee( )
   {
     return monthlyFee;
   }

   /** mutator method for monthlyFee
   *  @param monthlyFee new value for monthlyFee
   *  @return a reference to this object
   */
   public CheckingAccount setMonthlyFee( double monthlyFee
   {
     if ( monthlyFee >= 0.0 )
        this.monthlyFee = monthlyFee;

     return this;
   }

   /* toString method
   *  @return String containing formatted balance and month
   *    invokes superclass toString to format balance
   */
   @Override
   public String toString( )
   {
     return super.toString( )
            + "; monthly fee is " + MONEY.format( monthlyFe
   }
}
```

Description

Example 10.13 shows Version 5 of the *CheckingAccountClient* class. In this class, we again instantiate a *CheckingAccount* object with an initial balance of $100.00 and a monthly fee of $7.50 (line 9). We then call *withdraw* (line 12), so that the resulting balance is less than the monthly fee. Next we call the *applyMonthlyFee* method (line 16). We then check whether the balance is negative (line 17). If so, we output a warning message that the account is overdrawn (line 18). In any case, we output the new balance (line 19). The output of Example 10.13 is shown in **Figure 10.8**.

Figure 10.8 Output from *CheckingAccountClient*, Version 5

Description

Example 10.13 *CheckingAccountClient* Class, Version 5

```
 1 /*   CheckingAccount Client, Version 5
 2      Anderson, Franceschi
 3 */
 4
 5 public class CheckingAccountClient
 6 {
 7  public static void main( String [ ] args )
 8  {
 9     CheckingAccount c5 = new CheckingAccount( 100.00, 7.50 );
10     System.out.println( "New checking account:\n" + c5 );
11
12     c5.withdraw( 95 );
13     System.out.println( "\nAfter withdrawing $95:\n" + c5 );
14
15     System.out.println( "\nApplying the monthly fee:" );
16     c5.applyMonthlyFee( );
17     if ( c5.getBalance( ) < 0.0 )
18          System.out.println( "Warning: account is overdrawn!" );
19     System.out.println( c5 );
20 }
21}
```

Description

Table 10.5 compiles all the inheritance rules we have discussed.

Inheritance Rules

Superclass Members	Inherited by Subclass?	Directly Accessible by Subclass?	Directly Accessible by Client of Subclass?
public fields	yes	yes, by using field name	yes
public methods	yes	yes, by calling method from other subclass methods	yes, by calling method using a subclass object reference
protected fields	yes	yes, by using field name	no, must use accessors and mutators
protected methods	yes	yes, by calling method from other subclass methods	no
private fields	no	no, must use accessors and mutators	no, must use accessors and mutators
private methods	no	no	no
constructors	no	yes, using `super( arg list )` in a subclass constructor	no
public or *protected* inherited methods that have been overridden in the subclass	no	yes, using `super.methodName ( arg list )`	no

10.4 Programming Activity 1: Using Inheritance

For this Programming Activity, you will create the *SavingsAccount* class, which inherits directly from the *BankAccount* class. The *SavingsAccount* class is similar to the *CheckingAccount* class in that both classes inherit from *BankAccount*. **Figure 10.9** shows the resulting hierarchy.

Figure 10.9 Bank Account Hierarchy

Description

The *SavingsAccount* class inherits from the version of the *BankAccount* class in which the *balance* is declared to be *private*. The *SavingsAccount* subclass adds an annual *interestRate* instance variable, as well as supporting methods to access, change, and apply the interest rate to the account balance.

Instructions

Copy the source files in the Programming Activity 1 folder for this chapter to a folder on your computer. Load the *SavingsAccount.java* source file and search for five asterisks in a row (*****). This will position you to the six locations in the file where you will add code to complete the *SavingsAccount* class. The *SavingsAccount.java* file is shown in **Example 10.14**.

Example 10.14 *SavingsAccount.java*

```java
/* SavingsAccount class
*  Anderson, Franceschi
*/

import java.text.DecimalFormat;

// 1. ***** indicate that SavingsAccount inherits
//          from BankAccount
public class SavingsAccount
{
   public final double DEFAULT_RATE = .03;
   // 2. ****** define the private interestRate instance variable
   // interestRate, a double, represents an annual rate

   // 3 ***** write the default constructor
   /** default constructor
   *   explicitly calls the BankAccount default constructor
   *   set interestRate to default value DEFAULT_RATE
   *   print a message to System.out indicating that the
   *     constructor is called
   */

   // 4 ***** write the overloaded constructor
   /** overloaded constructor
   *   explicitly calls BankAccount overloaded constructor
   *   call setInterestRate method, passing interestRate
   *   print a message to System.out indicating that
   *     constructor is called
   *  @param  balance      starting balance
   *  @param  interestRate starting interest rate
   */

   // 5 ****** write this method:
   /** applyInterest method, no parameters.
   *   call the deposit method, passing a month's worth of interest
   *   remember that the interestRate instance variable is annual rate
   *
   *   @return a reference to this object
   */

   /** accessor method for interestRate
   *  @return  interestRate
   */
   public double getInterestRate( )
   {
     return interestRate;
   }

   /** mutator method for interestRate
   *  @param  interestRate new value for interestRate
   *          interestRate must be >= 0.0
   *            if not, do not change the value
   *          stores interestRate as input value / 100
   *          that is, 3.5 is stored as .035
   *  @return  a reference to this object
   */
   public SavingsAccount setInterestRate( double interestRate )
   {
     if ( interestRate >= 0.0 )
        this.interestRate = interestRate / 100;

     return this;
   }

   // 6 *****  write this method
   /* toString method
   *  @return a String containing formatted balance and interestRate
   *    invokes superclass toString to format balance
   *    formats interestRate as percent using a DecimalFormat object
   *    To create a DecimalFormat object for formatting percentages
   *    use this pattern in the constructor: "0.00%"
   */

}
```

Description

When you have completed the six tasks, load, compile, and run the Teller application (*Teller.java*), which you will use to test your *SavingsAccount* class. When the Teller application begins, you will be prompted with a dialog box for a starting balance. If you press “Enter” or the “OK” button without entering a balance, the Teller application will use the default constructor to instantiate a *SavingsAccount* object. If you enter a starting balance, the Teller application will prompt you for an interest rate and will instantiate a *SavingsAccount* object using the overloaded constructor. Once the *SavingsAccount* object has been instantiated, the Teller application will open the window shown in **Figure 10.10**, which provides buttons for calling the *SavingsAccount* methods to test your code.

Figure 10.10 The Teller Window

Description

Below the buttons is a ledger that displays the current state of the savings account. As you click on the various buttons, the ledger will display the operation performed and the values of the balance and the interest rate when that operation is complete.

The operations performed by each button are already coded for you and are the following:

- *Change* interest rate—prompts for a new interest rate and calls your *setInterestRate* method
- *Apply interest*—calls your *applyInterest* method
- *Deposit*—prompts for the deposit amount and calls the *deposit* method inherited from *BankAccount*
- *Withdraw*—prompts for the withdrawal amount and calls the *withdraw* method inherited from *BankAccount*
- *Display account information*—calls your *toString* method and displays the result in a dialog box
- *Exit*—exits the program

Figure 10.11 shows the Teller window after several operations have been performed.

Figure 10.11 Sample Teller Window After Performing Several

Operations

Description

DISCUSSION QUESTIONS

1. Explain why the Teller application can call the *withdraw* and *deposit* methods using a *SavingsAccount* object reference, even though you did not define these methods in the *SavingsAccount* class.
2. **Explain why your** *applyInterest* **method in the** *SavingsAccount* **class needs to call the** *deposit* **method of the** *BankAccount* **class.**

Traffic Light

10.5 *Abstract* Classes and Methods

In our Bank Account hierarchy, we could instantiate *BankAccount* objects, *CheckingAccount* objects, and *SavingsAccount* objects. In some situations, however, we will design a class hierarchy where one or more classes at the top of the hierarchy are not intended to be instantiated. Rather, they typically specify patterns for methods that subclasses in the hierarchy must implement. Often, the superclasses do not implement these methods. In these situations, we do not intend that these superclasses will be used to instantiate objects, and we define the superclasses as ***abstract***.

An ***abstract* class** is a class that is intended to be extended, rather than instantiated. Usually, an *abstract* class contains at least one ***abstract* method**, that is, a method that specifies an API that subclasses should implement, but does not provide an implementation for the method.

An *abstract* class cannot be used to instantiate objects. An *abstract* class can be extended, however, so that its subclasses can complete the implementation of the *abstract* methods and the subclasses can be instantiated.

A class is declared to be *abstract* by including the *abstract* keyword in the class header, as shown in the following syntax:

```
accessModifier abstract class ClassName
```

Description

An *abstract* method is defined by including the *abstract* keyword in the method header and by using a semicolon to indicate that there is no code for the method, as shown in the following syntax:

```
accessModifier abstract returnType methodName( argument list );
```

Description

Note that we do not include opening and closing curly braces for the method body—just a semicolon to indicate that the *abstract* method does not have a body.

Java imposes a few restrictions on *abstract* methods: constructors cannot be defined as *abstract*; and an *abstract* method cannot be declared as *private* or *static*.

For example, to draw figures, we can set up the hierarchy shown in **Figure 10.12**. The root superclass under *Object* is the *abstract Figure* class, and we derive two **concrete** (non-*abstract*) subclasses: *Circle* and *Square*. In the UML diagram, the name of the *Figure* class is set in italics to indicate that it is an *abstract* class.

Figure 10.12 The *Figure* Hierarchy

Description

All figures will have an (*x, y*) coordinate and a color, so the *Figure* class defines three fields: two *ints*, *x* and *y*, and a *Color* object named *color*.

We want all classes in the hierarchy to provide a *draw* method to render the figure; however, the *Figure* class has nothing but a point to draw, so its *draw* method has nothing to do. Thus, we do not provide an implementation of the *draw* method in the *Figure* class; instead, we define the *draw* method as an *abstract* method. Like the *abstract* class name, we indicate that the *draw* method is *abstract* by setting it in italics in the UML.

Let's look at the code for the *Figure* hierarchy in detail. **Example 10.15** shows the *abstract Figure* class. We define the class as *abstract* in the class header (line 7). The constructors (lines 13–22 and lines 24–34) initialize the *x* and *y* values and instantiate the *Color* object that all figures will have in common. The *Figure* class also provides accessor and mutator methods for its instance variables. The *abstract draw* method (lines 94–97) provides the API for the *draw* method, but no implementation—just a semicolon. The *Circle* and *Square* subclasses of the *Figure* class will provide appropriate implementations of the *draw* method.

Example 10.15 The *abstract Figure* Class

```java
/** abstract Figure superclass for drawing shapes
*  Anderson, Franceschi
*/
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;

public abstract class Figure
{
  private int x;
  private int y;
  private Color color;

  /** default constructor
  *   sets x and y to 0
  *   sets color to black
  */
  public Figure( )
  {
    x = 0;
    y = 0;
    color = Color.BLACK;
  }

  /** overloaded constructor
  *   @param  x      starting x coordinate for figure
  *   @param  y      starting y coordinate for figure
  *   @param  color  figure color
  */
  public Figure( int x, int y, Color color )
  {
    this.x = x;
    this.y = y;
    this.color = color;
  }

  /** accessor method for color
  *   @return current figure color
  */
  public Color getColor( )
  {

    return color;
  }

  /** mutator method for color
  *   @param color  new color for figure
  *   @return a reference  to this object
  */
  public Figure setColor( Color color )
  {
    this.color = color;

    return this;
  }

  /** accessor method for x
  *   @return current x value
  */
  public int getX( )
  {
    return x;
  }

  /** mutator method for x
  *   @param x  new value for x
  *   @return a reference to this object
  */
  public Figure setX( int x )
  {
    this.x = x;

    return this;
  }

  /** accessor method for y
  *   @return current y value
  */
  public int getY( )
  {
    return y;
  }

  /** mutator method for y
  *   @param y new y value
  *   @return a reference to this object
  */
  public Figure setY( int y )
  {
     this.y = y;

     return this;
  }

  /** abstract draw method
  *   @param gc GraphicsContext for drawing figure
  */
  public abstract void draw( GraphicsContext gc );
}
```

Description

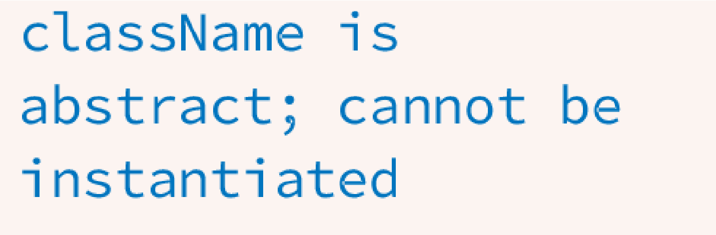
COMMON ERROR TRAP

Do not include opening and closing curly braces in the definition of an *abstract* method. Including them would mean that the method is implemented, but does nothing. Instead, indicate an unimplemented method by using only a semicolon.

When a subclass inherits from an *abstract* class, it can provide implementations for any, all, or none of the *abstract* methods. If the subclass does not completely implement all the *abstract* methods of the superclass, then the subclass must also be declared *abstract*. If, however, the subclass implements all the *abstract* methods in the superclass, and the subclass is not declared *abstract*, then the class is not *abstract* and we can instantiate objects of that subclass.

COMMON ERROR TRAP

Attempting to instantiate an object of an *abstract* class will generate the following compiler error:



```
className is
abstract; cannot be
instantiated
```

Description

where *className* is the name of the *abstract* class.

Example 10.16 shows the *Circle* class, which inherits from the *Figure* class and adds a *radius* instance variable, as well as a constant for the minimum radius. In the overloaded constructor, we pass the *x, y,* and *color* parameters to the constructor of the *Figure* class (line 35). On lines 61–71, the *Circle* class implements the *draw* method. We get the (*x, y*) coordinate and the color for the circle by calling the accessor methods of the *Figure* class because the *x, y*, and *color* instance variables are declared *private*.

Example 10.16 The *Circle* Class

```
/* Circle class
*  inherits from abstract Figure class
*  Anderson, Franceschi
*/

import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;

public class Circle extends Figure
{
   private final int MIN_RADIUS = 15;
   private int radius;

   /** default constructor
   *   calls default constructor of Figure class
   *   sets radius to minimum value
   */
   public Circle( )
   {
      super( );
      radius = MIN_RADIUS;
   }

   /** overloaded constructor
   *   sends x, y, color parameters to Figure constructor
   *   sends radius to setRadius method
   *   @param x      starting x coordinate
   *   @param y      starting y coordinate
   *   @param color  color for circle
   *   @param radius radius of circle
   */
   public Circle( int x, int y, Color color,
                             int radius )
   {
      super( x, y, color );
      setRadius( radius );
   }

   /** mutator method for radius
   *   @param radius  new value for radius
   *   @return a reference to this object
   */
   public Circle setRadius( int radius )
   {
      if ( radius > MIN_RADIUS )
         this.radius = radius;
      else
         this.radius = MIN_RADIUS;

      return this;
   }

   /** accessor method for radius
   *   @return radius
   */
   public int getRadius( )
   {
      return radius;
   }

   /** draw method
   *  sets color and draws a circle
   *  @param gc  GraphicsContext for drawing the circle
   */
   @Override
   public void draw( GraphicsContext gc )
   {
       gc.setFill( getColor( ) );
       gc.fillOval ( getX( ), getY( ),
                     radius * 2, radius * 2 );
   }
}
```

Description

Similarly, **Example 10.17** shows the *Square* class, which also inherits from the *Figure* class. The *Square* class adds a *length* instance variable, as well as a constant for the minimum length, and uses code similar to the *Circle* class to call the constructors of the *Figure* class (lines 20 and 35) and to implement its own version of the *draw* method (lines 61–71).

Example 10.17 The *Square* Class

```
/* Square class
*  inherits from abstract Figure class
*  Anderson, Franceschi
*/

import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;

public class Square extends Figure
{
   private final int MIN_LENGTH = 10;
   private int length;

   /** default constructor
   *   calls default constructor of Figure class
   *   sets length to minimum value
   */
   public Square( )
   {
     super( );
     length = MIN_LENGTH;
   }

   /** overloaded constructor
   *   sends x, y, and color parameters to Figure constructor
   *   sends length to setLength method
   *   @param x      starting x coordinate
   *   @param y      starting y coordinate
   *   @param color  color for square
   *   @param length length of square
   */
   public Square( int x, int y, Color color,
                  int length )
   {
      super( x, y, color );
      setLength( length );
   }

   /** mutator method for length
   *   @param length  new value for length
   *   @return a reference to this object
   */
   public Square setLength( int length )
   {
      if ( length > MIN_LENGTH )
         this.length = length;
      else
         this.length = MIN_LENGTH;

      return this;
   }

   /** accessor method for length
   *   @return length
   */
   public int getLength( )
   {
      return length;
   }

   /** draw method
   *   sets color and draws a square
   *   @param gc  GraphicsContext for drawing the square
   */
   @Override
   public void draw( GraphicsContext gc )
   {
      gc.setFill( getColor( ) );
      gc.fillRect( getX( ), getY( ),
                   length, length );
   }
}
```

Description

Because we want to instantiate *Circle* and *Square* objects, we do not declare these classes *abstract* and they are forced to implement the *draw* method. **Example 10.18** shows a graphical application, *TrafficLight*, which paints a traffic light, shown in **Figure 10.13**. On lines 13 and 14, we declare two *ArrayLists*, one to hold *Circle* objects and one to hold *Square* objects. In the *start* method, we instantiate both *ArrayLists* and add three *Square* objects to *squaresList* and three *Circle* objects to *circlesList* (lines 26–40). Then, we create the traffic light by calling the *draw* methods for all the *Squares* in the *squaresList* (lines 42–43), then calling the *draw* method for all the *Circles* in the *circlesList* (lines 45–46).

Figure 10.13 The *TrafficLight* Application

Example 10.18 The *TrafficLight* Application

```java
/* Figure Hierarchy Client
 * Anderson, Franceschi
*/
import javafx.application.Application;
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;
import javafx.stage.Stage;

import java.util.ArrayList;

public class TrafficLight extends Application
{
   private ArrayList<Square> squaresList;
   private ArrayList<Circle> circlesList;

   @Override
   public void start( Stage stage )
   {
     GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
                           stage, "Traffic Light", 700, 400 );

     final int SQUARE_SIZE = 80, CIRCLE_RADIUS = 20;
     final int SQUARE_X = 300, CIRCLE_X = SQUARE_X + 20;
     final int SQUARE_Y = 100, CIRCLE_Y = SQUARE_Y + 20;

     squaresList = new ArrayList<Square>( );
     squaresList.add( new Square( SQUARE_X, SQUARE_Y,
                                  Color.BLACK, SQUARE_SIZE ) );
     squaresList.add( new Square( SQUARE_X, SQUARE_Y + SQUARE_SI
                                  Color.BLACK, SQUARE_SIZE ) );
     squaresList.add( new Square( SQUARE_X, SQUARE_Y + ( SQUARE_
                                  Color.BLACK, SQUARE_SIZE ) );

     circlesList = new ArrayList<Circle>( );
     circlesList.add( new Circle( CIRCLE_X, CIRCLE_Y,
                                  Color.RED, CIRCLE_RADIUS ) );
     circlesList.add( new Circle( CIRCLE_X, CIRCLE_Y + SQUARE_SI
                                  Color.YELLOW, CIRCLE_RADIUS )
     circlesList.add( new Circle( CIRCLE_X, CIRCLE_Y + ( SQUARE_
                                  Color.GREEN, CIRCLE_RADIUS ) )

     for ( Square s : squaresList )
       s.draw( gc );

     for ( Circle c : circlesList )
       c.draw( gc );
   }

   public static void main( String [ ] args )
   {
     launch( args );
   }
}
```

Description

Java’s restrictions on declaring and using *abstract* classes and methods are summarized in Table 10.6.

Restrictions for *abstract* Classes and *abstract* Methods Within Classes

abstract classes	Classes must be declared *abstract* if the class contains any *abstract* methods.
	abstract classes can be extended.
	abstract classes cannot be used to instantiate objects.
abstract methods within classes	*abstract* methods cannot be declared within a non-*abstract* class.
	An *abstract* method must consist of a method header followed by a semicolon.
	abstract methods cannot be declared as *private* or *static*.
	A constructor cannot be declared *abstract*.

Description

10.6 Polymorphism

An important concept in inheritance is that an object of a class is also an object of any of its superclasses. That concept, “is a”, is the basis for an important OOP feature, called **polymorphism**, which simplifies the processing of various objects in the same class hierarchy. The word *polymorphism*, which is derived from the word fragment *poly* and the word *morpho* in the Greek language, literally means “multiple forms.”

Polymorphism allows us to use the same method call for any object in the hierarchy. We make the method call using an object reference of the superclass. At run time, the JVM determines to which class in the hierarchy the object actually belongs and calls the version of the method implemented for that class.

To use polymorphism in our application, the following conditions must be true:

- The classes are in the same hierarchy.
- The subclasses override the same method.
- A subclass object reference is assigned to a superclass object reference (that is, a subclass object is referenced by a superclass reference).
- The superclass object reference is used to call the method.

For example, we can take advantage of polymorphism in our traffic light graphical application by calling the *draw* method for either a *Circle* or *Square* object using a *Figure* object reference. Although we cannot instantiate an object from an *abstract* class, Java allows us to define object references of an *abstract* class.

Example 10.19 shows the rewritten traffic light graphical application. Instead of using separate *ArrayLists* for *Circle* and *Square* objects, we can declare and instantiate only one *ArrayList* of *Figure* references (lines 13 and 25). As each *Circle* and *Square* object is instantiated, we add its object reference to the *ArrayList* of *Figure* references (lines 27–39).

This greatly simplifies drawing the traffic light because we step through just one *ArrayList*, *figuresList*, calling the *draw* method for each element (lines 41-42). For the method call, it doesn't matter whether the object reference in *figuresList* is a *Circle* or *Square* reference. We just call the *draw* method using that reference. At run time, the JVM determines whether the object is a *Circle* or a *Square* and calls the appropriate *draw* method for the object type. Because the *ArrayList* is composed of *Figure* references, any element can be either a *Circle* or a *Square*—because a *Circle* and a *Square* are both *Figures*. The output of this application is identical to that of Example 10.18, as shown in Figure 10.13.

Example 10.19 Traffic Light Application Using Polymorphism

```
/* Figure hierarchy Client
 * Anderson, Franceschi
*/
import javafx.application.Application;
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;
import javafx.stage.Stage;

import java.util.ArrayList;

public class TrafficLightPolymorphism extends Application
{
   private ArrayList<Figure> figuresList;

   @Override
   public void start( Stage stage )
   {
     GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
                          stage, "Traffic Light", 700, 400 );

     final int SQUARE_SIZE = 80, CIRCLE_RADIUS = 20;
     final int SQUARE_X = 300, CIRCLE_X = SQUARE_X + 20;
     final int SQUARE_Y = 100, CIRCLE_Y = SQUARE_Y + 20;

     figuresList = new ArrayList<Figure>( );

     figuresList.add( new Square( SQUARE_X, SQUARE_Y,
                                  Color.BLACK, SQUARE_SIZE ) );
     figuresList.add( new Square( SQUARE_X, SQUARE_Y + SQUARE_SIZE,
                                  Color.BLACK, SQUARE_SIZE ) );
     figuresList.add( new Square( SQUARE_X, SQUARE_Y + ( SQUARE_SIZE * 2 ),
                                  Color.BLACK, SQUARE_SIZE ) );

     figuresList.add( new Circle( CIRCLE_X, CIRCLE_Y,
                                  Color.RED, CIRCLE_RADIUS ) );
     figuresList.add( new Circle( CIRCLE_X, CIRCLE_Y + SQUARE_SIZE,
                                  Color.YELLOW, CIRCLE_RADIUS ) );
     figuresList.add( new Circle( CIRCLE_X, CIRCLE_Y + ( SQUARE_SIZE * 2 ),
                                  Color.GREEN, CIRCLE_RADIUS ) );

     for ( Figure f : figuresList )
        f.draw( gc );

   }

   public static void main( String [ ] args )
   {
     launch( args );
   }
}
```

10.7 Programming Activity 2: Using Polymorphism

In this Programming Activity, you will complete the implementation of the Tortoise and the Hare race. The Tortoise runs a slow and steady race, while the Hare runs in spurts with rests in between. **Figure 10.14** shows a sample run of the race. In this figure, we show only one tortoise and one hare; however, using polymorphism we can easily run the race with any number and combination of tortoises and hares.

Figure 10.14 A Sample Run of the Tortoise and the Hare Race

Description

The class hierarchy for this Programming Activity is shown in **Figure 10.15**.

Figure 10.15 *Racer* Hierarchy

Description

The code for the *Racer* class, which is the superclass of the *Tortoise* and *Hare* classes, is shown in **Example 10.20**. The

Racer class has three instance variables (lines 10–12): a *String* *ID*, which identifies the type of racer; and *x* and *y* positions, both of which are *ints*. The class has the usual constructors, as well as accessor and mutator methods for the *x* and *y* positions and ID. These instance variables and methods are common to all racers, so we define them in the *Racer* class. Individual racers, however, will differ in the way they move and in the way they are drawn. Thus, in line 8, we declare the *Racer* class to be *abstract*, and in lines 78–85, we define two *abstract* methods, *move* and *draw*. Classes that inherit from the *Racer* class will need to provide implementations of these two methods (or be declared *abstract* as well).

Example 10.20 The *abstract Racer* Class

```
/**  Racer class
*    Abstract class intended for racer hierarchy
*    Anderson, Franceschi
*/

import javafx.scene.canvas.GraphicsContext;

public abstract class Racer
{
  private String ID;  // racer ID
  private int x;      // x position
  private int y;      // y position

  /** default constructor
  *    Sets ID to blank
  */
  public Racer( )
  {
    ID = "";
  }

  /** constructor
  *    @param ID   racer ID
  *    @param x    x position
  *    @param y    y position
  */
  public Racer( String ID, int x, int y )
  {
    this.ID = ID;
    this.x = x;
    this.y = y;
  }

  /** accessor for ID
  *   @return  ID
  */
  public String getID( )
  {
    return ID;
  }

  /** accessor for x
  *   @return  current x value
  */
  public int getX( )
  {
    return x;
  }

  /** accessor for y
  *   @return  current y value
  */
  public int getY( )
  {
    return y;
  }

  /** mutator for x
  *   @param  x new value for x
  *   @return a reference to this object
  */
  public Racer setX( int x )
  {
    this.x = x;
    return this;
  }

  /** mutator for y
  *   @param  y new value for y
  *   @return a reference to this object
  */
  public Racer setY( int y )
  {
    this.y = y;
    return this;
  }

  /** abstract method for Racer's move
  */
  public abstract void move( );

  /** abstract method for drawing Racer
  *   @param   gc    GraphicsContext
  */
  public abstract void draw( GraphicsContext gc );
}
```

Description

The *Tortoise* and *Hare* classes inherit from the *Racer* class. Their only job is to pass constructor arguments to the *Racer* class and implement the *draw* and *move* methods. For this Programming Activity, we have provided the *Tortoise* and *Hare* classes with the *draw* and *move* methods already written.

Your job is to add *Tortoise* and *Hare* objects to an *ArrayList* of *Racer* objects, as specified by the user. Then you will add code to run the race by stepping through the *ArrayList*, calling *move* and *draw* for each *Racer* object.

Instructions

Copy the source files in the Programming Activity folder for this chapter to a folder on your computer. Open the *PolymorphismController.java* file.

1. Write the code to determine which racers will run the race. Search for five asterisks in a row (*****). This will position you inside the *prepareToRace* method.

```
/** prepareToRace method
*    @param input     racer type entered by the user
*                     racer types are 't' or 'T' for Tortoise,
*                                     'h' or 'H' for Hare
*/
private void prepareToRace( char input )
{
   final int START_LINE = 60;     // x position of start of race
   final int RACER_SPACE = 50;    // spacing between racers

   /** 1. ***** Student writes this switch statement
   *  input parameter contains the racer type
   *      entered by the user
   *  If input is 'T' or 't',
   *     add a Tortoise object to the ArrayList named racerList,
   *            which is an instance variable of this class
   *  The API of the Tortoise constructor is:
   *          Tortoise( String ID, int x, int y )
   *   a sample call to the constructor is
   *          new Tortoise( "Tortoise", START_LINE, yPos )
   *          where START_LINE is a constant local variable
   *            representing the starting x position for the race
   *          and yPos is an instance variable representing
   *             the racer's y position
   *
   *  If input is 'H' or 'h',
   *      add a Hare object to the ArrayList named racerList
   *  The API of the Hare constructor is:
   *          Hare( String ID, int x, int y )
   *      a sample call to the constructor is
   *          new Hare( "Hare", START_LINE, yPos )
   *          where START_LINE is a constant local variable
   *            representing the starting x position for the race
   *          and yPos is an instance variable representing
   *             the racer's y position
   *
   *  After adding a racer to the ArrayList racerList,
   *          increment yPos by the value of
   *          the constant local variable RACER_SPACE
   *
   *  if input is anything other than 'T', 't',
   *          'H' or 'h', do nothing
   */
   // write your switch statement here

   /** end of student code, part 1 */

} // end prepareToRace
```

Description

2. Next, write the code to display the racers at the starting position. Again, search for five asterisks (*****). This will position you inside the *getReady* method, which is called whenever a new *Racer* is added. The method draws the finish line and displays the racers at the starting position. The code to display the finish line is already written. For this task, you will write code to loop through the *ArrayList* of

Racers, calling the *draw* method for each racer. The portion of the *getReady* method where you will add your code is shown below.

```
/** getReady method
 *  @param gc   GraphicsContext context
 *  draws the finish line and draws the racers
 */
 protected void getReady( GraphicsContext gc )
 {
   // draw the finish line
   finishX = (int) canvas.getWidth( ) - 20;
   gc.setStroke( Color.BLUE );
   gc.strokeLine( finishX, 0, finishX, canvas.getHeight( ) );

   // display racers before race begins
   /* 2. ***** student writes this code
   *  loop through instance variable ArrayList racerList,
   *    which contains Racer object references,
   *    calling draw for each element. (Do not call move!)
   *  The API for draw is:
   *    void draw( GraphicsContext gc )
   *    where gc is the graphics context
   *    passed to this getReady method
   */
   // student code goes here

   /** end of student code, part 2 */

   } // end getReady
```

Description

3. Finally, write the code to run the race. Again, search for five asterisks (*****); this will position you inside the *runRace* method, which is called when the user presses the “Start Race” button. Task 3 is similar to task 2 in that you will loop through the *ArrayList* of *Racers*. In this task, however, you will call both the *move* and *draw* methods. The portion of the *runRace* method where you will add your code is shown below.

```
/** runRace method
 *  @param gc   GraphicsContext context
 *  moves and draws racers
 */
 public void runRace( GraphicsContext gc )
 {
 gc.setStroke( Color.BLUE );
 gc.strokeLine( finishX, 0, finishX, canvas.getHeight( ) );

 /* 3. ***** student writes this code
 *    loop through instance variable ArrayList racerList,
 *    which contains Racer object references,
 *    calling move, then draw for each element
 *  The API for move is:
 *      void move( )
 *  The API for draw is:
 *      void draw( GraphicsContext gc )
 *        where gc is the GraphicsContext object
 *        passed to this runRace method
 */
 // student code goes here

 /** end of student code, part 3 */

 } // end runRace
```

Description

When you have finished writing the code, compile the source code and run the *PolymorphismApplication* file. Try several runs of the race with a different number of racers and with a different combination of *Tortoises* and *Hares*. **Figure 10.16** shows the race with four *Tortoises* and three *Hares*.

Figure 10.16 Another Run of the Race

Description

DISCUSSION QUESTIONS

1. Explain how polymorphism simplifies this application.
2. If you wanted to add another racer, for example, an aardvark, explain what code you would need to write and what existing code, if any, you would need to change.

Select your shipping option > 1
Your shipping cost is $14.00
```

10.8 Interfaces

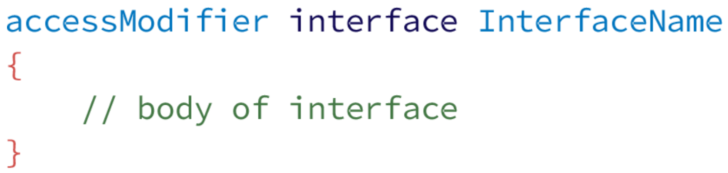
In Java, a class can inherit directly from only one class; that is, a class can *extend* only one class. To allow a class to inherit behavior from multiple sources, Java provides the **interface**. Interfaces are often used to provide a specification for performing common tasks. They can also be used to promote code reusability.

An interface typically specifies behavior that a class will *implement*.

Interface members can be any of the following:

- constants
- methods
- classes
- other interfaces

To define an interface, we use the following syntax:



```
accessModifier interface InterfaceName
{
    // body of interface
}
```

Description

Like classes, the Java convention is to name interfaces starting with a capital letter and capitalizing internal words.

All interfaces are *abstract*; thus, they cannot be instantiated. The *abstract* keyword, however, is usually omitted from the interface definition. If the interface's access modifier is *public*, its members are implicitly *public* as well.

SOFTWARE ENGINEERING TIP

When naming interfaces, start with a capital letter and capitalize any internal words.

Any field defined in a *public* interface is implicitly *public*, *static*, and *final*. These keywords can be specified, but typically we omit them because they are implicit. When we define a constant in the interface, we must also assign a value to that field. Note that because all fields are *static*, interfaces cannot have instance variables.

We can define various types of methods in interfaces:

- *public abstract* methods
- *public default* methods
- *public* or *private static* methods
- *private* methods

To define an *abstract* method, we provide only the method header followed by a semicolon. We do not provide a body for the method.

For the other method types, we do provide a method body; that is, *default, static,* and *private* methods are not *abstract*.

Private methods, introduced in Java version 9, allow us to define methods that provide a service to another method in the interface. For example, several methods in the interface may contain common code. By putting that common code into a *private* method, we can eliminate duplication of code. Each method can simply call the *private* method to access the needed functionality.

To inherit from an interface, our class declares that it *implements* the interface, using the following syntax:

```
accessModifier class ClassName extends SuperclassName
                                   implements Interface1, Interface2, ...
```

Description

The *extends* clause is optional if our class inherits only from the *Object* class. A class can *implement* 0, 1, or more interfaces. If our class *implements* more than one interface, the interfaces are specified in a comma-separated list of interface names.

When our class implements an interface, we inherit any *default* and *public static* methods, but we must provide method bodies for all the *abstract* methods.

Default methods, introduced in Java version 8, are *public* methods with a method body that all classes implementing the interface inherit. *Default* methods solve a problem: how can we add a new method to an existing interface? For example, assume we have defined an interface that specifies three *abstract* methods. Any class that implements our interface must provide method bodies for those three methods. Then suppose we want to add new functionality to the interface that would require adding a fourth method. If we add that fourth method as *abstract*, any existing class that implements the interface will no longer compile. We don’t want to break existing code!

So we have two options. The first option is to define a new interface that *extends* our original interface, that is, the new interface would inherit the original three *abstract* methods, and we would add the fourth method to the new interface as an *abstract* method. If existing classes want to take advantage of the new functionality, those classes would need to change their code to implement the new interface and thus add a body for the fourth method. The second simpler option is to add the fourth method to the original interface as a *default* method that provides some basic functionality. In this way, classes that already implement the original interface would automatically inherit the new functionality without needing to change their code. In addition, a class that implements an interface can optionally override any *default* methods. Thus, if the basic functionality is not appropriate, the implementing class can provide their own custom version of the method by overriding the *default* method.

Let’s consider the general problem of parsing a string of characters. We could have two applications: determining whether a password contains required characters, and converting a *String* containing hexadecimal digits to a decimal number. In each application, we need to parse (analyze) a *String* character by character. In the second application, we also need to validate the *String*.

Figure 10.17 shows the interfaces and classes used in these two applications. In this figure, we introduce the <<interface>> notation and a new UML symbol, the dotted line, which indicates a class that implements an interface.

Figure 10.17 UML for String Parsing Interfaces and Classes

Description

Each application needs to process the characters of the *String,* determining whether each character of the *String* is a digit, a letter, or another character (neither a digit nor a letter). But each application handles digits, letters, and other characters differently. We create an interface, *StringHandler,* shown in Example 10.21, that allows the implementing class to define a strategy for processing a *String*, one character at a time. The *StringHandler* interface specifies three *abstract* methods, and a *default parse* method that iterates through the *String* determining the type of each character, and calling the appropriate method. Any class that implements the *StringHandler* interface automatically inherits the *parse* method, and must implement the *processLetter*, *processDigit,* and *processOther* methods*.*

Example 10.21 The *StringHandler* Interface

```
 1 /*  StringHandler interface
 2 *   Anderson, Franceschi
 3 */
 4
 5 public interface StringHandler
 6 {
 7   // abstract methods to implement
 8   void processLetter( char c );
 9   void processDigit( char c );
10   void processOther( char c );
11
12   /** default parse method
13   * @param s the String to parse
14   */
15   default void parse( String s )
16   {
17     for ( int i = 0; i < s.length( ); i++ )
18     {
19       char c = s.charAt( i );
20       if ( Character.isDigit( c ) )
21         processDigit( c );
22       else if ( Character.isLetter( c ) )
23         processLetter( c );
24       else
25         processOther( c );
26     }
27   }
28 }
```

Description

The *parse* method, at lines 12–27, takes the *String* to parse as a parameter and walks through the *String*, a character at a time, determining the type of character, and calling the appropriate method of the *StringHandler* interface. In order to determine whether a character is a digit or a letter, the *parse* method calls two *static* methods of the *Character* wrapper class, *isDigit* and *isLetter*, shown in **Table 10.7**. Any class that implements the *StringHandler* interface must provide fully implemented versions of the three *abstract* methods:

processDigit, *processLetter*, and *processOther*. Additionally, if the implementing class needs to process the *String* in a different order, perhaps from the last letter to the first, that class can write its own version of the *parse* method that overrides the *parse* method in the interface.

Some *Static* Methods of the *Character* Wrapper Class

Useful *Static* Methods of the *Character* Class

Return value	Method name and argument list
`boolean`	`isDigit( char ch )` returns *true* if *ch* represents a digit from ’0’ to ‘9’; *false* otherwise.
`boolean`	`isLetter( char ch )` returns *true* if *ch* represents a letter from ‘a’ to ‘z’ or ‘A’ to ‘Z’; *false* otherwise.
`int`	`getNumericValue( char ch )` returns the integer value of the specified Unicode character ch.

Description

We are now ready to design a specialized class that implements the *StringHandler* interface to parse the string with a particular objective in mind. In our example, the first application processes a password to determine its strength. A strong password must contain at least eight characters, at least one digit, and at least one special character. A password containing fewer than six characters is considered weak; otherwise, we consider that the password security level is medium.

The *PasswordSecurityHandler* class, shown in **Example 10.22**, implements the *StringHandler* interface (line 9); thus, it provides implementations of the *processLetter, processDigit*, and *processOther* methods. The *default parse* method meets this application's needs, so we do not override the *default* implementation of the *parse* method.

Example 10.22 The *PasswordSecurityHandler* Class

```
/*  PasswordSecurityHandler class
 *  Implements methods of the StringHandler interface
 *  to parse a String containing a password.
 *
 *  Anderson, Franceschi
*/

public class PasswordSecurityHandler
                    implements StringHandler
{
  private int length;
  private boolean digit;
  private boolean otherCharacter;

  /** default constructor
  *  sets length to 0, digit and otherCharacter flags to false
  */
  public PasswordSecurityHandler( )
  {
    length = 0;
    digit = false;
    otherCharacter = false;
  }

  /** processLetter method
  * @param c  character to process
  * adds 1 to length
  */
  @Override
  public void processLetter( char c )
  {
    length++;
  }

  /** processDigit method
  * @param c  character to process
  * adds 1 to length, sets digit flag to true
  */
  @Override
  public void processDigit( char c )
  {
    length++;
    digit = true;
  }

  /** processOther method
  * @param c  character to process
  * adds 1 to length,
  * sets otherCharacter flag to true
  */
  @Override
  public void processOther( char c )
  {
    length++;
    otherCharacter = true;
  }

  /** securityLevel method
  * @return  "weak" if password contains fewer than 6 characters
  *          "strong" if password has at least 8 characters, at least
  *                  one digit, and at least one other character
  *                  that is neither a letter nor a digit
  *          "medium" otherwise
  */
  public String securityLevel( )
  {
    if ( length < 6 )
      return "weak";
    else if ( length >= 8 && digit && otherCharacter )
      return "strong";
    else
      return "medium";
  }
}
```

Description

We define three instance variables (lines 11–13): *length* to hold the number of characters in the password and two flag variables, *digit* and *otherCharacter,* which will indicate whether a digit and a special character were found in the password. The constructor (lines 15–23) initializes *length* to 0 and the flag variables to *false*. The *processLetter* method (lines 25–33) simply increments the *length* variable. The *processDigit* method (lines 35–44) increments *length* and also sets the *digit* flag to *true* to indicate that at least one digit has been found. Similarly, the *processOther* method (lines 46–56) increments *length* and sets the *otherCharacter* flag to *true* to indicate that at least one special character has been found.

The *securityLevel* method (lines 58–73) tests the strength of the password based on its length and the *digit* and *otherCharacter* flags that were set as the password was processed and returns either “weak,” “medium,” or “strong.”

Example 10.23 shows a client program for parsing a password. We ask the user to enter a password at lines 12–16. At line 18, we instantiate a *PasswordSecurityHandler* object. We then call the *parse* method (line 19), passing the password entered by the user. After the password has been parsed, we call the *securityLevel* method of the *PasswordSecurityHandler* class and output the strength of the password (lines 21–22). **Figure 10.18** shows the output of Example 10.23 when the user enters the password *open@jbc*.

Figure 10.18 Output from Example 10.23

Description

Example 10.23 The *PasswordSecurityHandlerClient* Class

```
/* PasswordSecurityHandlerClient
* Anderson, Franceschi
*/

import java.util.Scanner;

public class PasswordSecurityHandlerClient
{
  public static void main( String [ ] args )
  {
    Scanner scan = new Scanner( System.in );
    System.out.println( "A strong password has at least 8 \n"
          + "characters and contains at least one digit \n"
          + "and one special character." );
    System.out.print( "Enter a password > " );
    String password = scan.next( );

    PasswordSecurityHandler psh = new PasswordSecurityHandler( );
    psh.parse( password );

    System.out.println( password + "'s security is "
               + psh.securityLevel( ) );
  }
}
```

Description

For the second application, where we analyze a *String* representing a hexadecimal number, we reuse the *StringHandler* interface. This application determines whether the *String* contains only valid hexadecimal characters and calculates the decimal equivalent of the hex value represented by the *String*.

As we discussed earlier, a class can implement several interfaces. We now define another interface, *Validator*, shown in Example 10.24, which specifies one *abstract* method to implement: *isValid*. We created the *Validator* interface because determining whether a string is valid is a generic operation and not necessarily specific to parsing a hexadecimal number. Thus, other classes can also implement the *Validator* interface.

Example 10.24 The *Validator* Interface

```
 1 /** Validator interface
 2 *   Anderson, Franceschi
 3 */
 4 
 5 @FunctionalInterface
 6 public interface Validator
 7 {
 8   // abstract method to implement
 9   boolean isValid( );
10 }
```

Description

If the interface has only one *abstract* method to implement, the interface is called a **functional interface** and can be used with **lambda expressions.** We cover lambda expressions later in the text. To ensure that the interface we are defining is, in fact, **a functional interface,** we can precede the definition with the *@FunctionalInterface* annotation. Because *Validator* has only one method to implement and is thus a functional interface, we precede its definition with the above annotation (line 5).

The *HexStringHandler* class, shown in **Example 10.25**, implements both the *StringHandler* and the *Validator* interfaces (line 11). Again, the *default parse* method meets our needs, so we do not override that method. Our *HexStringHandler* class has two instance variables (lines 13–14): a flag variable, *validHex*, which will indicate whether the string being parsed contains only valid hex characters, and *number*, which will hold the decimal equivalent of the hex value. The default constructor (lines 16–24) initializes these variables to *true* and *0*, respectively. The decimal equivalent of the hex number is calculated as each character of the *String* is parsed in the *processLetter* method (providing that the letter is a valid hex digit) and the *processDigit* method. The *processLetter* and *processDigit* methods use the *static getNumericValue* method of the *Character* wrapper class, also shown in Table 10.7, to retrieve the numeric equivalent of the character being processed. If the *processLetter* method (lines 26–40) finds that the letter is not valid or if the *processOther* method (lines 53–62) is called—indicating that the character is neither a letter nor a digit—the *validHex* flag is set to *false*.

Example 10.25 *HexStringHandler* Class

```
/* HexStringHandler class
*  Implements the StringHandler interface
*  to parse a String that contains a hex number
*  into its decimal equivalent
*  Implements the Validator interface to determine
*  validity of String
*  Anderson, Franceschi
*/

public class HexStringHandler
               implements StringHandler, Validator
{
  private boolean validHex;
  private int number;

  /** default constructor
  *  initializes number to 0
  *  and validHex to true
  */
  public HexStringHandler( )
  {
    validHex = true;
    number = 0;
  }

  /** processLetter method
  * @param c  the character to process
  * if c is between 10 and 15 (hex A through F),
  * uses its value to update the decimal value (number)
  * otherwise, character is invalid letter
  */
  @Override
  public void processLetter( char c )
  {
    int n = Character.getNumericValue( c );
    if ( n >= 10 && n <= 15 ) // valid hex character?
      number = 16 * number + n; // update number
    else // invalid hex character
      validHex = false;
  }

  /** processDigit method
  * @param c  the character to process
  * uses numeric value of c to update the decimal value (number)
  */
  @Override
  public void processDigit( char c )
  {
    int n = Character.getNumericValue( c );
    number = 16 * number + n; // update number
  }

  /** processOther method
  * @param c  the character to process
  * character is not a valid hex digit
  */
  @Override
  public void processOther( char c )
  {
    // c is an invalid hex character
    validHex = false;
  }

  /** isValid method
  * @return true if all characters
  * in String are valid hex characters,
  * else returns false
  */
  public boolean isValid( )
  {
    return validHex;
  }

  /** getNumber method
  * @return if valid, returns the calculated decimal value
  * else, returns -1
  */
  public int getNumber( )
  {
    if ( isValid( ) )
      return number;
    else
      return -1;
  }
}
```

Description

At lines 64–72, the *isValid* method returns *true* if the parsed string represents a valid hexadecimal number, and *false* otherwise. At lines 74–84, the *getNumber* method returns the decimal number if the *String* parsed contains only hexadecimal digits, and *–1* otherwise.

Example 10.26 shows a similar client program for the hex conversion application. We ask the user to enter a hexadecimal number at lines 12–13. At lines 15–16, we instantiate a *HexStringHandler.* At line 16, we call the *parse* method, passing it the hex *String* entered by the user. After parsing the *String*, we test if the *String* entered by the user is a valid hexadecimal number by calling the *isValid* method of the *HexStringHandler* class (line 18). If it is valid, we call the *getNumber* method of the *HexStringHandler* class to output the decimal equivalent of that number (line 19); otherwise, we output a message that the hex number was not valid (line 21). **Figure 10.19** shows the output of Example 10.26 when the user enters the valid hex number *A56E*.

Figure 10.19 Output from Example 10.26

Description

Example 10.26 The *HexStringHandlerClient* Class

```
/*  HexStringHandlerClient class
*   Anderson, Franceschi
*/

import java.util.Scanner;

public class HexStringHandlerClient
 {
  public static void main( String [ ] args )
  {
    Scanner scan = new Scanner( System.in );
    System.out.print( "Enter a hexadecimal number > " );
    String hex = scan.next( );

    HexStringHandler hsh = new HexStringHandler( );
    hsh.parse( hex );

    if ( hsh.isValid( ) )
      System.out.println( hex + " = " + hsh.getNumber( ) );
    else
      System.out.println( hex + " is not a valid hex number." );
  }
}
```

Description

Polymorphism can also be used with interfaces. Although interfaces cannot be instantiated, we can assign an object of a class that implements an interface to an interface reference, and we use that reference to call the methods of the interface.

To illustrate polymorphism with interfaces, let's assume that we are a company that needs to calculate shipping costs for items our customers purchase. We have decided to offer three different pricing strategies based on the weight of the item. With flat-rate shipping, we charge a fixed fee per pound. For standard shipping, we charge a base rate for the first 5 pounds, then a fixed rate for each additional pound. And for express shipping, we add a fixed fee to the standard shipping charge.

Note that in each case, we are calculating a price based on weight. To handle this situation, we can create a *ShippingCost* interface and derive three classes that implement the *ShippingCost* interface, each performing its appropriate shipping cost calculation. The UML for this application is shown in **Figure 10.20**.

Figure 10.20 UML for the Shipping Strategy

Description

The *ShippingCost* interface is shown in **Example 10.27**. This interface has one *abstract* method, *calculateShipping*, that accepts the weight as a parameter and returns the shipping cost (line 9).

Example 10.27 The *ShippingCost* Interface

```
1 /** Shipping Cost
2 *   Anderson, Franceschi
3 */
4
5 @FunctionalInterface
6 public interface ShippingCost
7 {
8    double calculateShipping( double weight );
9 }
```

Description

We can now define three classes that implement the *ShippingCost* interface: *FlatRateShipping*, *StandardShipping*, and *ExpressShipping*, with each providing a custom version of the *calculateShipping* method.

Example 10.28 shows the *FlatRateShipping* class. In line 6, we specify that this class implements the *ShippingCost* interface, and in lines 10–14 we provide the *calculateShipping* method, which simply returns the weight multiplied by a constant rate.

Example 10.28 The *FlatRateShipping* Class

```
/** FlatRateShipping
*    cost is .50/pound
*    Anderson, Franceschi
*/

public class FlatRateShipping implements ShippingCost
{
   private final double RATE_PER_POUND = .50;

   @Override
   public double calculateShipping( double weight )
   {
      return RATE_PER_POUND * weight;
   }
}
```

Description

Example 10.29 shows the *StandardShipping* class, which also implements the *ShippingCost* interface (line 7). Its *calculateShipping* method (lines 13–21) computes a fixed charge for the first 5 pounds, plus a dollar for each additional pound.

Example 10.29 The *StandardShipping* Class

```
 1 /** StandardShipping
 2 *    cost is $2.50 for the first 5 pounds,
 3 *       and $1 for each additonal pound
 4 *    Anderson, Franceschi
 5 */
 6
 7 public class StandardShipping implements ShippingCost
 8 {
 9     private final double BASE_WEIGHT = 5;
10     private final double BASE_CHARGE = 2.5;
11     private final double EXTRA_POUND_RATE = 1.00;
12
13    @Override
14    public double calculateShipping( double weight )
15    {
16       if ( weight > BASE_WEIGHT )
17         return BASE_CHARGE
18              +  ( ( weight - BASE_WEIGHT ) * EXTRA_POUND_RATE );
19       else
20         return BASE_CHARGE;
21    }
22 }
```

Description

Because for express shipping we charge the standard rate plus a fixed fee, we want to use the same calculation as the standard shipping and just add the fixed fee. Rather than repeat the code for the standard shipping calculation, we can define the *ExpressShipping* class as extending the *StandardShipping* class. **Example 10.30** shows the *ExpressShipping* class. In line 6, we specify that *ExpressShipping* inherits from *StandardShipping*. Note that we don’t need to specify that this class implements the *ShippingCost* interface because *StandardShipping* already does that. Any subclass automatically implements any interfaces implemented by the superclass. In lines 10–14, we override the *calculateShipping* method defined in the *StandardShipping* superclass. Inside our method, we call the version of the *calculateShipping* method in the *StandardShipping* class to determine the standard fee (line 13) and add the express fixed fee to the returned value.

Example 10.30 The *ExpressShipping* Class

```
 1 /** ExpressShipping
 2 *   cost is $10, in addition to standard shipping
 3 *   Anderson, Franceschi
 4 */
 5
 6 public class ExpressShipping extends StandardShipping
 7 {
 8    private final double EXPRESS_SURCHARGE = 10;
 9
10    @Override
11    public double calculateShipping( double weight )
12    {
13       return EXPRESS_SURCHARGE + super.calculateShipping( weight );
14    }
15 }
```

Description

Putting all this together, **Example 10.31** shows a client class, *ShippingCalculator*, that allows a user to select a shipping option and then calculates the shipping cost for an item. At lines 17–22, we prompt the user for the weight of the item and provide a menu from which the user can select a shipping option. Then, using a *switch* expression (lines 24–30), we declare a reference to the *ShippingCost* interface and assign an object reference of the appropriate class to it (lines 26, 27, and 28). If the user selects a valid option, we call the *calculateShipping* method using the *shippingCost* reference (lines 33–34). As a result, the correct method for the selected pricing strategy is called at runtime. **Figure 10.21** shows the output of the program when the user selects express shipping for an item that weighs 6.5 pounds.

Figure 10.21 Output from Example 10.31

Description

This application meets the four requirements for polymorphism. All classes are in the same hierarchy; the subclasses override the same method; we assign subclass references to a superclass/interface reference; and we use the superclass/interface reference to call the method.

Example 10.31 The *ShippingCalculator* Class

```
 1 /** ShippingCalculator
 2 *   Anderson, Franceschi
 3 */
 4 import java.util.Scanner;
 5 import java.text.NumberFormat;
 6
 7 public class ShippingCalculator
 8 {
 9    public static void main( String [ ] args )
10    {
11      Scanner scan = new Scanner( System.in );
12      NumberFormat money = NumberFormat.getCurrencyInstance( );
13
14      System.out.print( "What is the weight of the item? " );
15      double weight = scan.nextDouble( );
16
17      System.out.println( "Our shipping options are: "
18                          + "\n\t1 Express shipping: 1-2 business days"
19                          + "\n\t2 Standard shipping: 3-5 business days"
20                          + "\n\t3 Flat Rate: 6-8 business days" );
21      System.out.print( "Select your shipping option > " );
22      int option = scan.nextInt( );
23
24      ShippingCost shippingCost = switch ( option )
25      {
26         case 1 -> new ExpressShipping( );
27         case 2 -> new StandardShipping( );
28         case 3 -> new FlatRateShipping( );
29         default -> null;
30      };
31
32      if ( shippingCost != null )
33         System.out.println( "Your shipping cost is "
34             + money.format( shippingCost.calculateShipping( weight ) ) );
35      else
36         System.out.println( "No valid shipping option selected." );
37    }
38 }
```

CHAPTER REVIEW

10.9 Chapter Summary

- Inheritance lets us organize related classes into ordered levels of functionality, called hierarchies. The advantage is that we write the common code only once and reuse it in multiple classes.
- A subclass inherits methods and fields of its superclass. A subclass can have only one direct superclass, but many subclasses can inherit from a common superclass.
- Inheritance implements the “is a” relationship between classes. Any object of a subclass is also an object of the superclass.
- All classes inherit from the *Object* class.
- To specify that a subclass inherits from a superclass, the subclass uses the *extends* keyword in the class definition, as in the following syntax:

```
accessModifier class ClassName extends SuperclassName
```

Description

- A subclass does not inherit constructors or *private* members of the superclass. However, the superclass constructors are still available to be called from the subclass, and the *private* fields of the superclass are implemented as fields of the subclass object.

- To access *private* fields of the superclass, the subclass needs to call the accessor and mutator methods provided by the superclass.
- To call the constructor of the superclass, the subclass constructor uses the following syntax:

  
  ```
  super( argument list );
  ```

  Description

  If used, this statement must be the first statement in the subclass constructor.
- A subclass can override an inherited method by providing a new version of the method. The new method's API must be identical to the inherited method. To call the inherited version of the method, the subclass uses the *super* object reference using the following syntax:

  
  ```
  super.methodName( argument list )
  ```

  Description
- Any field declared using the *protected* access modifier is inherited by the subclass. As such, the subclass can directly access the field without calling its accessor or mutator method.
- An *abstract* class can be used to specify APIs for methods that subclasses should implement. An *abstract* class cannot be used to instantiate objects. A class is declared to be *abstract* by including the *abstract* keyword in the class header.
- An *abstract* class typically has one or more *abstract* methods. An *abstract* method specifies the API of the method, but does not provide an implementation. The API of an *abstract* method is followed by a semicolon.
- When a subclass inherits from an *abstract* class, it can provide implementations for any, all, or none of the *abstract* methods. If the subclass does not implement all the *abstract* methods of the superclass, then the subclass must

also be declared as *abstract*. If, however, the subclass implements all the *abstract* methods in the superclass and is not declared *abstract*, then the class is not *abstract* and we can instantiate objects of that subclass.

- Polymorphism simplifies the processing of various objects in a hierarchy by allowing us to use the same method call for any object in the hierarchy. We assign an object reference of a subclass to a superclass reference, then make the method call using the superclass object reference. At run time, the JVM determines to which class in the hierarchy the object actually belongs and calls the appropriate version of the method for that class.
- Interfaces allow a class to inherit behavior from multiple sources. Interface members can be classes, constants, *abstract* methods, *default* methods, *private* or *public* non-*abstract* *static* methods, *private* non-*static* non-*abstract* methods, or other interfaces.
- To define an interface, use the following syntax:

```
accessModifier interface InterfaceName
{
  // body of interface
}
```

Description

- To use an interface, a class header includes the *implements* keyword and the name of the interface, as in the following syntax:

```
accessModifier class ClassName implements InterfaceName
```

Description

- A class that implements an interface must provide full implementations of any *abstract* methods, and can either accept or override any *default* methods.
- To specify that a subclass both inherits from a superclass and uses an interface, a class header includes both the *extends* and the *implements* keywords as in the syntax that follows:

```
accessModifier class ClassName extends SuperclassName
                               implements Interface1, Interface2, ...
```

Description

10.10 Exercises, Problems, and Projects

10.10.1 Multiple Choice Exercises

1. The *extends* keyword applies to
    - a class inheriting from another class.
    - a variable.
    - a method.
    - an expression.

6. A Java class can inherit from two or more classes.
    - true
    - false

9. In Java, multiple inheritance is implemented using the concept of
    - an interface.
    - an *abstract* class.
    - a *private* class.

13. Which of the following is inherited by a subclass?
    - all instance variables and methods
    - *public* instance variables and methods only
    - *protected* instance variables and methods only
    - *protected* and *public* instance variables and methods

18. What Java keyword is used in a class header when a class is defined as inheriting from an interface?
    - *inherits*
    - *includes*

- *extends*
- *implements*

23. A Java class can implement one or more interfaces.

    - true
    - false

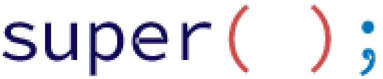
26. How do you instantiate an object from an *abstract* class?

    - With any constructor.
    - With the default constructor only.
    - You cannot instantiate an object from an *abstract* class.

30. When a class overrides a method, what object reference is used to call the method inherited from the superclass?

    - *inherited*
    - *super*
    - *class*
    - *methodName*

35. Where should the following statement be located in the body of a subclass constructor?



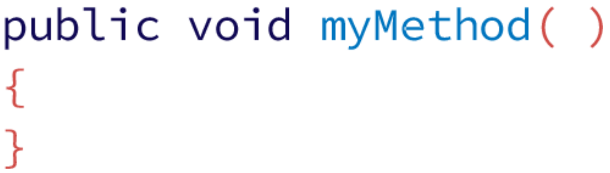
```
super( );
```

    - It should be the last statement.
    - It should be the first statement.
    - It can be anywhere.

39. If a class contains an *abstract* method, then

    - the class must be declared *abstract*.
    - the class is not *abstract*.
    - the class may or may not be *abstract*.
    - all of the above

44. What can you tell about the following method?



```
public void myMethod( )
{
}
```

Description

- This method is *abstract*.
- This method is not *abstract*.

10.10.2 Reading and Understanding Code

For Questions 12 to 20, consider the following three classes:

```
public class A

{
  private int number;
  protected String name;
  public double price;

  public A( )
  {
   System.out.println( "A( ) called" );
  }

  private void foo1( )
  {
   System.out.println( "A version of foo1( ) called" );
  }

  protected int foo2( )
  {
   System.out.println( "A version of foo2( ) called" );
   return number;
  }

  public String foo3( )
  {
   System.out.println( "A version of foo3( ) called" );
   return "Hi";
  }
}
public class B extends A
{
 private char service;
 public B( )
 {
   super( );
   System.out.println( "B( ) called" );
 }

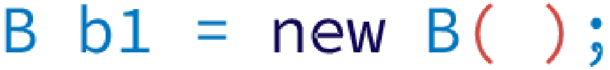
 public void foo1( )
 {
   System.out.println( "B version of foo1( ) called" );
 }

 protected int foo2( )
 {
   int n = super.foo2( );
   System.out.println( "B version of foo2( ) called" );
   return ( n + 5 );
 }
 public String foo3( )
 {
   String temp = super.foo3( );
   System.out.println( "B version of foo3( )" );
   return ( temp + " foo3" );
  }
}

public class C extends B
{
  public C( )
  {
   super( );
   System.out.println( "C( ) called" );
  }
  public void foo1( )
  {
   System.out.println( "C version of foo1( ) called" );
  }
}
```

Description

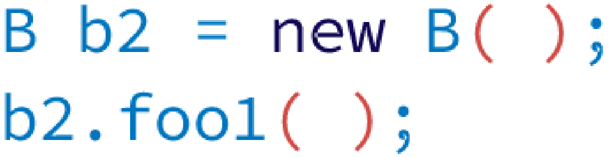
1. Draw the UML diagram for the class hierarchy.
2. What fields and methods are inherited by which class?
3. What fields and methods are not inherited?
4. What is the output of the following code sequence?



```
B b1 = new B( );
```

Description

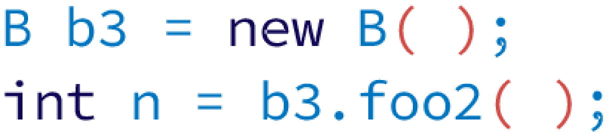
5. What is the output of the following code sequence?



```
B b2 = new B( );
b2.foo1( );
```

Description

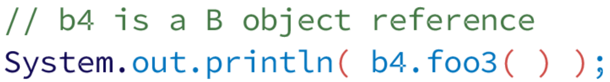
6. What is the output of the following code sequence?



```
B b3 = new B( );
int n = b3.foo2( );
```

Description

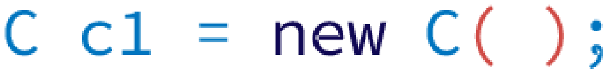
7. What is the output of the following code sequence?



```
// b4 is a B object reference
System.out.println( b4.foo3( ) );
```

Description

8. What is the output of the following code sequence?



```
C c1 = new C( );
```

Description

9. What is the output of the following code sequence?

```
// c2 is a C object reference
c2.foo1( );
```

Description

10.10.3 Fill In the Code

For Questions 21 to 25, consider the following class *F* and the interface *I*:

```
public class F
{
 private String first;
 protected String name;

 public F( )
 { }

public F( String first, String name )
{
  this.first = first;
  this.name = name;
}

public String getFirst( )
{
 return first;
}
public String getName( )
{
 return name;
}
public String toString( )
{
 return  "first: " + first + "\tname: " + name ;
}
public boolean equals( Object f )
{
 if ( ! ( f instanceof F ) )
     return false;
 else
 {
     F objF = ( F ) f;
     return( first.equals( objF.first ) && name.equals( objF.name ) );
  }
 }
}
public interface I
{
  String TYPE = "human";
 int age( );
}
```

Description

1. The *G* class inherits from the *F* class. Code the class header of the *G* class.

```
// your code goes here
```

2. Inside the *G* class, which inherits from the *F* class, declare a *private* instance variable for the middle initial and code a constructor with three parameters, calling the constructor of the *F* class and assigning the third parameter, a *char*, to the new instance variable.

```
// your code goes here
```

3. Inside the *G* class, which inherits from the *F* class, code the *toString* method, which returns a printable representation of a *G* object reference.

```
// your code goes here
```

4. Inside the *G* class, which inherits from the *F* class, code the *equals* method, which compares two *G* objects and returns *true* if they have identical instance variables; *false* otherwise.

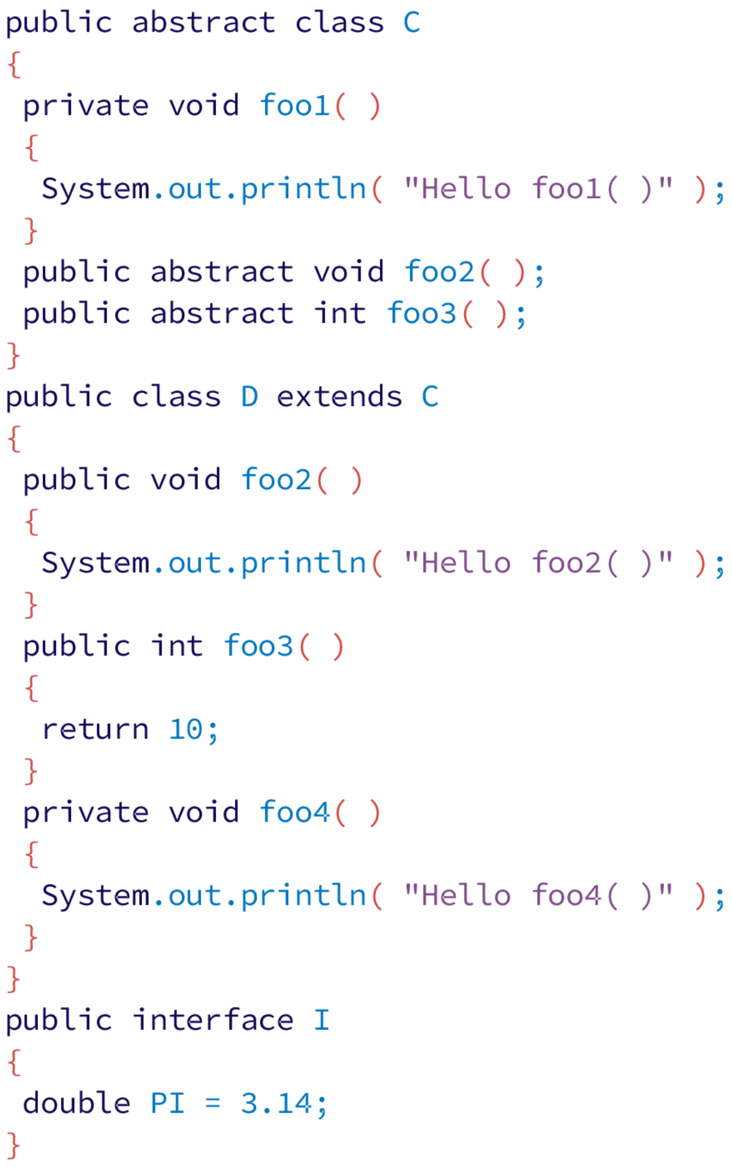
```
// your code goes here
```

5. The *K* class inherits from the *F* class and the *I* interface; code the class header of the *K* class.

```
// your code goes here
```

10.10.4 Identifying Errors in Code

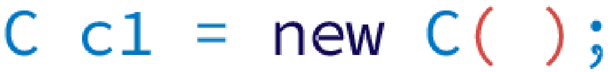
For Questions 26 to 31, consider the following two classes, *C* and *D*, and interface *I*:



```
public abstract class C
{
 private void foo1( )
 {
  System.out.println( "Hello foo1( )" );
 }
 public abstract void foo2( );
 public abstract int foo3( );
}
public class D extends C
{
 public void foo2( )
 {
  System.out.println( "Hello foo2( )" );
 }
 public int foo3( )
 {
  return 10;
 }
 private void foo4( )
 {
  System.out.println( "Hello foo4( )" );
 }
}
public interface I
{
 double PI = 3.14;
}
```

Description

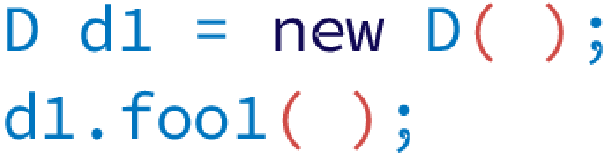
1. Where is the error in this code sequence?



```
C c1 = new C( );
```

Description

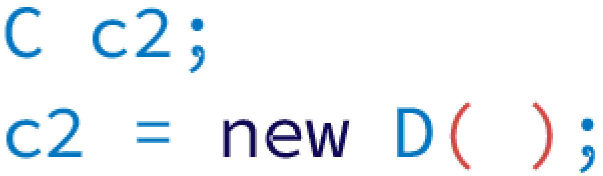
2. Where is the error in this code sequence?



```
D d1 = new D( );
d1.foo1( );
```

Description

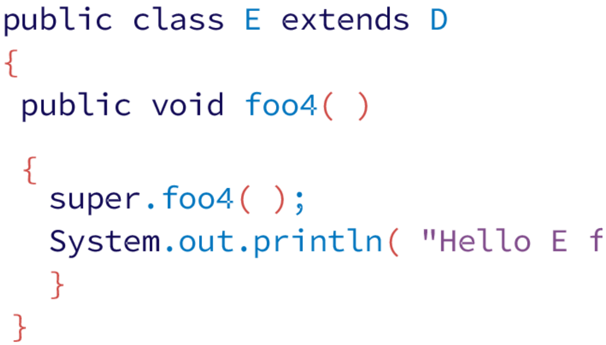
3. Is there an error in this code sequence? Why or why not?



```
C c2;
c2 = new D( );
```

Description

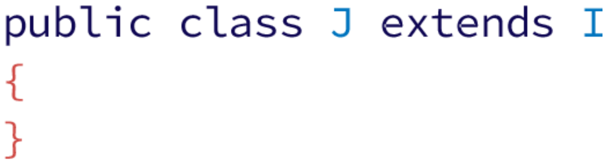
4. Where is the error in this new class?



```
public class E extends D
{
 public void foo4( )
 {
   super.foo4( );
   System.out.println( "Hello E f
   }
 }
```

Description

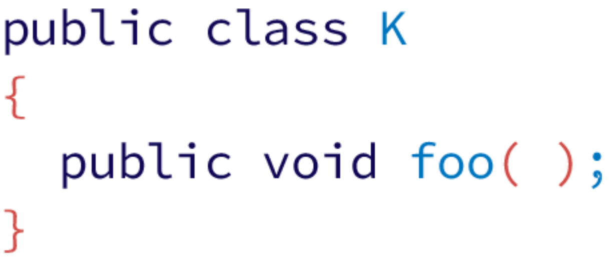
5. Where is the error in this class?



```
public class J extends I
{
}
```

Description

6. Where is the error in this class?



```
public class K
{
   public void foo( );
}
```

Description

10.10.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

For questions 32 to 35, explain what the problem is and how to fix it.

1. You coded the following class:

```
public class Z extends String, Integer
{
}
```

Description

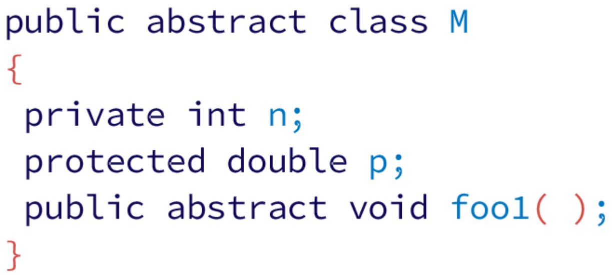
When you compile, you get the following message:

```
Z.java:1: error: '{' expected
public class Z extends String, Integer
                             ^
1 error
```

Description

Explain what the problem is and how to fix it.

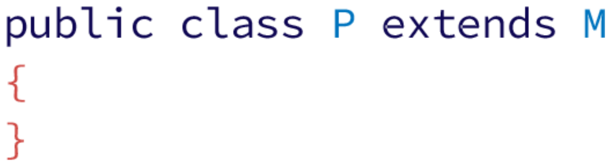
For Exercises 33 to 35, consider the following class:



```
public abstract class M
{
 private int n;
 protected double p;
 public abstract void foo1( );
}
```

Description

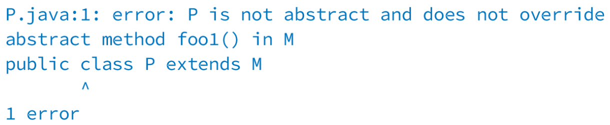
2. You coded the following class:



```
public class P extends M
{
}
```

Description

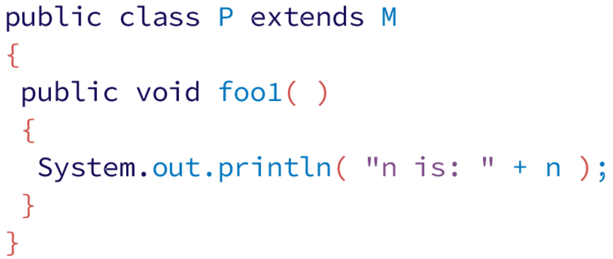
When you compile, you get the following message:



```
P.java:1: error: P is not abstract and does not override
abstract method foo1() in M
public class P extends M
       ^
1 error
```

Description

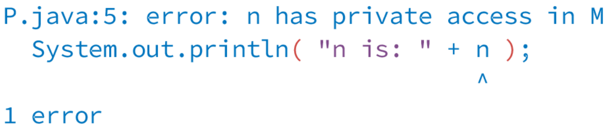
3. You coded the following class:



```
public class P extends M
{
 public void foo1( )
 {
  System.out.println( "n is: " + n );
 }
}
```

Description

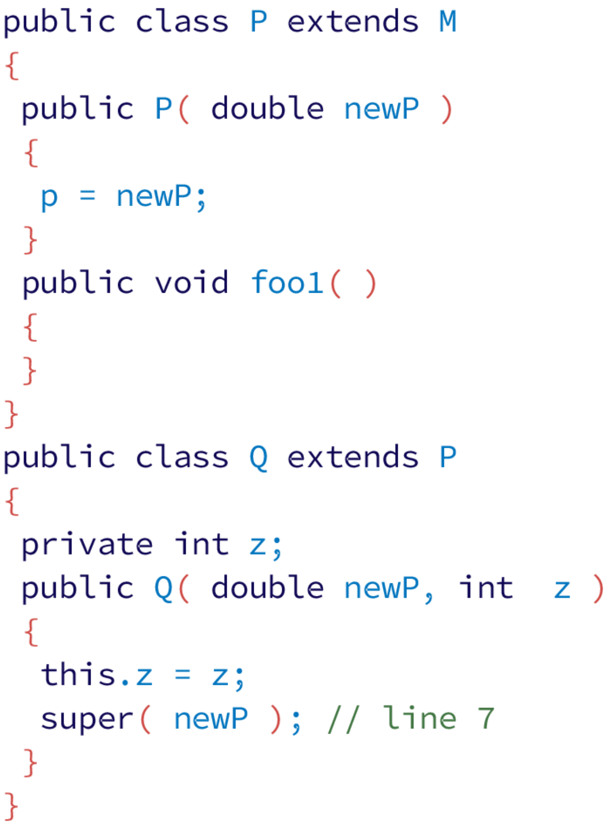
When you compile, you get the following message:



```
P.java:5: error: n has private access in M
  System.out.println( "n is: " + n );
                                 ^
1 error
```

Description

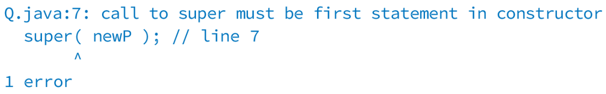
4. You coded the following classes:



```
public class P extends M
{
 public P( double newP )
 {
  p = newP;
 }
 public void foo1( )
 {
 }
}
public class Q extends P
{
 private int z;
 public Q( double newP, int  z )
 {
  this.z = z;
  super( newP ); // line 7
 }
}
```

Description

When you compile, you get the following message:



```
Q.java:7: call to super must be first statement in constructor
  super( newP ); // line 7
       ^
1 error
```

Description

10.10.6 Write a Short Program

For Exercises 36 to 40, consider the following class:

```
   public class Game
   {
    private String description;
    public Game( String description )
    {
     setDescription( description );
    }
    public String getDescription( )
    {
     return description;
    }
   public void setDescription( String description )
   {
    this.description = description;
   }
    public String toString( )
   {
    return "description: " + description ;
   }
  }
```

Description

1. Write a class encapsulating a PC-based game, which inherits from *Game*. A PC-based game has the following additional attributes: the minimum megabytes of RAM needed to play the game, the number of megabytes needed on the hard drive to install the game, and the minimum GHz performance of the CPU. Code the constructor and the *toString* method of the new class. You also need to include a client class to test your code.
2. Write a class encapsulating a board game, which inherits from *Game*. A board game has the following additional attributes: the number of players and whether the game can end in a tie. Code the constructor and the *toString*

method of the new class. You also need to include a client class to test your code.

3. Write a class encapsulating a sports game, which inherits from *Game*. A sports game has the following additional attributes: whether the game is a team or individual game, and whether the game can end in a tie. Code the constructor and the *toString* method of the new class. You also need to include a client class to test your code.
4. Write a class encapsulating a trivia game, which inherits from *Game*. A trivia game has the following additional attributes: the ultimate money prize and the number of questions that must be answered to win the ultimate money. Code the constructor and the *toString* method of the new class. You also need to include a client class to test your code.
5. Write a class encapsulating a board game, which inherits from *Game*. A board game has the following additional attributes: the minimum number of players, the maximum number of players, and whether there is a time limit to finish the game. Code the constructor and the *toString* method of the new class. You also need to include a client class to test your code.

   For Exercises 41 to 45, consider the following class:

```
public class Store
{
 public final double SALES_TAX_RATE = 0.06;
 private String name;
 public Store( String name )
 {
  setName( name );
 }
 public String getName( )
 {
  return name;
 }
 public void setName( String name )
 {

  this.name = name;
 }
 public String toString( )
 {
  return ( "name: " + name );
 }
}
```

Description

6. Write a class encapsulating a web store, which inherits from *Store*. A web store has the following additional attributes: an Internet address and the programming language in which the website was written. Code the constructor and the *toString* method of the new class. You also need to include a client class to test your code.
7. Write a class encapsulating a music store, which inherits from *Store*. A music store has the following additional attributes: the number of titles it offers and its address. Code the constructor and the *toString* method of the new class. You also need to include a client class to test your code.
8. Write a class encapsulating a bike store, which inherits from *Store*. A bike store has the following additional

attributes: the number of bicycle brands that it carries and whether it sponsors a bike club. Code the constructor and the *toString* method of the new class. You also need to include a client class to test your code.

9. Write a class encapsulating a grocery store, which inherits from *Store*. A grocery store has the following additional attributes: annual revenues and whether it is an independent store or part of a chain. Code the constructor and the *toString* method of the new class; also code a method returning the annual taxes paid by the store. You also need to include a client class to test your code.
10. Write a class encapsulating a restaurant, which inherits from *Store*. A restaurant has the following additional attributes: how many people are served every year and the average price per person. Code the constructor and the *toString* method of the new class; also code a method returning the average taxes per year. You also need to include a client class to test your code.

10.10.7 Programming Projects

1. Write a superclass encapsulating a rectangle. A rectangle has two attributes representing the width and the height of the rectangle. It has methods returning the perimeter and the area of the rectangle. This class has a subclass, encapsulating a parallelepiped, or box. A parallelepiped has a rectangle as its base, and another attribute, its length; it has two methods that calculate and return its area and volume. You also need to include a client class to test these two classes.
2. Write a superclass encapsulating a circle; this class has one attribute representing the radius of the circle. It has

methods returning the perimeter and the area of the circle. This class has a subclass, encapsulating a cylinder. A cylinder has a circle as its base, and another attribute, its length; it has two methods, calculating and returning its area and volume. You also need to include a client class to test these two classes.

3. Write an *abstract* superclass encapsulating a shape: A shape has two *abstract* methods: one returning the perimeter of the shape, another returning the area of the shape. It also has a constant field named PI. This class has two non-*abstract* subclasses: one encapsulating a circle, and the other encapsulating a rectangle. A circle has one additional attribute, its radius. A rectangle has two additional attributes, its width and height. You also need to include a client class to test these two classes.
4. Write an *abstract* superclass encapsulating a vehicle: A vehicle has two attributes: its owner's name and its number of wheels. This class has two *non-abstract* subclasses: one encapsulating a bicycle, and the other encapsulating a motorized vehicle. A motorized vehicle has the following additional attributes: its engine volume displacement, in liters; and a method computing and returning a measure of horsepower—the number of liters times the number of wheels. You also need to include a client class to test these two classes.
5. Write an *abstract* superclass encapsulating some food; it has two attributes: its description and the number of calories per serving. It also has an *abstract* method taking a number of servings as a parameter and returning the number of calories. This class has two non-*abstract* subclasses: one encapsulating a liquid food (such as a

drink, for instance), and the other encapsulating a fruit. A liquid food has an additional attribute: its viscosity. A fruit has an additional attribute: its season. You also need to include a client class to test these two classes.

6. Write an *abstract* superclass encapsulating a college applicant: A college applicant has two attributes: the applicant's name and the college the applicant is applying to. This class has two non-*abstract* subclasses: one encapsulating an applicant for undergraduate school, and the other encapsulating an applicant for graduate school. An applicant for undergraduate school has two additional attributes: an SAT score and a GPA. An applicant for graduate school has one additional attribute: the college of origin. It also has a method that returns “from inside” if the college of origin is the same as the college applied to; otherwise, it returns “from outside.” You also need to include a class to test these two classes.
7. Write an *abstract* superclass encapsulating a vacation: A vacation has two attributes: a budget and a destination. It has an *abstract* method returning by how much the vacation is over or under budget. This class has two non--*abstract* subclasses: one encapsulating an all-inclusive vacation, and the other encapsulating a vacation bought piecemeal. An all-inclusive vacation has three additional attributes: a brand (for instance ClubMed®); a rating, expressed as a number of stars; and a price. A piecemeal vacation has two additional attributes: a set of items (hotel, meal, airfare, …), and a set of corresponding costs. You also need to include a class to test these two classes.
8. Write an *abstract* superclass encapsulating a part, with two attributes: the part number, and a budget cost for it. This

class has two non-*abstract* subclasses: one encapsulating a self-manufactured part, and the other encapsulating an outsourced part. A self-manufactured part has a cost and a drawing number; it also has a method returning whether it is over budget or under budget. An outsourced part has a set of suppliers, each with a price for the part. It also has a method to retrieve the lowest-cost supplier for a part and the corresponding cost. You also need to include a class to test these two classes.

9. Write an *abstract* superclass encapsulating a number; this class has one *abstract* void method: *square*. This class has two non-*abstract* subclasses: one encapsulating a rational number, and the other encapsulating a complex number. A rational number is represented by two integers, the numerator and the denominator of the rational number. A complex number is represented by two real numbers, the real part and the complex part of the complex number. You also need to include a class to test these two classes.
10. Define an *abstract UtilityCustomer* class that has one instance variable, an account number, and an *abstract* method, *calculateBill*, that returns the bill amount as a *double*. Also define the constructor, accessors, mutators, and a *toString* method that outputs the account number. Define a *GasCustomer* class that inherits from the *UtilityCustomer* class, and adds an instance variable *cubicMetersUsed* and a constant for the price of gas per cubic meter. Also define an *ElectricCustomer* class that also inherits from the *UtilityCustomer* class and adds a *kWattHourUsed* instance variable along with two constants for the price of electricity per kilowatt hour, plus a flat power delivery fee ($30) that is added to every bill. For each subclass, define the constructor, accessor, and mutator for

its instance variable, a *toString* method, which calls the *toString* method of the *UtilityCustomer* class, and an implementation for the *calculateBill* method. Create a client that instantiates several *GasCustomer* and *ElectricCustomer* objects, adds them to an *ArrayList* of *UtilityCustomer* objects, and then using polymorphism, steps through the *ArrayList*, calling the *calculateBill* method and outputting the bill amount for each customer.

10.10.8 Technical Writing

1. In a large organization, programmers develop a library of classes as they work on various projects. Discuss, in such an environment, how inheritance can be helpful in reusing code and therefore saving time.
2. Other programming languages allow multiple inheritance; that is, a class can inherit from several classes. In Java, a class can extend only one class, but can implement several interfaces. Discuss potential problems that can arise in other programming languages that allow inheritance from multiple classes.

10.10.9 Group Project (for a group of 1, 2, or 3 students)

1. Design and code a program that allows the user to select a drawing style for a graphics program. The styles should be black and white, grayscale, or inverted color. To do this, define a *DrawingStyle* interface with these methods: *setColor* and *setOutline*. Both methods accept a *GraphicsContext* object and a *Color*, convert the color appropriately, and call the *GraphicsContext* methods *setFill* or *setStroke*, respectively, with the new color value.

For each style, define the following classes that implement the *DrawingStyle* interface: *BlackAndWhite*, *Grayscale*, and *InvertColor*.

In the client class, define a *DrawingStyle* instance variable. Prompt the user for the desired style, and assign a reference to an object of the appropriate class that implements the *DrawingStyle* interface. The application should then call *setColor* and *setOutline* to set the fill or stroke color using a reference to the *DrawingStyle* object. Make a drawing of your choice using the selected drawing style.

Hint: Look up the *grayscale* and *invert* methods of the *Color* class. The *BlackAndWhite* class can simply convert any color whose average value for the red, green, and blue components is >= 0.5 to white; otherwise, it converts the color to black.

Introduction

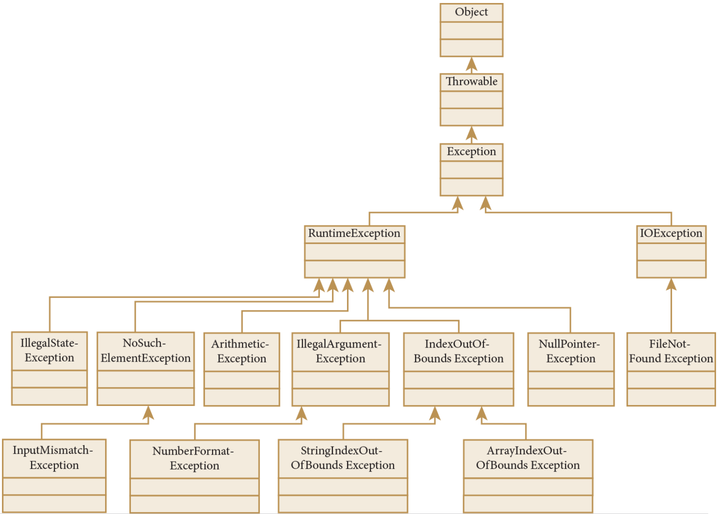
Programs often use existing data accumulated by an organization, such as a university, a government, or a corporation. Typically, the volume of data is significant, making data entry through the keyboard impractical.
Furthermore, these large amounts of data typically reside in two types of storage:

- disk files
- databases

Working with databases is beyond the scope of this book. In most of this chapter, we concentrate on reading from and writing to files.

But there is a prerequisite to all this: understanding the concept of exceptions, their associated classes, and exception handling.



Object
Throwable
Exception
RuntimeException
IOException
IllegalState-Exception
NoSuch-ElementException
Arithmetic-Exception
IllegalArgument-Exception
IndexOutOf-Bounds Exception
NullPointer-Exception
FileNot-Found Exception
InputMismatch-Exception
NumberFormat-Exception
StringIndexOut-OfBounds Exception
ArrayIndexOut-OfBounds Exception

```
Message: data.txt (The system cannot find the file specified)

toString( ): java.io.FileNotFoundException: data.txt (The system cannot
find the file specified)

        at EchoFileData.main(EchoFileData.java:16)
```

11.1 Simple Exception Handling

By now we have discovered that sometimes our program doesn’t work, even though we didn’t get any compiler errors. At run time, logic errors can surface. For example, we might attempt to divide an integer by 0 or try to access the 11th element in a 10-element array. Java is a robust language and does not allow these “illegal” operations to occur unnoticed.

These illegal operations generate **exceptions**. Some exceptions are generated by the Java Virtual Machine, while others are generated by constructors or other methods. For example, a method might generate an exception when it detects an attempted illegal operation or an illegal parameter.

By default, when an exception is generated in an application that does not have a graphical user interface, the program will terminate. In many cases, however, we can attempt to recover from the exception and continue running the program. This is called **handling the exception**. For the programmer to handle an exception, Java provides two tools:

- exception classes
- the *try*, *catch*, and *finally* blocks

The *Exception* class is the superclass of all exception classes, which encapsulate specific exceptions such as integer division by 0, attempting to access an out-of-bounds array index, unsuccessfully converting a *String* to a number, using a *null* object reference to call a method, trying to open a file that does not exist, and others.

Figure 11.1 is an inheritance hierarchy showing only a few of the Java exception classes. The *Exception* class and *RuntimeException* and its subclasses are in the *java.lang* package. The *IOException* class and its subclass, *FileNotFoundException*, are in the *java.io* package.

Figure 11.1 Inheritance Hierarchy for Various *Exception* Classes

Description

We want to avoid situations when an exception occurs and abruptly terminates the execution of our program. Java provides *try* and *catch* blocks to allow us to handle exceptions so that our code can continue to run. We put the code that might generate an exception inside the *try* block, and we put the code to recover from the exception inside a *catch* block. If an exception is thrown by the code inside the *try* block, then execution will jump to the *catch* block, where we provide code to handle that exception. If nothing illegal happens in the *try* block, the code in the *catch* block will be skipped.

The minimum syntax for a *try* and *catch* block is as follows:

```
try
{
  // code that might generate an exception
}
catch ( ExceptionClass exceptionObjRef )
{
  // code to recover from the exception
}
```

The curly braces are required for both the *try* body and the *catch* body even if the bodies have only one statement, or even no statements.

COMMON ERROR TRAP

Omitting curly braces around the *try* and *catch* blocks will generate a compiler error. A *catch* clause listing several *Exception* classes as parameters will also generate a compiler error. Use multiple *catch* blocks instead.

Any variable defined within the *try* block is local to that block; that is, the variable cannot be referenced after the *try* block, not even in the *catch* block. Note that the *ExceptionClass* parameter of the *catch* clause specifies one and only one *ExceptionClass*. Listing zero or two or more *ExceptionClasses* in the *catch* clause will generate a compiler error.

Java distinguishes between two types of exceptions:

- unchecked, those that are subclasses of *Error* or *RuntimeException*
- checked, any other exception class

An **unchecked exception**, such as an *ArithmeticException* caused by attempting integer division by 0, a *NumberFormatException*, or a *NullPointerException*, does not have to be handled with a *try* and *catch* block. In other words, if we omit the *try* and *catch* blocks, our code will compile without an error. If one of these unchecked exceptions is generated at run time, however, the JVM will catch it and print output similar to that shown in Figure 11.2 (discussed later in this section).

Figure 11.2 Output of Example 11.1

Description

Code that could generate a **checked exception**, such as an *IOException*, must be coded within a *try* block. Optionally, the method header can acknowledge that the checked exception could occur by using a *throws* clause. This is required; otherwise, the program will not compile. Thus, when we perform I/O on a file, our code must deal with a potential *IOException*.

In the *catch* block, we can use the *Exception* parameter as an object reference to get more information about what caused the exception. Table 11.1 shows three methods inherited by the *Exception* classes.

Useful Methods of Exception Classes

Methods of Exception Classes

Return value	**Method name and argument list**
`String`	`getMessage( )` returns a message indicating the cause of the exception
`String`	`toString( )` returns a *String* containing the exception class name and a message indicating the cause of the exception
`void`	`printStackTrace( )` prints the line number of the code that caused the exception, along with the sequence of method calls leading up to the exception

Description

We demonstrate these three methods, as well as how to use *try* and *catch* blocks to detect and handle an exception if it occurs, in **Example 11.1**. When we want to read data from a file, we first must open the file for reading. At line 15, we declare and instantiate a *File* object for a file named *data.txt* located in the current folder. At line 16, we declare and instantiate a

Scanner object so we can read from the input stream represented by that *File* object. The *Scanner* constructor, whose API is shown below, *throws* a *FileNotFoundException* if the file is not found.

Example 11.1 Using *try* and *catch* Blocks

```
 1 /* Reading a Text File
 2    Anderson, Franceschi
 3 */
 4
 5 import java.io.File;
 6 import java.io.FileNotFoundException;
 7 import java.util.Scanner;
 8
 9 public class EchoFileData
10 {
11   public static void main( String [ ] args )
12   {
13     try
14     {
15       File inputFile = new File( "data.txt" );
16       Scanner file = new Scanner( inputFile );
17
18       while ( file.hasNextInt( ) )
19       {
20         int number = file.nextInt( );
21         System.out.println( number );
22       }
23     }
24     catch ( FileNotFoundException fnfe )
25     {
26       System.out.println( "Message: " + fnfe.getMessage( ) );
27       System.out.println( "\ntoString( ): " + fnfe + "\n" );
28       fnfe.printStackTrace( );
29     }
30   }
31 }
```

Description

```
public Scanner( File source ) throws FileNotFoundException
```

Description

The *FileNotFoundException* is a checked exception. Thus, we need to place the code that can generate that exception (line 16) inside a *try* block (lines 13–23). At lines 24–29, we use a *catch* block to handle the exception if it occurs. Note that there are other exceptions that can be thrown in this program.

The *File* constructor, as well the *hasNextInt* and *nextInt* methods of the *Scanner* class, can throw exceptions; however, all those exceptions are unchecked exceptions and do not require the use of *try/catch* blocks.

When the program runs, if there is no file named *data.txt* in the current folder, the *try* block stops executing at line 16. Next, the *catch* block is executed, and we print the values from the *getMessage*, *toString*, and *printStackTrace* methods of the -*FileNotFoundException* class. Figure 11.2 shows the output of Example 11.1 when there is no file named *data.txt* in the current folder. As we can see, the only difference between the return values from the *getMessage* and *toString* methods is that the *toString* method returns the exception class name, as well as the message. The output of the *printStackTrace* method may look familiar. It is similar to a message that the JVM prints when an *ArithmeticException*, *StringIndexOutOfBoundsException*, or *ArrayIndexOutOfBoundsException* occurs when we do not have *try* and *catch* blocks.

11.2 Catching Multiple Exceptions

If the code in the *try* block might generate multiple types of exceptions, we can provide multiple *catch* blocks, one for each possible exception. When an exception is generated, the JVM searches the *catch* blocks in order. The first *catch* block with a parameter that matches the exception thrown will execute; any remaining *catch* blocks will be skipped.

Remember that subclass objects are also objects of their superclasses, so an exception will match any *catch* block for an exception that names any of its superclasses. For example, a *NumberFormatException* will match a *catch* block with a *RuntimeException* parameter, and all exceptions will match a *catch* block with an *Exception* parameter. Therefore, when coding several *catch* blocks, put the *catch* blocks for the specialized exceptions first, followed by more general exceptions.

SOFTWARE ENGINEERING TIP

Arrange *catch* blocks to handle the more specialized exceptions first, followed by more general exceptions.

Furthermore, after a *try* block and its associated *catch* blocks, we may optionally add a *finally* block, which will always be executed, whether an exception occurred or not. In the *finally* block, we can include some clean-up code. We will demonstrate a *finally* block when we read from a file later in this chapter.

Here is the syntax for using a *try* block, several *catch* blocks, and a *finally* block:

```
try
{
   // code that might generate an exception
}
catch ( Exception1Class e1 )
{
   // code to handle an Exception1Class exception
}
...
catch ( ExceptionNClass eN )
{
   // code to handle an ExceptionNClass exception
}
finally
{
   // code to execute regardless of whether an exception occurs
}
```

Description

Again, the curly braces around the various blocks are required, whether these blocks contain zero, one, or more statements.

SOFTWARE ENGINEERING TIP

Whenever possible, use a simple *if/else* statement to detect an unchecked exception, rather than *try* and *catch* blocks. This will improve the performance of your code.

Having provided several examples of exceptions, we must also consider this: Not every problem needs to be addressed by generating an exception. As a matter of fact, generating and handling exceptions considerably slows down execution of our code due to the processing overhead. Often, for example when using Java’s I/O classes, we will have no choice but to use *try* and *catch* blocks. Sometimes, however, we can use a simple *if/else* statement instead of *try* and *catch* blocks. For example, we can test if the value of the divisor is not zero before attempting a division, rather than placing the code in a *try* block and catching an *ArithmeticException*.

How do we know if a constructor or a method *throws* an exception and what type of exception it *throws*? As always, our best source of information is the Java Class Library on Oracle’s Java website. After we have identified a constructor or a method that we would like to use, we simply look at its description in order to determine whether it *throws* any exceptions, and, if so, which ones.

REFERENCE POINT

Consult the Oracle Java Class Library to see if a constructor or a method *throws* an exception and, if so, what type of exception.

11.3 Reading Text Files Using *Scanner*

Java supports two file types, text and binary. In text files, data is stored as characters; in binary files, data is stored as raw bytes. Different classes are used for writing and reading each file type. The type of a file is determined when the file is written and depends on which classes were used to write to the file. Thus, to read from an existing file, we must know the file's type in order to select the appropriate classes.

In this section, we concentrate on text files.

As we have seen from Example 11.1, the *Scanner* class can be used to read from a text file. If the file is not found, the *Scanner* constructor throws a *FileNotFoundException*. More exceptions can be thrown by *Scanner* methods while reading the file.

Table 11.2 shows some constructors of the *Scanner* and *File* classes and methods of the *Scanner* class for reading from a file, as well as the exceptions that each method can throw.

Useful Methods of the *Scanner* and *File* Classes for Reading from a File

File Constructor	**Exceptions Thrown**
`File( String pathname )` constructs a *File* object with the *pathname* file name so that the file name is platform-independent	`NullPointerException`

***Scanner* Constructor and Methods**	**Exceptions Thrown**
`Scanner( File file )` constructs a *Scanner* object for reading from a file	`FileNotFoundException`

Return Value	**Method Name and Argument List**	**Exceptions Thrown**
`boolean`	`hasNext( )` returns *true* if there is another token in the input stream	`Both methods throw an IllegalStateExceptio`
`boolean`	`hasNextLine( )` returns *true* if there is another line or line separator in the input stream	
`boolean`	`hasNextlnt( )`	`All these methods throw an IllegalStateExceptio`
`boolean`	`hasNextDouble( )`	
`boolean`	`hasNextFloat( )` ... returns *true* if there is another token in the input stream of the specified data type	
`String`	`next( )` returns the next token	`Both methods throw`

	in the input stream as a *String*	`NoSuchElementExceptio` `IllegalStateExceptio`
`String`	`nextLine( )` returns the remainder of the line as a *String*. Positions the pointer to the next line.	

`int`	`nextInt( )`	`All these methods throw InputMismatchExceptio`
		`NoSuchElementExceptio`
		`IllegalStateExceptio`

`double`	`nextDouble( )`	
`float`	`nextFloat( )` ... returns the next token in the input stream as the specified data type	
`void`	`close( )` releases the resources associated with an open input stream	None

Description

In **Example 11.2**, we read a text file named *movies.txt*, which contains titles of classic movies and the movies' running times in minutes. Each movie occupies two lines in the file: the title on one line and the running time on the following line. Each line in the file, including the last line, is terminated by a *newline* character. In this example, we simply read the movie titles and running times and echo them to the console. However, we could read this file to find the longest or shortest movie, or to instantiate *Movie* objects to be stored in an *ArrayList* or other data structure for further processing.

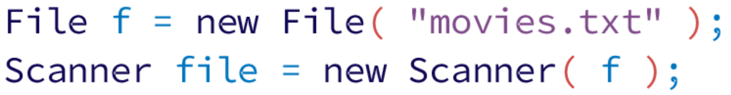
Example 11.2 Reading from a Text File

```
 1 /** Classic Movies - Reading from a text file
 2 *   Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6 import java.io.File;
 7 import java.util.NoSuchElementException;
 8 import java.io.FileNotFoundException;
 9
10 public class ClassicMovies
11 {
12  public static void main( String [ ] args )
13  {
14   try ( Scanner file = new Scanner( new File( "movies.txt" ) ) )
15   {
16    while ( file.hasNext( ) ) // test for the end of the file
17    {
18     String movieTitle = file.nextLine( );
19
20     if ( ! file.hasNextInt( ) )
21     {
22      System.out.println( "Invalid file format" );
23      String invalidData = file.nextLine( ); // skip the line
24     }
25     else
26     {
27      int runningTime = file.nextInt( );
28      String newLine = file.nextLine( ); // read newline character
29      System.out.println( movieTitle + ", "
30               + runningTime + " minutes" );
31     }
32    }
33   }
34
35   catch ( FileNotFoundException fnfe )
36   {
37    System.out.println( "Unable to find movies.txt, exiting" );
38   }
39
40   catch ( NoSuchElementException nsee )
41   {
42    System.out.println( "Attempt to read past the end of the file" );
43   }
44  }
45 }
```

Description

Lines 7–8 import the *NoSuchElementException* and *FileNotFoundException* classes. The *IllegalStateException* class does not need to be imported because it is in the *java.lang* package. Line 14 instantiates a *Scanner* object from a *File* object, passing the name of the file to be read, *movies.txt*, as the argument to the *File* constructor.

The *File* object is used only as the argument of the *Scanner* constructor; it is not used anywhere else in the program. In this case, instead of creating a *File* object reference, many programmers prefer to use an anonymous *File* object as the argument of the *Scanner* constructor. In other words, instead of writing the following two statements:



```
File f = new File( "movies.txt" );
Scanner file = new Scanner( f );
```

Description

we use the following single statement:

```
Scanner file = new Scanner( new File( "movies.txt" ) );
```

Description

It is a matter of preference as to which code we use.

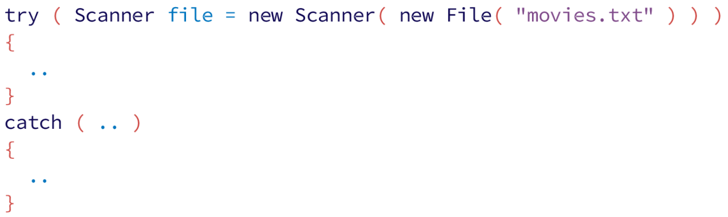
When we associate a file with an input stream or output stream, we are **opening the file**. As we read the data in a file, a **file pointer** keeps track of the next data to read. When we open the file, the file pointer is set to the beginning of the file. When we are finished with a file, we can call the *close* method (shown in Table 11.2) to release the resources associated with the file. Calling the *close* method is optional. When the program finishes executing, all of its resources are released, including the resources of any unclosed files. Nevertheless, it is good practice, in general, to call the *close* method, especially if we will be opening a number of files (or opening the same file multiple times). In contrast, the standard input stream (*System.in*), the standard output stream (*System.out*), and the standard error stream (*System.err*) are open when the program begins. They are intended to stay open and should not be closed.

SOFTWARE ENGINEERING TIP

Either use a *try*-with-resources statement or close files when you have finished processing their data. Do not close the standard input, output, or error devices.

At lines 14–33, we use a ***try*-with-resources** statement. A **resource** is an object reference, for example a *Scanner*, that should be closed after we no longer need it. A *try*-with-resources is a statement that declares one or more resources. Using a *try*-with-resources statement guarantees that the resource will be automatically closed at the end of the *try* block. If we did not use a *try*-with-resources statement at line 14, we would need to close the *Scanner* in the *finally* block to guarantee that it is closed. Closing the *Scanner* as the last statement of the *try* block would not guarantee that the *Scanner* is closed because if an exception occurs, the *try* block will not finish executing.

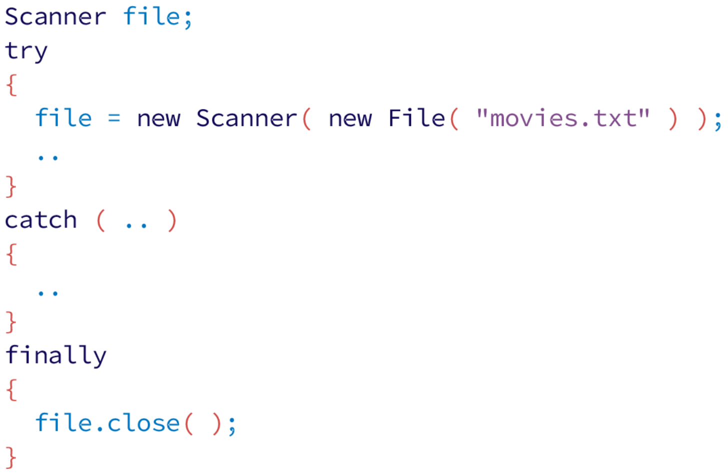
Thus, the following code:



```
try ( Scanner file = new Scanner( new File( "movies.txt" ) ) )
{
  ..
}
catch ( .. )
{
  ..
}
```

Description

is equivalent to:



```
Scanner file;
try
{
  file = new Scanner( new File( "movies.txt" ) );
  ..
}
catch ( .. )
{
  ..
}
finally
{
  file.close( );
}
```

Description

The *Scanner* constructor throws a *FileNotFoundException* if the file does not exist. We catch this exception at lines 35–38.

Since the program cannot continue without the file being open, we print a message to the user that we were not able to find the file and that the program is exiting. Thus, instead of facing a *FileNotFoundException* with a stack trace, the user now sees a friendly message explaining the problem.

If no exception is thrown, we begin to read the file. The *while* loop condition, at line 16, uses the *Scanner hasNext* method to test whether the file pointer has reached the end of the file. If not, *hasNext* returns *true*, and we execute the *while* loop body. Since the movie title could contain more than one word, we use the *nextLine* method to read the entire line (line 18).

We then test whether the next token in the file is an *int* (line 20). If not, then the running time is not a whole number. We output a message that the file format is invalid, then skip the line by using the *nextLine* method to read whatever data is on that line into the *String invalidData* (lines 22–23). Another option is to use a *try/catch* block to read the running time. With that option, calling the *nextInt* method to read the invalid data would generate an *InputMismatchException*, which we would need to handle. Given that exception handling results in additional processing overhead, our using the *hasNextInt* method of the *Scanner* class to test whether the file format is valid makes the code more efficient.

If the next token is an *int*, we read the running time using the *nextInt* method (line 27). At this point, it is worthwhile to discuss the difference between the *nextLine* method and the other *Scanner next…* methods (such as *next/nextInt/nextDouble*, etc.). The *nextLine* method reads any part of the line that has not already been read, including leading and trailing white space (spaces, tabs, and the *newline* character) and moves the file pointer to the next line. The *nextLine* method does not include the *newline* character in its returned *String*. In contrast, the *nextInt* method and its *next…* method counterparts skip leading white space, then read the next token on the line, stopping when trailing white space is encountered. That means that after we have read the running time using the *nextInt* method, the *newline* character is still in the input stream. If we then attempt to read the next movie title using the *nextLine* method, the *nextLine* method would instead read just the *newline* character that follows the running time and return an empty *String*. So on line 28, we insert an additional call to the *nextLine* method to remove that *newline* character from the input stream.

On lines 29–30, we echo the title and running time to the console.

We continue looping through the file until there is no more data to read.

An attempt to access a file after it has been closed generates an *IllegalStateException*. Because we use a *try*-with-resources statement, the *Scanner* will be closed after the last *catch* block. Thus, we cannot access the file after it has been closed and do not need to *catch* an *IllegalStateException*. If we attempt to read beyond the end of the file, the *nextLine* or *nextInt* methods will throw a *NoSuchElementException*. We catch this exception on lines 40–43, and output a message explaining the cause of the exception.

Let's assume the file *movies.txt* contains the data shown in **Figure 11.3**. When the program in Example 11.2 runs, it will produce the output shown in **Figure 11.4** if the file is found, and the output in **Figure 11.5** if the file is not found.

11.4 The *java.io* Package

In addition to the *Scanner* class in the *java.util* package, Java provides a number of classes in the *java.io* package for reading from files and for writing to files. We will use only a few of those classes here. **Table 11.3** describes a group of classes designed for data input.

Selected Input Classes

Input Classes

Class	**Description**
`Scanner`	Class to read and parse characters in text files
`InputStream`	*Abstract* superclass representing an input stream of raw bytes
`FileInputStream`	Input stream to read raw bytes of data from files
`ObjectInputStream`	Class to read/recover objects from a file written using *ObjectOutputStream*

Description

Figure 11.6 shows an inheritance hierarchy for the Java classes described in Table 11.3.

Figure 11.6 The Inheritance Hierarchy for Input Classes

Description

Table 11.4 describes a group of classes designed for data output, and **Figure 11.7** shows an inheritance hierarchy for Java output classes in Table 11.4.

Selected Output Classes

Output Classes

Class	**Description**
`Writer`	*Abstract* superclass for writing characters to output streams
`OutputStream`	*Abstract* superclass representing

	an output stream of raw bytes
`FileWriter`	Convenience class for writing characters to files
`PrintWriter`	Convenience class to output basic data types, *Strings*, and objects
`FileOutputStream`	Output stream to write raw bytes of data to files
`ObjectOutputStream`	Class to write objects to a file

```

11.5 Recovering from an Exception

In the next example, we read data from a file and use that data to draw a flag. **Figure 11.8** shows the contents of the *HungarianFlag.txt* file. We also show how to catch and recover from an exception; that is, how to enable our program to continue to run when an exception occurs. The data is organized in a similar manner, but it is simpler than what is used by the GIF run-length encoding algorithm:

Figure 11.8 The *HungarianFlag.txt* File

Description

- The first line is an integer storing the width of the flag.
- Each line thereafter contains four numbers. The first number, an integer, stores the number of consecutive pixels (as we go left to right on the flag image) of the same color; the next three numbers store the red, green, and blue coefficients of that color as *doubles* between 0 and 1.

The width of the Hungarian flag represented by our file is 300, it has 15,000 consecutive red pixels (i.e., 15,000 divided by 300, which is equal to 50, red lines), then 15,000 consecutive white pixels (i.e., 50 white lines), and 15,000 consecutive green pixels (i.e., 50 green lines).

Example 11.3 shows the *GIFDecoding* class. Its constructor accepts an already instantiated *Scanner* parameter and reads the data in the associated file into three instance variables: *width*, an *int*; *lengthList*, an *ArrayList* of *Integers*; and *colorList*, an *ArrayList* of *Color* references. The *lengthList* and *colorList* are parallel *ArrayLists*; that is, the color stored at a given index in *colorList* applies to the number of pixels stored in *lengthList* at that same index.

Example 11.3 The *GIFDecoding* Class

```java
/* GIF decoding class
   Anderson, Franceschi
*/

import java.io.*;
import java.util.*;
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;

public class GIFDecoding
{
  private int width; // the width of the GIF

  // ArrayList instance variables:
  // colorList stores Color references
  // lengthList stores integers, the length of each run
  private ArrayList<Color> colorList;
  private ArrayList<Integer> lengthList;

  /* GIFDecoding constructor
   * @param file a Scanner, already open for reading a GIF file
   * initializes width with the first int in file
   * fills the two ArrayLists with the
   * ints and colors stored in file
  */
  public GIFDecoding( Scanner file )
  {
    colorList = new ArrayList<Color>( );
    lengthList = new ArrayList<Integer>( );

    try
    {
      width = file.nextInt( );
      int length;
      double red, green, blue;

      while ( file.hasNext( ) )
      {
        length = file.nextInt( );
        lengthList.add( length );

        red = file.nextDouble( );
        green = file.nextDouble( );
        blue = file.nextDouble( );
        colorList.add( Color.color( red, green, blue ) );
      }
    }
    catch ( InputMismatchException ime )
    {
      System.out.println( "Invalid file format; exiting" );
    }
    catch ( Exception e )
    {
      System.out.println( e.getMessage( ) );
    }
    finally
    {
      file.close( );
    }
  }

  /*
   * drawGIF method
   * @param gc a GraphicsContext reference, the graphics context
   * @param x an int, the drawing's upper left corner x coordinate
   * @param y an int, the drawing's upper left corner y coordinate
  */
  public void drawGIF( GraphicsContext gc, int x, int y  )
  {
    // draw the gif
    Color currentColor;
    int index = 0;
    int deltaX = 0;
    for ( int length : lengthList )
    {
      currentColor = colorList.get( index );
      gc.setStroke( currentColor );

      // draw one or more lines using length pixels with currentCo
      while ( length >= width - deltaX )
      {
        gc.strokeLine( x + deltaX, y, x + width, y );
        y++;
        length = length - ( width - deltaX );
        deltaX = 0;
      }

      if ( length > 0 )
        gc.strokeLine( x + deltaX, y, x + deltaX + length, y );

      deltaX = deltaX + length;
      index++;
    }
  }
}
```

Description

Inside the *try* block, we first read the width of the flag at line 33 and assign it to *width*. At lines 37–46, we loop through the remaining lines of the file, reading the number of pixels (line 39) and their three color components (lines 42–44). With the three color components, we create a *Color* object and add it to *colorList* at line 45; we add the number of consecutive pixels of that color to *lengthList* at line 40.

We catch an *InputMismatchException* at lines 48–51, in case the data inside the file is not what we expect, and exit. A *NoSuchElementException* and an *IllegalStateException* can also be thrown by the *nextInt* and *nextDouble* methods. We catch them both in the generic *Exception catch* block at lines 52–55. We close the *Scanner* in the *finally* block (lines 56–59).

The *drawGIF* method (lines 62–94) accepts a *GraphicsContext* parameter and uses it to draw the GIF. The upper-left coordinates of the GIF are defined by the *x* and *y* parameters passed to *drawGIF*. At lines 74–93, we loop through all the lengths stored in *lengthList*. At line 76, we retrieve the corresponding color for the current pixels and set the stroke color of the *GraphicsContext* to that color at line 77. Because the number of consecutive pixels of the same color can be larger than the width of the drawing, several consecutive lines could have the same color. Thus, we draw the GIF one line at a time using a *while* loop (lines 79–86). After the loop, we draw a line with the current color if there are pixels left over (lines 88–89).

In **Example 11.4**, we ask the user to input a file name, instantiate a *Scanner* to read the file, create and instantiate a *GIFDecoding* object, then call the *drawGIF* method to draw the flag. If there is no file in the current folder with the name entered by the user or if the user mistypes the file name, a *FileNotFoundException* is thrown. Instead of terminating the program, we use the *try* and *catch* blocks to recover from erroneous user input. We use a *do/while* loop at lines 25–40 that keeps asking the user for a file name as long as no file with that name can be found in the current folder. At line 23, we declare a *boolean* variable, *fileFound*, initialized to *false*. As long as *fileFound* is *false* (line 40), we keep entering the loop and asking the user for a file name. If the user enters an invalid file name, our code instantiating the *Scanner file* (line 33) will throw a *FileNotFoundException*. We will then skip line 34 and execute the catch block (lines 36–39). Thus, *fileFound* will remain *false* and our loop condition will remain *true*. When the user enters a valid file name, *file* will be successfully instantiated and no exception will be thrown. Line 34 will execute, changing *fileFound* to *true* and we will then exit the loop.

Example 11.4 Reading a File and Drawing the Corresponding GIF

```
/* Drawing a GIF
   Anderson, Franceschi
*/

import java.io.*;
import java.util.Scanner;
import javafx.application.Application;
import javafx.scene.canvas.GraphicsContext;
import javafx.scene.paint.Color;
import javafx.stage.Stage;

public class DrawAGIF extends Application
{
  final int WIDTH = 500;
  final int HEIGHT = 300;

  @Override
  public void start( Stage stage )
  {
    Scanner scan = new Scanner( System.in );
    Scanner file = null;
    String filename = "";
    boolean fileFound = false;

    do
    {
      try
      {
        System.out.print( "Enter the name of the file > " );
        filename = scan.next( );

        File inputFile = new File( filename );
        file = new Scanner( inputFile );
        fileFound = true;
      }
      catch ( FileNotFoundException fnf )
      {
        System.out.println( "Unable to find " + filename );
      }
    } while ( !fileFound );

    // set up window title and size
    GraphicsContext gc = JIGraphicsUtility.setUpGraphics(
            stage, "Draw a flag", WIDTH, HEIGHT );
    gc.setFill( Color.LIGHTSKYBLUE );
    gc.fillRect( 0, 0, WIDTH, HEIGHT );

    GIFDecoding flag = new GIFDecoding( file );
    flag.drawGIF( gc, 50, 50 );
  }

  public static void main( String [ ] args )
  {
    launch( args );
  }
}
```

Description

COMMON ERROR TRAP

Failing to initialize a variable that is assigned a value in a *try* block, then accessed after the *try* block, will generate a compiler error.

Notice that we declare and initialize the variables *file* and *filename* at lines 21 and 22 before we enter the *try* block. If we do not initialize them and then try to access them in the *catch* block or after the *try*/*catch* blocks, we will receive the following compiler error (shown for *filename*):

```
variable filename might not have been initialized
```

At lines 42–46, we create a *GraphicsContext*, instantiate a *GIFDecoding* object using *file* at line 48, and draw the flag at line 49.

When we run and enter *HungarianFlag.txt* at the prompt, the window shown in **Figure 11.9** appears.

Figure 11.9 Output of Example 11.4

Description

SOFTWARE ENGINEERING TIP

Write code to catch and handle exceptions generated by invalid user input. Although the methods of the *Exception* class are good debugging tools, they are not necessarily appropriate to use in the final version of a program. Try to write user-friendly error messages.

11.6 Writing and Appending to Text Files

In the previous sections, we learned how to read data from a text file. But how did the data get into the file in the first place? It could be that someone put the data into the file using a text editor, such as Notepad in Windows, or TextEdit in MacOS. Typing data into a file is convenient when the amount of data is small. But very often files contain a significant amount of data, typically written to the file by a computer program. For instance, a web server writes to log files to keep track of the visitors accessing the website, how the visitors got to the website, the time they arrived, etc. If the web server comes under attack from a hacker, these log files can be consulted to determine where the hacker came from, who the hacker was, and other information.

In this section, we will learn how to write to a text file. But before going into the details, we must distinguish among several situations:

- Creating/writing to a new file, that is, the file does not exist.
- Writing to an existing file and replacing the contents of the file with new data.
- Writing to an existing file, but keeping the contents of the file and adding data at the end of the file. This is called **appending** to the file.

Java provides us with the necessary tools to perform all the preceding actions. **Table 11.5** summarizes what will happen, depending on the action we perform and whether the file already exists.

Writing or Appending to an Existing or New File

Operation	If the File Exists …	If the File Does Not Exist …
write	the current contents of the file are deleted, and writing starts at the beginning of the file	the file is created and writing starts at the beginning of the file
append	data is added to the end of the file, keeping the existing contents	the file is created and writing starts at the beginning of the file

Description

11.6.1 Writing to Text Files

The data that we write to files can be primitive data types, such as *ints*, *doubles*, or *booleans*, or even objects, such as *Strings*.

FileWriter, a subclass of the *Writer* class, is designed to write characters to a file. It has several constructors, one of which takes a file name and a mode as its two arguments. The *boolean mode* variable specifies whether we are writing (*false*) or appending (*true*) to the file.

The *PrintWriter* class is designed for converting basic data types to characters and writing them to a text file. The *PrintWriter* class provides *print* and *println* methods for all primitive data types, as well as for *Strings* and objects, that is, it calls the *toString* method of the object's class. The *print* method writes the argument value to the file, whereas the *println* method writes the argument value to the file followed by a *newline* character. The constructors and method APIs are shown in **Table 11.6**.

Useful Classes, Constructors, and Methods for Writing to a Text File

Classes, Constructors, and Methods for Writing to a Text File

Class	**Constructors**	**Exceptions thrown**
`FileWriter`	`FileWriter( String filename, boolean mode )` constructs a *FileWriter* object from a *String* representing the name of a file; if *mode* is *false*, we will write to the file; if *mode* is *true*, we will append to the file	`IOException`
`PrintWriter`	`PrintWriter( Writer wr )` constructs a *PrintWriter* object from the *Writer* object *wr*	None
	Method APIs	
`PrintWriter`	`void print( int i )`	None

	`void print( double d )`
	`void print( char c )`
	`void print( boolean b )`
	`...`
	`void println( int i )`
	`void println( double d )`
	`...`
	writes the argument to a text file	

`PrintWriter`	`void close( )` releases the resources associated with the *PrintWriter* object	None

Description

Example 11.5 shows how we can use the *FileWriter* and *PrintWriter* classes to write *Strings* and primitive data types to a text file named *ItalianFlag.txt*. We write data for the Italian flag that can later be read and drawn using the *DrawAGIF* example.

Example 11.5 Writing *Strings* and Primitive Data Types to a Text File

```
 1 /*  Writes a GIF encoding to a file
 2     Anderson, Franceschi
 3 */
 4
 5 import java.io.*;
 6
 7 public class WriteFlagToFile
 8 {
 9   private static final int HEIGHT = 10;
10
11   public static void main( String [ ] args )
12   {
13     try
14     {
15       FileWriter fw = new FileWriter( "ItalianFlag.txt", false );
16       PrintWriter pw = new PrintWriter( fw );
17       pw.println( 30 ); // width of GIF
18       // write HEIGHT lines of color and pixels data
19       for ( int i = 0; i < HEIGHT; i++ )
20       {
21         pw.print( 10 ); // 10 green pixels
22         pw.print( ' ' ); // white space character
23         pw.print( 0.0 ); // red color component
24         pw.println( " 1.0 0.0" ); // green and blue color components
25
26         pw.println( "10 1.0 1.0 1.0" ); // 10 white pixels
27         pw.println( "10 1.0 0.0 0.0" ); // 10 red pixels
28       }
29
30       pw.close( );
31     }
32
33     catch ( IOException ioe )
34     {
35       System.out.println( ioe.getMessage( ) );
36     }
37   }
38 }
```

Description

Line 15 instantiates a *FileWriter* object to write to the file *ItalianFlag.txt*. The *FileWriter* constructor could throw an *IOException*. Our code catches that exception at lines 33–36. This is the only *catch* block because the methods of the *PrintWriter* class do not throw exceptions.

Line 16 instantiates a *PrintWriter* object, which we will use to write to the file. At lines 17–28, using the *PrintWriter* object *pw*, we call the methods *print* and *println*, passing various *String* and primitive data type arguments (*int*, *char*, and *double*) to be written to the file. When we want a *newline* character appended to the output, we call *println*, rather than *print*.

On line 30, we close the file. Although calling the *close* method is optional when we are reading a file, it is essential to call the *close* method when we are writing to a file. Closing the file flushes any buffered data to the output file. If we omit calling the *close* method, we may find that the file is empty when the program ends.

After this program is executed, the file *ItalianFlag.txt* will contain the data shown in **Figure 11.10**. Because we wrote all the output to the file *ItalianFlag.txt*, there is no output to the console.

Figure 11.10 The *ItalianFlag.txt* File After Running Example 11.5

Description

11.6.2 Appending to Text Files

Appending text to a file is similar to writing text; the only difference is that the second argument of the *FileWriter* constructor is *true*, instead of *false*.

Example 11.6 shows how the *FileWriter* and *PrintWriter* classes can be used in a Java program to append text to our file named *ItalianFlag.txt*.

Example 11.6 Appending to a Text File

```java
/*  Appends to a file
    Anderson, Franceschi
*/

import java.io.*;
import java.util.*;

public class AppendToFlagFile
{
  static final int PIXELS = 10;

  public static void main( String [ ] args )
  {
    int lines = 0;
    Scanner scan = new Scanner( System.in );
    boolean goodInput = false;

    do
    {
      try
      {
        // prompt for input; expected value is an int
        System.out.print( "Enter a number of lines (20 to 50) "
                + "to append > " );
        lines = scan.nextInt( );
        if ( lines >= 20 && lines <= 50 )
          goodInput = true;
      }

      catch ( InputMismatchException ime )
      {
        // consume invalid data left in input stream
        String garbage = scan.nextLine( );
        System.out.print( "You did not enter an integer; "
                + "please enter an integer > " );
      }
    } while ( !goodInput );

    try
    {
      FileWriter fw = new FileWriter( "ItalianFlag.txt", true );
      PrintWriter pw = new PrintWriter( fw );
      // append lines of color and pixels data for this flag
      for ( int i = 0; i < lines; i++ )
      {
        pw.println( PIXELS + " 0.0 1.0 0.0" ); // PIXELS green pixels
        pw.println( PIXELS + " 1.0 1.0 1.0" ); // PIXELS white pixels
        pw.println( PIXELS + " 1.0 0.0 0.0" ); // PIXELS red pixels
      }
      pw.close( );
    }

    catch ( IOException ioe )
    {
      System.out.println( ioe.getMessage( ) );
    }
  }
}
```

Description

Example 11.6 is similar to Example 11.5. The major difference is that when we instantiate the *FileWriter* object (line 41), the second argument is *true*, which means that we will append to the file *ItalianFlag.txt*. If the file *ItalianFlag.txt* exists, we will start writing at the end of its current contents, whereas if the file does not exist, it will be created. In this program, we ask the user how many lines he or she wants to append to the file. At lines 18–37, we loop until the user inputs an integer whose value is between 20 and 50, inclusive. We use a *boolean* variable, *goodInput*, to monitor the validity of the value entered by the user. As long as *goodInput* is *false* (line 37), we keep asking the user for a new value. If the user does not enter an integer, we execute the *catch* block and flush the input stream (lines 32–33). If we instead leave the invalid user input in the input stream, we would attempt to read that invalid user input again at line 25 at the next iteration of the loop. If the user enters an integer, we test that the value is between 20 and 50 at line 26. If the input is valid, we change *goodInput* to *true* and exit the loop.

COMMON ERROR TRAP

Opening a file for writing will cause the existing file data to be deleted. If you intend to add new data to a file while maintaining the original contents, open the file for appending.

If the *ItalianFlag.txt* file is the one that was created by Example 11.5, we can use two approaches to check if we did append to the file when we ran this program: We can open the file in Notepad and check that it contains the extra lines. We can also run Example 11.4 again, using the newly created file, and we can verify that the drawing is larger than before.

```
AA123
BWI
SFO
235
239.5
```

```
AA123,BWI,SFO,235,239.5
AA200,BOS,JFK,150,89.3
AA900,LAX,CHI,201,201.8
```

```
Flight[flightNumber=AA123, origin=BWI, destination=SFO,
    numPassengers=235, avgTicketPrice=239.5]
Flight[flightNumber=AA200, origin=BOS, destination=JFK,
    numPassengers=150, avgTicketPrice=89.3]
Flight[flightNumber=AA900, origin=LAX, destination=CHI,
    numPassengers=201, avgTicketPrice=201.8]
```

11.7 Reading Structured Text Files

Sometimes a text file is organized so that each line represents data related to a particular record or object. For instance, an airline company could have data stored in a file where each line represents a flight segment, with the following comma-separated data:

- flight number

- origin airport
- destination airport
- number of passengers
- average ticket price

Such a file could contain the following data:

```
AA123,BWI,SFO,235,239.5

AA200,BOS,JFK,150,89.3

AA900,LAX,CHI,201,201.8

. . .
```

Description

As we read the file, we should **parse** each line, that is, separate the line into the individual pieces of data (flight number, origin airport, etc.), called **tokens.** In this case, the comma is the **delimiter**; that is, a comma separates one token from the next. We will store the tokens from each line into a corresponding *FlightRecord* object.

11.7.1 Parsing a *String* Using *Scanner*

In addition to accepting input from the console and text files, *Scanner* can also be used to parse *Strings*, that is, to separate *Strings* into tokens.

A constructor of the *Scanner* class, which takes a *String* to parse, is shown in **Table 11.7**.

Useful Constructor and Method of the *Scanner* Class for Parsing a *String*

Constructor	**Exceptions Thrown**
`Scanner(`	None

`String source`
`)`

constructs a *Scanner* object that produces tokens from the specified *String*

Method API

Return value	Method name and argument list	

`Scanner`	`useDelimiter(`
	`String pattern`
	`)`
		None

sets this *Scanner* object's delimiters based on the specified *pattern*

Description

Scanner's default delimiters are the white space characters. We can specify different delimiters through the *useDelimiter* method (also shown in Table 11.7), which accepts as its argument a *String* representing a **regular expression**. Regular expressions allow us to specify a pattern against which to match sequences of characters using standard characters as well as **meta-characters**, which have special meanings. Further discussion of regular expressions is outside the scope of this book. For our purposes, we can specify a delimiter consisting of a single or multiple specific characters as a simple *String* argument for the *useDelimiter* method. For example, to parse a *String* like *AA123,BWI,SFO,*235,239.5, we call the *useDelimiter* method and pass a comma as its argument.

Example 11.7 shows how the *Scanner* class can be used in a Java program to parse a *String*.

Example 11.7 Demonstrating How to Parse a *String* with the *Scanner* Class

```
 1 /* Demonstrating how to parse a String with the Scanner class
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6 import java.util.InputMismatchException;
 7 import java.util.NoSuchElementException;
 8
 9 public class UsingScannerToParseAString
10 {
11   public static void main( String [ ] args )
12   {
13     String flightRecord1 = "AA123,BWI,SFO,235,239.5";
14
15     try ( Scanner parse = new Scanner( flightRecord1 ) )
16     {
17       // set the delimiter to a comma
18       parse.useDelimiter( "," );
19
20       System.out.println( parse.next( ) ); // flight number
21       System.out.println( parse.next( ) ); // origin airport
22       System.out.println( parse.next( ) ); // destination airport
23       System.out.println( parse.nextInt( ) ); // number of passengers
24       System.out.println( parse.nextDouble( ) ); // average ticket price
25     }
26
27     catch ( InputMismatchException ime )
28     {
29       System.out.println( "Error in data format" );
30     }
31
32     catch ( NoSuchElementException nse )
33     {
34       System.out.println( "No more tokens" );
35     }
36
37     catch ( IllegalStateException ise )
38     {
39       ise.printStackTrace ( );
40     }
41   }
42 }
```

Description

At line 15, the *Scanner* object *parse* is instantiated using the constructor with a *String* argument, *flightRecord1*, the *String* that we want to tokenize (see line 13). At lines 17–18, we call the *useDelimiter* method to set the delimiter to a comma.

At lines 20–24, we call the *next, nextInt,* and *nextDouble* methods to retrieve the five tokens of *flightRecord1* and process them, echoing them to the console. Since we know the format of the *String flightRecord1*, we can call the appropriate method based on the data type we expect to find at that position in the *String*. Although these methods throw exceptions, these exceptions are unchecked exceptions and thus the *try* and *catch* blocks are not mandatory. The *nextInt, nextDouble*, … methods will throw an *InputMismatchException* if the token retrieved cannot be converted to the expected data type. They will throw a *NoSuchElementException* if there are no more tokens to retrieve. Finally, they will throw an *IllegalStateException* if the *Scanner* object has been closed. We *catch* all these exceptions at lines 27–40, from the most specific to the most general and in the order in which they are most likely to be thrown.

REFERENCE POINT

You can read more about the *Scanner* class at *www.oracle.com/technetwork/java.*

When the program in Example 11.7 runs, it will produce the output shown in **Figure 11.11**.

Figure 11.11 Output from Example 11.7

Description

If we want to process all the tokens as *Strings* with a loop construct, we can call the *hasNext* method to check if there are more tokens to process as in the following:

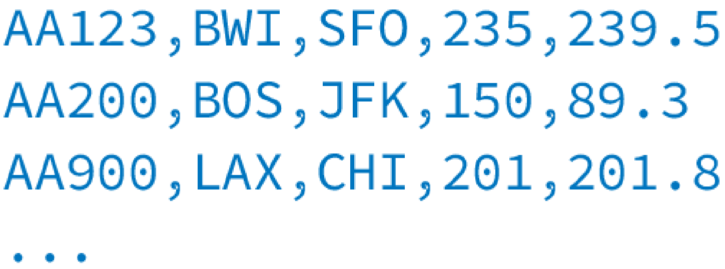
```
while ( parse.hasNext( ) )
  System.out.println( parse.next( ) );
```

Description

Eventually, when all tokens have been retrieved, the *hasNext* method returns *false*, which causes us to exit the *while* loop.

11.7.2 Reading Structured Data Using Scanner

Let’s say that we have a file named *flights.txt* containing many flight records, and we want to read the data into variables. Suppose that each line in the file is in the same format as the *flightRecord1 String* in Section 11.7.1; that is, the file looks like the following:



```
AA123,BWI,SFO,235,239.5
AA200,BOS,JFK,150,89.3
AA900,LAX,CHI,201,201.8
...
```

Description

where each line represents a flight segment with the following comma-separated data: flight number, origin airport, destination airport, number of passengers, and average ticket price.

First, we build a class called *Flight*, encapsulating a flight record as reflected by the data in the file. Each line read from the file will be parsed and used to instantiate a *Flight* object. Since we do not know how many lines (i.e., how many flight records) are in the file, we place all the flight records into an *ArrayList* object as opposed to a fixed-length array.

A recent and useful addition to Java is the concept of a ***Record*** class. A *Record* class is a simplified version of a class with instance variables and no functionality. The basic syntax for a Record class is as follows:

```
record RecordClassName( parameterList ) { }
```

Description

This is the equivalent, in a single line, to writing a class with instance variables, an overloaded constructor, accessors, as well as an *equals* and *toString* method. The name of the accessors does not start with get; it is the same as the parameters listed in the parameter list. A *Record* class is very convenient when all we need is to store data without manipulating it. **Example 11.8** shows the *Flight Record* class. The corresponding accessors are automatically generated and are named *flightNumber*, *origin*, *destination*, *numPassengers*, and *avgTicketPrice*. Note that not only are there no mutators generated, but the instance variables are *final*. It is also possible to add static instance variables and methods to a

Record class, as well as to override the accessors.

Example 11.8 The *Flight Record* Class

```java
/* The Flight Record class
   Anderson, Franceschi
*/

record Flight( String flightNumber,
               String origin, String destination,
               int numPassengers, double avgTicketPrice ) { }
```

Description

Example 11.9 shows our client class, which reads the file *flights.txt*, parses each line using *Scanner*, then instantiates a *Flight* object and adds it to the *ArrayList* named *listFlights*.

Example 11.9 Demonstrating How to Read Structured Data from a File

```
/* Reading structured data from a text file
   Anderson, Franceschi
*/

import java.io.File;
import java.io.FileNotFoundException;

import java.util.Scanner;
import java.util.InputMismatchException;
import java.util.ArrayList;

public class ReadFlights
{
   public static void main( String [ ] args )
   {
     // instantiate ArrayList to hold Flight objects
     ArrayList<Flight> listFlights = new ArrayList<Flight>( );

     try
     {
       Scanner file = new Scanner( new File( "flights.txt" ) );

       while ( file.hasNext( ) ) // test for the end of the file
       {
          // read a line
          String stringRead = file.nextLine( );

          // process the line read
          Scanner parse = new Scanner( stringRead );
          parse.useDelimiter( "," );
          String flightNumber = parse.next( );
          String origin = parse.next( );
          String destination = parse.next( );

          try
          {
             int numPassengers = parse.nextInt( );
             double avgTicketPrice = parse.nextDouble( );

             Flight frTemp = new Flight(
                    flightNumber, origin, destination,
                    numPassengers, avgTicketPrice );

             // add Flight obj to listFlights
             listFlights.add( frTemp );
          }

          catch ( InputMismatchException ime )
          {
             System.out.println( "Error in flight record: "
                       + stringRead + "; record ignored" );
          }
       }

       // release resources associated with flights.txt
       file.close( );
     }

     catch ( FileNotFoundException fnfe )
     {
        System.out.println( "Unable to find flights.txt" );
     }

     catch ( Exception ioe )
     {
        ioe.printStackTrace( );
     }

     // print the Flights read
     for ( Flight flight : listFlights )
         System.out.println( flight );
   }
}
```

Description

Lines 5–10 import the classes needed for input, parsing, and exception handling, as well as *ArrayList*. The *Flight Record* class is also used in this program, but is assumed to be in the same folder as the *ReadFlights* class.

In this example, we instantiate two *Scanner* objects: one to read the lines from the file into a *String* and a second *Scanner* object to parse the *String*.

With the first *Scanner* object (instantiated on line 21), we use the *nextLine* method to read one line at a time (line 26). We provide *catch* blocks for both *FileNotFoundException* (lines 59–62) and *Exception* (lines 64–67). The *Scanner* constructor can throw a *FileNotFoundException* and the *File* constructor can throw a *NullPointerException*. Both *FileNotFoundException* and *NullPointerException* are subclasses of *Exception*. Remember that when an exception occurs, the *catch* blocks are scanned, in order, for a match between the *catch* block parameter and the type of exception that occurred. Because the *FileNotFoundException* is a subclass of *Exception*, a *FileNotFoundException* will also match a *catch* block for an *Exception*. Therefore, we need to put the *catch* block for the *FileNotFoundException* before the *catch* block for *Exception*. This way, if the file does not exist, the exception will match the first *catch* block, which handles the *FileNotFoundException*, and we will be able to output a meaningful message for the user. If the *File* constructor throws a *NullPointerException*, which we don’t expect to happen, that will match the *catch* block for *Exception* and we print the stack trace.

As we read each line from the file, we instantiate a second *Scanner* object (line 29) and pass the data we extract as our arguments to the *Flight* constructor to instantiate a *Flight* object (lines 40–42).

The *Flight* object is then added to the *ArrayList listFlights* at lines 44–45. The *ArrayList listFlights* is declared and instantiated at lines 16–17, before the *try* block so that *listFlights* is available for printing the *Flight* objects at lines 69–71, after we finish reading the file. If the *flights.txt* file contains the data shown in **Figure 11.12**, the program will produce the output shown in **Figure 11.13**.

Figure 11.12 Contents of *flights.txt*

11.8 Programming Activity 1: Reading from a Structured Text File

In this activity, you will read from a text file using an end-of-file controlled *while* loop performing this activity:

> Read a text file containing transaction items for a bank account. Loop through all the transaction items and calculate the new balance of the bank account. Assume that we do not know the number of transaction items (i.e., lines) in the file.

The framework will display the current transaction and current balance so that you can check the correctness of your code as the program executes.

For example, **Figure 11.14** demonstrates the animation: We are currently scanning a check for the amount of $200.00. The original balance was $0.00 and the new balance is –$200.00. Ideally, this is not your bank account.

Figure 11.14 Animation Showing a $200 Check and the New Balance

Description

Instructions

In this chapter's folder in the supplied code, you will find the Programming Activity 1 folder. Copy the contents of the folder onto a folder on your disk.

- Open the file *transactions.txt* with a text editor. You will see that each line contains a transaction name and transaction amount separated by a colon, as shown in **Figure 11.15**.
- Note that the transaction amounts are positive or negative. For instance:
    - A check or a withdrawal has a negative amount.
    - A deposit has a positive amount.
    - An unknown transaction has either a positive or negative amount.
- Now open the *AccountingDrawing.java* file. Search for five asterisks (*****) to find the *balanceCheckBook* method where you will add your code. The method header has already been coded for you. Write the code to read all the transactions from the file *transactions.txt*, process each transaction against the account, and calculate the balance after all the transactions in that file have been processed.

Figure 11.15 Contents of the *transactions.txt* File

Description

The code for the *balanceCheckBook* method is shown in **Example 11.10**.

Example 11.10 The *balanceCheckBook* Method in *Accounting Drawing.java*

```
public void balanceCheckBook( )
{
  // ***** Write the body of this method *****
  //
  // Using a while loop, read the file transactions.txt
  // The file transactions.txt contains money
  // transactions between you and your bank
  //
  // You will need to call the method animate inside
  // the body of the loop reading the file contents
  //
  // The animate method takes 3 arguments:
  //    a String, representing the type of transaction
  //    a double, representing the transaction money amount
  //    a double, representing the new checkbook balance
  // So if these 3 variables are:
  //    transactionName, currentAmount, and balance,
  // then the call to animate will be:
  //
  //  animate( transactionName, currentAmount, balance );
  //
  // You should make that call in the body of your while
  // loop, after you have updated the checkbook balance
  //
  //
  // end of student code
  //
}
```

Description

- Begin with a checkbook balance of 0.00.
- To process the transactions, you will need to read one line at a time from the *transactions.txt* file and parse the *String* that you retrieve. You can use the *Scanner* class for this. The delimiter will be a colon. Then process the transaction; you do not need to check the type of transaction. Just add the amount of the transaction to the checkbook balance. Adding a negative transaction amount will decrease the balance, as expected. Be sure to use *try/catch* blocks where appropriate.
- After you have processed each transaction, call the *animate* method. This method belongs to the *AccountingDrawing* class, so you will call *animate* without using an object reference. The API of the *animate* method is the following:

```
public void animate( String currentTransaction,
                     double currentAmount,
                     double currentBalance )
```

Description

- As you can see, the *animate* method takes three arguments: *currentTransaction* is the transaction name ("Deposit," for example), *currentAmount* is the amount of the transaction (-*45.00*, for example), and *currentBalance* is the current balance of the checkbook. Assuming that you have a *String* variable called *transactionName*, a *double* variable called *amount*, and another *double* called *balance*, a call to *animate* will look like the following:

```
animate( transactionName, amount, balance );
```

Description

- When you call *animate*, the window will display the current transaction graphically. It will also display the transaction amount (red if negative, blue if positive), and the current checkbook balance (in black). By adding the previous checkbook balance to the current transaction amount, you will be able to determine if your program is working correctly.
- When you reach the end of the file, print the final balance and write it to a file named *balance.txt*.

To test your code, compile and run the *AccountingApplication.java* application file.

If you have time …

- Modify the file *transactions.txt* by deleting or adding transactions manually with a text editor. Run the program again and check that your code still gives the correct result.
- Using a text editor, modify the file *transactions.txt* by entering a positive amount to all transactions. Change your *balanceCheckBook* method so that it determines which

transactions are positive and which are negative. Run the program again and check that your code still gives the correct result.

Troubleshooting

If your method implementation does not animate or animates incorrectly, check these items:

- Verify that you coded the call to *animate* at the proper time.
- Verify that you coded the condition for exiting the loop correctly.
- Verify that you coded the body of the loop correctly.

DISCUSSION QUESTIONS

1. What exceptions can occur during this program?
2. Explain why we use the *Scanner* class.

```
Paris
Baltimore
Seattle
San Francisco
Boston
Los Angeles
Madrid
Barcelona
Buenos Aires
```

```

-100.48
200.39
150.00
```

```
Number of cities starting with B: 4

Total expenses are $1,450.89
```

11.9 Streams

Streams were introduced with Java 8 to support aggregate sequential and parallel operations on a collection of elements. The *Stream* interface (*java.util.stream* package) specifies functionality to perform those operations on a collection of objects. It uses generics, so we need to specify the type of object that a *Stream* will be working on. The *java.util.stream* package includes more specialized stream interfaces such as *IntStream*, *DoubleStream*, or *LongStream*. *Streams* cannot directly access individual elements and thus are designed for performing computations on all or a subset of their elements.

A *Stream* computation goes through a **stream pipeline**. A stream pipeline includes a source of elements that is first converted into a *Stream*; then zero or more operations are performed on those elements, for example filtering or selecting, resulting in another *Stream*. A final operation, for example counting or summing, is then performed, producing a result. **Table 11.8** lists some of the methods of the *Stream* interface.

Selected Methods of the *Stream* Interface

Return Value	Method and Description
`long`	`count( )` returns the number of elements in this *Stream*
`Stream`	`filter( Predicate<? super T> predicate )` returns a *Stream* made of the elements of this *Stream* that satisfy *predicate*
`Optional`	`min( Comparator<? super T> comparator )` returns the minimum element of this *Stream* using the comparator
`Optional`	`max( Comparator<? super T> comparator )` returns the maximum element of this *Stream* using the comparator
`DoubleStream`	`mapToDouble( ToDoubleFunction <? super T > mapper )` returns a *DoubleStream* made up of the elements resulting from applying *mapper* to the *Stream* elements; *mapToInt* and *mapToLong* are similar methods

Description

Let's take a closer look at how we can use these methods, for example the *filter* method. If we want to process only the data in the *Stream* that meets some condition, we can use the *Predicate* interface in the *java.util.function* package. The *Predicate* interface uses generics and allows us to test if the data meets a condition. The *filter* method accepts a parameter of type *Predicate<? super T>.* That means the data type of the *Stream* being tested can be of class *T* or a superclass of *T*. Thus, if *cityPredicate* tests if a *String* meets some condition and *cityStream* is an existing *Stream* of type *String*, we can call the *filter* method as follows:

```
cityStream = cityStream.filter( cityPredicate );
```

Description

The *Predicate* interface has only one *abstract* method, *test*. **Table 11.9** shows the *test* method as well as the *abstract* methods of the *DoublePredicate, Comparator,* and *ToDoubleFunction* functional interfaces. Note that except for *DoublePredicate*, all these functional interfaces use generics. If we want *cityPredicate* to filter *Strings* that start with the letter *B*, we can implement the *test* method of the *Predicate* interface as shown in **Example 11.11**.

Methods of the *Predicate, DoublePredicate, Comparator*, and *ToDoubleFunction* Interfaces

Interface	**Abstract Method**
`Predicate`	`boolean test( T t )` tests *t* and returns *true* or *false*
`DoublePredicate`	`boolean test( double d )` tests *d* and returns *true* or *false*
`Comparator`	`int compare( T t1, T t2 )` compares *t1* and *t2* for order
`ToDoubleFunction`	`double applyAsDouble( T t )` converts *t* to a *double* and returns that value

Description

Example 11.11 Implementing the *Predicate* Interface

```
/*  Predicate testing whether a String starts with B
    Anderson, Franceschi
*/
import java.util.function.*;

public class StartWithBPredicate<T> implements Predicate<T>
{
  public boolean test( T t )
  {
    if ( !( t instanceof String ) )
      return false;
    else
    {
      String s = ( String ) t;
      return s.charAt( 0 ) == 'B';
    }
  }
}
```

Description

Below is how we can use the *StartWithBPredicate* test method to filter our *Stream*:

```
StartWithBPredicate<String> cityPredicate
    = new StartWithBPredicate<String>( );
cityStream = cityStream.filter( cityPredicate );
```

Description

Because the *Predicate* interface contains only one *abstract* method that must be implemented, it is a **functional interface**. Thus, we can use a **lambda expression** to replace the code above, as well as the code in Example 11.11, in a single statement as follows:

```
cityStream = cityStream.filter( city -> city.charAt( 0 ) == 'B' );
```

Description

Lambda expressions, introduced in Java version 8, can be used only with functional interfaces, which are interfaces that have only one *abstract* method to implement. A lambda expression contains the following elements:

- A comma-separated list of parameters enclosed in parentheses

- The data types of the parameters may be omitted. The parentheses may also be omitted if there is only one parameter (in the above example, *city* is the parameter).
- The arrow token, ->
- A method body, which can be a single expression or a block enclosed in curly braces
- If the body of the method consists of a single expression, the JVM evaluates the expression and returns its value (in the above example, the JVM returns the value of the expression `city.charAt( 0 ) == 'B'`). As an alternative, we can use a *return* statement, but that requires curly braces.

After we have filtered the *Stream*, we may want to perform a final operation, such as counting. In this example, we count how many cities in the *cities.txt* file start with the letter *B*. After filtering the *Stream*, we call the *count* method, which returns a result, as follows:

```
long count = cityStream.count( );
```

Description

Because the *filter* method returns a *Stream* reference, we can chain the method calls as follows:

```
long count = cityStream.filter( city -> city.charAt( 0 ) == 'B' )
                       .count( );
```

Description

COMMON ERROR TRAP

Do not confuse the *Path* interface with the *Paths* class. They work together but are different.

Before processing a *Stream*, we need to create one. **Table 11.10** shows some classes and methods that can be used for that purpose. The *stream* method of the *ArrayList* class, inherited from the *Collection* interface, returns a *Stream* consisting of the elements in the *ArrayList*. To create a *Stream* from the contents of a file, we can call the *static lines* method of the *Files* class and pass a *Path* argument for that file. The *Path* interface and the *Paths* and *Files* classes are all in the *java.nio.file* package. A *Path* can be obtained for a file by calling the *static get* method of the *Paths* class. As shown, the *get* method accepts a variable number of arguments for specifying folders in the path to the filename; if the file is located in the current folder, we just pass the name of the file. We can combine the two method calls in one statement as follows:

Useful Classes and Methods for Creating a *Stream*

Class	**Method**	**Exceptions Thrown**
`Paths`	`static Path get( String first, String... more )` returns a *Path* constructed with the *String* parameters	`InvalidPathException`
`Files`	`static Stream<String> lines( Path p )` reads all the lines from *p* and returns them as a *Stream*	`IOException, SecurityException`
`ArrayList`	`Stream stream( )` returns a *Stream* consisting of the elements in this *ArrayList*	

Description

```
Stream<String> cityStream = Files.lines( Paths.get( "cities.txt" ) );
```

Description

Example 11.12 shows how we can use *Streams* to perform some aggregate operations on the contents of two files, *cities.txt* and *expenses.txt*, shown in **Figures 11.16** and **11.17**.

Figure 11.16 The *cities.txt* File

Description

Figure 11.17 The *expenses.txt* File

Description

Example 11.12 Processing *Streams*

```
 1 /*  Reading file data into a Stream and processing it
 2 *   Anderson, Franceschi
 3 */
 4
 5 import java.io.IOException;
 6 import java.nio.file.*;
 7 import java.text.NumberFormat;
 8 import java.util.stream.Stream;
 9
10 public class FilterAndProcessStream
11 {
12   public static void main( String [ ] args  )
13   {
14    NumberFormat money = NumberFormat.getCurrencyInstance( );
15    String cityFile = "cities.txt";
16    String expenseFile = "expenses.txt";
17    try
18    {
19      // build a Stream using cities.txt
20      Stream<String> cityStream =
21        Files.lines( Paths.get( cityFile ) );
22      // select cities starting with a B and count them
23      long count = cityStream.filter( city -> city.charAt( 0 ) == 'B' )
24                             .count( );
25      System.out.println( "Number of cities starting with B: " + count );
26
27      // build a Stream using expenses.txt
28      Stream<String> numberStream =
29        Files.lines( Paths.get( expenseFile ) );
30      // select positive costs and add them up
31      double sum =
32        numberStream.mapToDouble( data -> Double.parseDouble( data ) )
33                    .filter( cost -> cost > 0.0 )
34                    .sum( );
35      System.out.println( "\nTotal expenses are " + money.format( sum ) );
36    }
37
38    catch ( InvalidPathException ipe )
39    {
40      System.out.println( ipe.getMessage( ) );
41    }
42
43    catch ( IOException ioe )
44    {
45      System.out.println( "Could not find file: " + ioe.getMessage( ) );
46    }
47
48    catch ( SecurityException se )
49    {
50      System.out.println( se.getMessage( ) );
51    }
52   }
53 }
```

Description

We count the number of cities that begin with *B* in *cities.txt* and calculate the total of the values that are greater than 0.0 in *expenses.txt*.

At lines 19–21, we build a *Stream* using the contents of the *cities.txt* file. At lines 22–24, we compute how many cities start with the letter *B*. We output that count at line 25.

At lines 27–29, we build a *Stream* using the contents of the *expenses.txt* file. At lines 30–34, we select the positive *doubles* from that *Stream* and calculate a sum. We output that total using a currency format at line 35. At line 32, we call the *mapToDouble* method in order to convert the *Stream* of *Strings* to a *DoubleStream*. Since *ToDoubleFunction* is a functional interface, we use the lambda expression

```
data -> Double.parseDouble( data )
```

Description

as the argument of *mapToDouble*. We then call the *filter* method of the *DoubleStream* interface at line 33, which accepts a *DoublePredicate* parameter. Our predicate test determines whether the cost is greater than 0.0. Since *DoublePredicate* is also a functional interface, we use the lambda expression

```
cost -> cost > 0.0
```

Description

as the argument of *filter*. At line 34, we call the *sum* method with the filtered *DoubleStream* in order to sum all its elements. Both the *filter* and *sum* methods are shown in **Table 11.11**.

The *filter* and *sum* Methods of the *DoubleStream* Interface

Return Value	Method and Description
`DoubleStream`	`filter( DoublePredicate predicate )` returns a *DoubleStream* made of the elements of this *DoubleStream* that satisfy *predicate*
`double`	`sum( )`

returns the sum of the elements in this *DoubleStream*

Description

11.10 Reading Formatted Open Data from a Remote Location

More and more organizations open their data to the general public, and to programmers in particular. In this section, we show how to access data located on a remote server, parse the data, convert the data to a *Stream*, and process the *Stream*.

11.10.1 Accessing Remote Data

There are many data sets that are open to the public. For this example, we have chosen to retrieve and process data on American movies made since 1900. The data is located at the following Uniform Record Locator (URL):

```
https://raw.githubusercontent.com/prust/wikipedia-movie-data/master/movies.json
```

Description

In order to access the data, we use the *URL* and *Scanner* classes. Some of their constructors and methods are listed in **Table 11.12**. The code sequence below shows how we can access and read the data. The *String resource* stores the name of the *URL* where the data source we want to process is located. We first create and instantiate a *URL* object using the URL of the resource that we want to access. If the resource's URL does not have proper syntax, the *URL* constructor throws a *URLMalformedException*. With the *URL* reference, we then call the *openStream* method, which returns an *InputStream* reference and will throw an *IOException* if there is no resource at that URL. We catch both exceptions. We now can read data from the remote resource with the *Scanner* named *dataSource*.

Useful Classes, Constructors, and Methods for Accessing Remote Data

Class	Constructor or Method	Exceptions Thrown
`URL`	`URL( String url )` constructs a URL object	`MalformedURLExceptio` will be thrown if *url* is not a properly formed URL
`URL`	`InputStream openStream( )` creates and returns an *InputStream* for this URL	`IOException`
`Scanner`	`Scanner( InputStream is )` constructs a *Scanner* object that can read from the *InputStream is*	

Description

```
 String GITHUB = "https://raw.githubusercontent.com/";
 String resource = GITHUB + "prust/wikipedia-movie-data/master/movies.json";
 try
 {
   URL url = new URL( resource );
  InputStream is = url.openStream( );
  Scanner dataSource = new Scanner( is );
   ..
}
catch ( MalformedURLException murle )
{
   ..
}
catch ( IOException ioe )
{
   ..
}
```

Description

11.10.2 JSON Formatting and Parsing

Many open data files are formatted in **XML** or **JSON**. XML stands for eXtended Markup Language. It is similar to HTML except that tags are user-defined instead of predefined. JSON stands for JavaScript Object Notation and is based on JavaScript syntax. JavaScript is an interpreted language that typically runs inside a browser. The JSON format is often the format of choice for transferring data over the Internet between a client and a server. The file that we access in **Example 11.13** is a JSON-formatted file. A JSON string includes two data - structures:

Example 11.13 Parsing a JSON

```
/*  JSON Parsing
*   Anderson, Franceschi
*/

import org.json.*;

public class JsonParsing
{
  public static void main( String [] args )
  {
    try
    {
      String json1 = "[Paris, New York, Rio]";
      JSONArray jsonArr = new JSONArray( json1 );
      String city1 = jsonArr.getString( 1 );
      System.out.println( "city1 is " + city1 );

      String json2 =
        "{'city':'Miami', 'state':'FL', 'country':'USA'}";
      JSONObject jsonObj = new JSONObject( json2 );
      String state = jsonObj.getString( "state" );
      System.out.println( "state is " + state );
    }
    catch( JSONException je )
    {
      System.out.println( "exception: " + je.toString( ) );
    }
  }
}
```

Description

- A JSON array
- A JSON object, representing a mapping of key/value pairs

Those two data structures can be nested. A JSON array is a list of comma-separated values enclosed in square brackets. A JSON object is enclosed in curly braces and includes a comma-separated list of key/value pairs. A colon separates a key from its associated value. Keys are strings enclosed in quotes. Values can be strings, numbers, true, false, null, an object, or an array.

Here are some examples of valid JSON strings:

```
{ "email":"jane45@gmail.com", "age": 21 }
{ "states": { "MD":"Maryland", "NY":"New York", "CA":"California" } }
[ "New York", "London", "Buenos Aires"]
{ "countries": ["USA", "China", "Brazil"] }
```

Description

The first JSON string is a JSON object that contains two key/value pairs.

The second JSON string is a JSON object that contains one key/value pair. The key states maps to a value that is a JSON object itself, containing three key/value pairs.

The third JSON string is a JSON array that contains three values.

The fourth JSON string is a JSON object that contains one key/value pair. The key countries maps to a JSON array that contains three values.

In order to parse a *JSON* string, we can use the *JSONObject* and *JSONArray* classes of the *org.json* package. Some of their constructors and methods are listed in **Table 11.13**. The *org.json* package does not come as part of the standard JDK distribution and needs to be downloaded. After you download (and unpack) the *org.json* package, either place it in the folder where the example is located, or, preferably, update the CLASSPATH environment variable to include the folder where the package is located.

Useful Classes, Constructors, and Methods for Parsing a JSON *String*

Class	Constructor or Method	Exceptions Thrown
`JSONObject`	`JSONObject( String json )` constructs a JSONObject	`JSONException` will be thrown if *json* cannot be parsed into a *JSONObject*
	`dataType getDataType( String key )` returns the value for that *key*. The data type can be a primitive data type or *String*	`JSONException` will be thrown if *key* is not found or the value for *key* is not compatible with the expected return type

`JSONArray`	`JSONArray( String json )` constructs a JSONArray	`JSONException` will be thrown if *json* cannot be parsed into a *JSONArray*
	`int length( )` returns the number of values in this *JSONArray*	
	`JSONObject getJSONObject( int index )` returns the *JSONObject* at *index*	`JSONException` will be thrown if *index* is invalid or there is no *JSONObject* at that *index*

Description

Example 11.13 shows how to use the *JSONArray* and *JSONObject* classes to parse two simple JSON strings. To convert a JSON *String* that contains array-like data, we construct a *JSONArray* object from the JSON *String* (lines 13–14). Since we want to retrieve a *String* value, we call the *getString* method at line 15, passing an integer argument representing the array index of the value we want to retrieve. To convert a JSON *String* that contains object-like data, we construct a *JSONObject* object from the JSON *String* (lines 18–20). Again, we want to retrieve a *String* value, and we call the *getString* method at line 15, passing a *String* argument representing the key for the value we want to retrieve.

Figure 11.19 shows the output of Example 11.13.

Figure 11.19 Output of Example 11.13

Description

Figure 11.20 shows sample contents of the data at the URL discussed previously. The JSON *String* from that URL contains an array of movie objects. All the objects have the same format and contain four key/value pairs. The keys are title, year, cast, and genres; the values for cast and genres are arrays themselves. The last movie object in the array is:

```
{"title":"Destroyer","year":2018,"cast":["Nicole Kidman",
"Tatiana Maslany","Sebastian Stan","Toby Kebbell","Scoot
McNairy"],"genres":["Crime","Thriller"]}
```

Description

Figure 11.20 Sample JSON Content Listing American Movies Data

Description

If we have read the entire data set into a *String* named *json*, we can use the following code sequence to retrieve the title and the year of the movie at index *i* within the array of movies:

```
// json is a String that contains the data in Figure 11.20
JSONArray jsonArray = new JSONArray( json );
// get the JSONObject at index i
JSONObject jsonMovie = jsonArray.getJSONObject( i );
// retrieve the title of the current movie
String title = jsonMovie.getString( "title" );
// retrieve the year of the current movie
int year = jsonMovie.getInt( "year" );
```

Description

First, we create and instantiate a *JSONArray* using the *String json*. With it, we call the *getJSONObject* method, passing the valid array index. The resulting *JSONObject*, *jsonMovie*, is a *JSONObject* with four key/value pairs, storing the data for one movie. We retrieve the title of that movie by calling the *getString* method and passing *title*. We retrieve the year of that movie by calling the *getInt* method and passing *year*.

11.10.3 Reading, Parsing, Streaming, and Processing Remote Data

Example 11.14 shows the *Movie Record* class. We just use that class to store data so it makes sense to use a *Record* class. To keep things simple, we only store the title and the year of each movie.

Example 11.14 The *Movie Record* Class

```
/* The Movie Record class
   Anderson, Franceschi
*/

record Movie( String title, int year ) { }
```

Description

Example 11.15 shows how we can read remote data, then parse it and process it. At lines 14–16, we declare a *String* storing the URL resource that we want to access. At lines 20–22, we create a *URL* for that *String*, an *InputStream* for the *URL*, and a *Scanner* ready to read from that *InputStream*. At lines 23–29, we read all the lines from the data source and accumulate them into a *String* named *json*. At lines 31–33, we convert *json* to a *JSONArray* and retrieve and output the number of elements (i.e., movies) in that *JSONArray*. Because the *JSONArray* stores all the movies, calling the *length* method of the *JSONArray* class at line 32 returns the number of movies in the data set. There are 28,795 movies.

Example 11.15 Reading, Parsing, and Processing Remote Data

```java
/* A class to analyze data from movies
   Anderson, Franceschi
*/

import java.io.*;
import java.net.*;
import java.util.*;
import org.json.*;

public class Movies
{
  public static void main( String args [ ] )
  {
    String GITHUB = "https://raw.githubusercontent.com/";
    String fileName = GITHUB +
      "prust/wikipedia-movie-data/master/movies.json";

    try
    {
      URL url = new URL( fileName );
      InputStream is = url.openStream( );
      Scanner file = new Scanner( is );
      String json = "";
      String s = null;
      while ( file.hasNext( ) )
      {
        s = file.nextLine( );
        json += s;
      }

      JSONArray jsonArray = new JSONArray( json );
      System.out.println( "There are " + jsonArray.length( )
                                       + " movies" );

      // Build ArrayList of MovieRecord objects
      ArrayList<Movie> movies = new ArrayList<Movie>( );

      for ( int i = 0; i < jsonArray.length( ); i++ )
      {
        JSONObject jsonMovie = jsonArray.getJSONObject( i );
        String title = jsonMovie.getString( "title" );
        int year = jsonMovie.getInt( "year" );
        if ( title.equals( "" ) )
          System.out.println( "Discarding (no title)" );
        else
          movies.add( new Movie( title, year ) );
      }

      // Ask user to enter a year
      Scanner scan = new Scanner( System.in );
      System.out.print( "Please enter a year > " );
      int year = scan.nextInt( );

      // Retrieve number of movies for that year
      long count = movies.stream( )
                         .filter( movie -> movie.year( ) == year )
                         .count( );
      System.out.println( "There were " + count
                          + " movies in " + year );
    }
    catch( MalformedURLException murle )
    {
      System.out.println( murle.getMessage( ) );
    }
    catch( IOException ioe )
    {
      System.out.println( ioe.getMessage( ) );
    }
    catch( JSONException jsone )
    {
      System.out.println( jsone.getMessage( ) );
    }
  }
}
```

Description

At lines 38–47, we loop through the *JSONArray jsonArray* collecting the title and year data into the *movies ArrayList* of *Movies*, which we declare and instantiate at line 36.

Sometimes open data contain erroneous or invalid data, and we want to process only valid data. Thus, we test if the movie title is the empty *String* at line 43 and add the corresponding *Movie* object to the *ArrayList* at line 46, only if the title is not empty. This is called **cleaning the data**.

After we have collected the movies, we ask the user to enter a year. At lines 54–59, we compute and output the number of movies for that year. At lines 55–57, we convert the *ArrayList* to a *Stream* and compute the number of movies for the year entered by the user.

Figure 11.21 shows the output of Example 11.15 when the user enters the year 2000.

Figure 11.21 Output of Example 11.15

Description

```
End of the file reached
Closing file
There are 2 flights from BWI
Average number of passengers: 200.0
```

11.11 Reading and Writing Objects to a File

Throughout this text, we have emphasized the benefits of object-oriented programming. Just as we can write text and primitive data types to a file and subsequently read them from the file, we can also write objects to a file and subsequently read them as objects. This is convenient for two reasons:

- We can write these objects directly to a file without having to convert the objects to primitive data types or *Strings*.
- We can read the objects directly from a file, without having to read *Strings* and convert these *Strings* to primitive data types in order to instantiate objects.

To read objects from a file, the contents of the file must have been written as objects. So our first order of business should be to learn how to write objects to a file.

11.11.1 Writing Objects to Files

The *ObjectOutputStream* class, coupled with the *FileOutputStream* class, provides the functionality to write objects to a file. The *FileOutputStream* class, a subclass of *OutputStream,* is used to write raw data, rather than characters, to a file.

The *ObjectOutputStream* class, also a subclass of *OutputStream*, provides a convenient way to write objects to a file. Its *writeObject* method takes one argument—the object to be written.

The classes, constructors, and methods we will use are shown in **Table 11.14**.

Useful Classes, Constructors, and Methods for Writing Objects to a File

Classes, Constructors, and Methods for Writing Objects to a File

Class	**Constructor**	**Exceptions thrown**
`FileOutputStream`	`FileOutputStream( String filename, boolean mode )` constructs a *FileOutputStream* object from a *String* representing the name of a file; if *mode* is *false*, we will write to the file; if *mode* is *true,* we will append to the file	`FileNotFoundExceptio`
`ObjectOutputStream`	`ObjectOutputStream( OutputStream out )` creates an *ObjectOutputStream* that writes to the *OutputStream out*	`IOException`
	Method API	

`ObjectOutputStream`	`void writeObject( Object o )`
	writes the object argument to a file. That object must be an instance of a class that implements the *Serializable* interface. Otherwise, a run-time exception will be generated
		`IOException,`
		`NotSerializableExcept`
		`InvalidClassExceptio`

Description

We will use the *Flight Record* class developed earlier in the chapter. However, in order for an object to be written to a file (and later to be read using the *ObjectInputStream* class), that object must implement the *Serializable* interface. When an object implements the *Serializable* interface, its state can be converted to a byte stream to be written to a file, such that this byte stream can be converted back into a copy of the object when read from the file. Therefore, our modified *Flight2 Record* class will implement *Serializable*, which is in the *java.io* package.

The *Serializable* interface has no methods to implement. As a result, the only things we have to worry about when writing a class implementing *Serializable* are the following:

- the *import* statement
- the class header showing the class *implements Serializable*

Example 11.16 shows the *Flight2 Record* class. This class is identical to the *FlightRecord* class except that it *imports Serializable* (line 5), and *implements* the *Serializable* interface (line 10).

Example 11.16 The *FlightRecord2* Class

```
 1 /* The Flight2 Record class
 2    Anderson, Franceschi
 3 */
 4
 5 import java.io.Serializable;
 6
 7 record Flight2( String flightNumber,
 8                 String origin, String destination,
 9                 int numPassengers, double avgTicketPrice )
10                 implements Serializable { }
```

Description

Example 11.17 shows how the *FileOutputStream* and *ObjectOutputStream* classes can be used in a Java program to write *Flight2* objects to a file named *objects*.

Example 11.17 Writing Objects to a File

```
 1 /* Demonstrating how to write objects to a file
 2    Anderson, Franceschi
 3 */
 4
 5 import java.io.FileOutputStream;
 6 import java.io.ObjectOutputStream;
 7 import java.io.FileNotFoundException;
 8 import java.io.IOException;
 9
10 public class WritingObjects
11 {
12   public static void main( String [ ] args )
13   {
14    // instantiate the objects
15    Flight2 fr1 = new Flight2( "AA31", "BWI", "SFO", 200, 235.9 );
16    Flight2 fr2 = new Flight2( "CO25", "LAX", "JFK", 225, 419.9 );
17    Flight2 fr3 = new Flight2( "US57", "BWI", "DEN", 175, 179.5 );
18
19    try
20    {
21     FileOutputStream fos = new FileOutputStream
22                                   ( "objects", false );
23              // false means we will write to objects
24
25     ObjectOutputStream oos = new ObjectOutputStream( fos );
26
27     // write the objects to the file
28     oos.writeObject( fr1 );
29     oos.writeObject( fr2 );
30     oos.writeObject( fr3 );
31
32     // release resources associated with the objects file
33     oos.close( );
34    }
35
36    catch ( FileNotFoundException fnfe )
37    {
38      System.out.println( "Unable to write to objects" );
39    }
40
41    catch ( IOException ioe )
42    {
43      ioe.printStackTrace( );
44    }
45  }
46 }
```

Description

Lines 14–17 declare and instantiate three *Flight2* objects that we will write to the *objects* file.

Lines 21 and 22 instantiate a *FileOutputStream* object for writing to the *objects* file, then line 25 instantiates an *ObjectOutputStream* object, which we will use to write the *Flight2* objects to the file.

At lines 27–30, using the *ObjectOutputStream* object *oos*, we call the *writeObject* method, passing the three *Flight2* objects we instantiated. The *writeObject* method takes a *Serializable* object as its parameter, here a *Flight2* object, and writes it to the file in such a way that the stream of bytes can be read using the *readObject* method from the *ObjectInputStream* class. Both the *ObjectOutputStream* constructor and the *writeObject* method can throw an *IOException*, which will be caught at line 41.

After this program is executed, the *objects* file will contain a representation of the three *Flight2* objects.

One more note about writing objects to files: A file containing objects can be quite large. Not only does the object data get written to the file, but also the name of the class, a description of each data field, and other information needed to reconstruct the objects when the file is subsequently read.

The *writeObject* method, however, does not write any *static* class variables to the file. Thus, we may consider declaring any constants as *static*, if appropriate.

The *writeObject* method does not write to the file any instance variable that is declared to be *transient*. Thus, we can save space in the file by declaring an instance variable as *transient*. An instance variable is a good candidate to be declared *transient* if we can easily reproduce its value, or if the variable has a value of 0 at the time the file is created. For example, suppose we have an instance variable whose value can easily be recalculated, we can declare it as *transient*; then, that instance variable will not be written to the object file.

SOFTWARE ENGINEERING TIP

To save disk space when writing to an object file, declare the class data as *static* or *transient* where appropriate.

We declare an instance variable as *transient* by inserting the keyword *transient* between the access modifier and the data type of the instance variable, as in the following syntax:

```
accessModifier transient dataType instanceVariableName
```

Description

11.11.2 Reading Objects from Files

Reading objects from a file somewhat parallels writing objects to a file.

The class *ObjectInputStream*, a subclass of *InputStream*, coupled with *FileInputStream*, provides the functionality we need. The *FileInputStream* class is used to read streams of binary data from a file.

ObjectInputStream is designed to read objects from a file. The *readObject* method, which does not take any arguments, reads the next object from the file and returns it. Because the *readObject* method returns a generic *Object*, we must type cast the returned object to the appropriate class. When the end of the file is reached, the *readObject* method throws an *EOFException*. This is in contrast to the *Scanner* class, which provides the *hasNext* method to test whether the end of the file has been reached.

The classes, constructors, and methods discussed previously are shown in **Table 11.15**.

Useful Classes, Constructors, and Methods for Reading Objects from a File

Classes, Constructors, and Methods for Reading Objects from a File		
Class	**Constructors**	**Exceptions thrown**
`FileInputStream`	`FileInputStream( String filename )` constructs a *FileInputStream* object from a *String* representing the name of a file	`FileNotFoundException`
`ObjectInputStream`	`ObjectInputStream( InputStream in )`	`IOException`

constructs an *ObjectInputStream* from the *InputStream in*

Method API

`ObjectInputStream`	`Object readObject( )`
	reads the next object and returns it. The object must be an instance of a class that implements the *Serializable* interface.When the end of the file is reached, an *EOFException* is thrown
		`IOException,`
		`ClassNotFoundExceptio`
		`EOFException`

Description

Example 11.18 shows how these *FileInputStream* and *ObjectInputStream* classes can be used in a Java program to read objects from a file. We assume that the file *objects* contains *Flight2* objects, as written in the previous section.

Example 11.18 Reading, Filtering, and Processing Objects

```java
/* Demonstrating how to read objects from a file
   Anderson, Franceschi
*/

import java.io.*;
import java.util.ArrayList;

public class ReadingObjectsIntoStream
{
  public static void main( String [ ] args )
  {
    ArrayList<Flight2> flights = new ArrayList<Flight2>( );
    try
    {
      FileInputStream fis = new FileInputStream ( "objects" );
      ObjectInputStream ois = new ObjectInputStream ( fis );

      try
      {
        while ( true )
        {
          // read object, type cast returned object to Flight2
          Flight2 temp = ( Flight2 ) ois.readObject( );

          // add the Flight2 object read to flights
          flights.add( temp );
        }
      } // end inner try block

      catch ( EOFException eofe )
      {
        System.out.println( "End of the file reached" );
      }

      catch ( ClassNotFoundException cnfe )
      {
        System.out.println( cnfe.getMessage( ) );
      }

      finally
      {
        System.out.println( "Closing file" );
        ois.close( );
      }
    } // end outer try block

    catch ( FileNotFoundException fnfe )
    {
      System.out.println( "Unable to find objects" );
    }

    catch ( IOException ioe )
    {
      ioe.printStackTrace( );
    }

    // calculate number of flights originating from BWI
    long count =
      flights.stream( )
             .filter( flight -> flight.origin( ).equals( "BWI" ) )
             .count( );
    System.out.println( "There are " + count + " flights from BWI" );

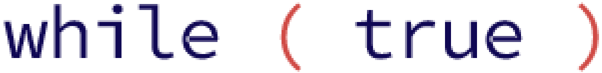
    // calculate average number of passengers on all flights
    double avgNumPassengers =
      flights.stream( )
             .mapToInt( Flight2::numPassengers )
             .average( )
             .getAsDouble( );
    System.out.println( "Average number of passengers: "
                      + avgNumPassengers );
  }
}
```

Description

Lines 5–6 import the needed classes from the *java.io* and *java.util* package. The *ClassNotFoundException* class is part of the *java.lang* package and does not need to be imported.

Line 15 associates a *FileInputStream* object with the *objects* file, and line 16 instantiates an *ObjectInputStream* object for reading the objects from the file.

The *while* loop, from lines 20 to 27, reads and adds each object in the file to the *ArrayList flights*, declared and instantiated at line 12. We continue reading until the *readObject* method throws an *EOFException*, which transfers control to the *catch* block (lines 30–33). Thus, our condition for the *while* loop is



```
while ( true )
```

In that *catch* block, we print a message that the end of the file was detected. Given this *while* loop construction, we do not need a priming read. Inside the *while* loop, we read an object, then print it. When the end of the file is detected, the statement adding the current object to *flights* (line 26) will not be executed.

On line 23, we read an object from the file and assign it to the *Flight2* object reference *temp*. Because the *readObject* method returns an *Object*, we need to type cast the return value to a *Flight2* object. The *readObject* method can also throw a *ClassNotFoundException* or an *IOException*, which will be caught at lines 35 or 52, respectively.

Because an *EOFException* will occur when the end of the file is reached, the *EOFException catch* block will always execute in a normal program run. Thus, any code following the *while* loop in the *try* block will not execute. To close the *objects* file, we use nested *try/catch* blocks. The inner *try* block (lines 18–28) encloses the *while* loop; its associated *catch* blocks handle the *EOFException* and *ClassNotFoundException*. The outer *try* block (lines 13–45) encloses the instantiations of the *FileInputStream* and *ObjectInputStream* objects, the inner *try* block, and the *finally* block where we close the file (line 43). We can close the file in the *finally* block because the *ois* object reference, declared in the outer *try* block, is visible (that is, in scope) inside the *finally* block.

The *catch* blocks following the outer *try* block handle any *FileNotFoundException* and any other *IOExceptions* that occur in the inner or outer *try* blocks.

It is important to place the *catch* clause with the *EOFException* ahead of the *catch* clause with the *IOException*; otherwise, the *EOFException catch* block will never be reached because *EOFException* is a subclass of *IOException*, and therefore will match an *IOException catch* block.

Figure 11.22 shows the console output when this program is executed. Note that after we read the last object in the file and we try to read another object, the code executes the *catch* block for the *EOFException*, then the *finally* block.

Figure 11.22 Output of Example 11.18

Description

At lines 57–62, we chain several method calls to compute and output the number of flights originating from *BWI*. After creating a *Stream* from *flights* at line 59, we filter the *Stream* and keep only the objects whose origin airport is *BWI*. The call to the *filter* method at line 60 is similar to the ones in Example 11.12. Again, we can use a lambda expression because *Predicate*, the parameter of the *filter* method, is a functional interface. This time, each element of the *Stream* is a *Flight2* reference rather than a *String*. With the *flight* reference, we call the *origin* method and compare the returned value to *BWI* as our filtering criteria. At line 61, we call the *count* method to retrieve the number of elements in the *Stream* resulting from the filtering operation.

At lines 64–71, we again chain several method calls to compute and output the average number of passengers for all flights. The call to the *mapToInt* method at line 67 is similar to the call to *mapToDouble* in Example 11.12.

When we have a *Stream* of objects and we want to get an *IntStream* (or *DoubleStream*) for the *int* (or *double*) instance variable values of these objects, we specify the method of the objects’ class using the following double colon notation in place of a lambda expression:

```
ClassName::methodName
```

Because we want to access an *IntStream* consisting of the number of passengers for all the flights, we use the *numPassengers* method of the *Flight2* class, and we write:

```
Flight2::numPassengers
```

Thus, in order to retrieve the average number of passengers, we first retrieve the *IntStream* of number of passengers at line 67 and call the *average* method at line 68.

Check: Amount = -$500.00

Your current account balance = -$500.00

11.12 Programming Activity 2: Reading Objects from a File

In this activity, you will read objects from a file and perform this activity:

> Read an object file containing bank account transaction objects. Loop through all the objects and calculate the new balance of the bank account. Assume that we do not know the number of transaction items, that is, objects, in the file.

Notice that this activity is identical to Programming Activity 1, except that the transactions you will read are stored in the file as objects.

The framework will display the current transaction and current balance so that you can check the correctness of your code as the program executes.

For example, **Figure 11.23** demonstrates the animation: We are currently scanning a check transaction for the amount of $500.00. The original balance was $0.00 and the new balance is now –$500.00.

Figure 11.23 Animation of a $500 Check and the New Balance

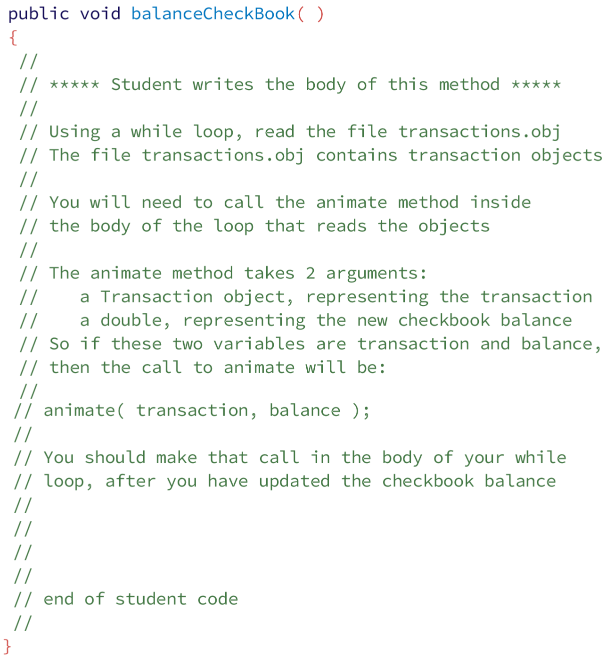
Description

Task Instructions: Reading from the transactions.obj File

In this chapter's folder in the supplied code, you will find a Programming Activity 2 folder. Copy the contents of the folder onto a folder on your computer.

- Open the *AccountingDrawing.java* file. Search for five asterisks (*****) to find the *balanceCheckBook* method where you will add your code. The method header has been coded for you. Write the code to read the transactions from the *transactions.obj* file, and calculate the balance after all the transactions in that file have been executed. This program first writes *Transaction* objects to the file *transactions.obj*; that code is provided. You need to code the body of the *balanceCheckBook* method in order to read that file. **Example 11.19** shows the student code section of the *AccountingDrawing.java* file.

Example 11.19 The *balanceCheckBook* Method



```
public void balanceCheckBook( )
{
  //
  // ***** Student writes the body of this method *****
  //
  // Using a while loop, read the file transactions.obj
  // The file transactions.obj contains transaction objects
  //
  // You will need to call the animate method inside
  // the body of the loop that reads the objects
  //
  // The animate method takes 2 arguments:
  //    a Transaction object, representing the transaction
  //    a double, representing the new checkbook balance
  // So if these two variables are transaction and balance,
  // then the call to animate will be:
  //
 // animate( transaction, balance );
 //
 // You should make that call in the body of your while
 // loop, after you have updated the checkbook balance
 //
 //
 //
 //
 // end of student code
 //
}
```

Description

- Begin with a checkbook balance of 0.00.
- To process the transactions, you will need to read one *Transaction* object at a time from the *transactions.obj* file; you will retrieve the transaction amount using the *getAmount* method of the *Transaction* class. The API for that method is:

```
public double getAmount( )
```

Description

- Then process the transaction; you do not need to check the type of transaction. Just add the amount to the checkbook balance.
- After you have processed each transaction, call the *animate* method. This method belongs to the *Accounting* class, so you will call *animate* without using an object reference. The API of the *animate* method is the following:

```
public void animate( Transaction currentTransaction,
                     double currentBalance )
```

Description

As you can see, the *animate* method takes two arguments:

- *currentTransaction* is the current *Transaction* object
- *currentBalance* is the current balance of the checkbook

Assuming that you have a *Transaction* object reference called *transactionObject* and a *double* called *balance*, a call to *animate* will look like the following:

```
animate( transactionObject, balance );
```

Description

- When you call *animate*, the window will display the current transaction graphically. It will also display the transaction amount (red if negative, blue if positive) and the current checkbook balance (in black). By adding the previous checkbook balance to the current transaction amount, you will be able to compute the current checkbook balance and check that your program is correct.
- Stop reading from the file when you reach the end of the file. You will need to set up a *catch* block to handle the *EOFException* that occurs when the end of the file is reached.

To test your code, compile and run the *AccountingApplication.java* application file.

If you have time …

- Modify the *initialize* method of the *AccountingController* class, adding another transaction. Run the program again and verify that your code still yields the correct result. To add another transaction, you could, for instance, write this code:

```
Withdrawal w2 = new Withdrawal( -200.00 );
transactionList.add( w2 );
```

Description

You can add a transaction of type *Check, Withdrawal, Deposit,* or *Unknown-Transaction* (all of which are subclasses of the *abstract* class *Transaction*).

Troubleshooting

If your method implementation does not animate or animates incorrectly, check these items:

- Verify that you have coded the call to *animate* at the proper time.
- Verify that you have coded the condition for exiting the loop correctly.
- Verify that you have coded the body of the loop correctly.

DISCUSSION QUESTIONS

1. Explain why we cannot simply read the *transactions.obj* file as a text file.
2. Explain why we need to type cast each object that we read from the file.

```
Enter your email address > mary.jb.com
Email address does not contain @
```

```
Enter your email address > john@jb.com
Your host is jb.com
```

11.13 User-Defined Exceptions

There will be times when we want to design our own exception class because the predefined Java exception classes do not fit our needs.

Suppose we are interested in designing a class encapsulating email addresses. We will call that class *EmailAddress*. To keep things simple, we will say that a legal email address is a *String* containing the @ character. In order to prevent instantiation of objects with illegal email addresses, we will design our *EmailAddress* constructor so that it throws an exception if its argument, a *String*, does not contain the @ character.

To do that, we first design an exception class that encapsulates an illegal email exception. We call our class *IllegalEmailException* and we will *throw* an exception when the argument to the *EmailAddress* constructor does not contain the

@ character. Oracle recommends that user-defined exceptions be checked exceptions.

More generally, when a user-defined exception class is defined as a subclass of an existing Java exception class, such as *Exception*, *IOException*, or *FileNotFoundException*, our class inherits the functionality of the existing exception class, which simplifies coding the new class. We extend the *Exception* class so that our exception is checked and we can associate a specific error message with the exception. We need to code only the constructor, and the constructor's job is to pass our message to the constructor of the superclass.

Thus, the general pattern of a user-defined exception class is:

```
public class ExceptionName extends ExistingExceptionClassName
{
  public ExceptionName( String message )
  {
    super( message );
  }
}
```

Description

Example 11.20 shows our *IllegalEmailException* class.

Example 11.20 The *IllegalEmailException* Class.

```
 1 /* The IllegalEmailException class
 2    Anderson, Franceschi
 3 */
 4
 5 public class IllegalEmailException extends Exception
 6 {
 7   public IllegalEmailException( String message )
 8   {
 9     super( message );
10   }
11 }
```

Description

The constructor for the class is coded at lines 7 to 10; it takes a *String* parameter and simply passes it to the superclass constructor.

The pattern for a method that *throws* a user-defined exception is:

```
accessModifier dataType methodName( parameter list )
                        throws ExceptionName
{
  if ( parameter list is legal )
      // process the parameter list
  else
      throw new ExceptionName( "Some message here" );
}
```

Description

The message we pass to the *ExceptionName* constructor will identify the type of error we detected. When a client program catches the exception, the client can call the *getMessage* method of the exception class in order to retrieve that message.

Example 11.21 shows our *EmailAddress* class.

Example 11.21 The *EmailAddress* Class

```
 1 /* The EmailAddress class
 2    Anderson, Franceschi
 3 */
 4
 5 public class EmailAddress
 6 {
 7   public static final char AT_SIGN = '@';
 8   private String email;
 9
10   public EmailAddress( String email )
11                      throws IllegalEmailException
12   {
13     if ( email.indexOf( AT_SIGN ) != - 1 )
14          this.email = email;
15     else
16          throw new IllegalEmailException
17                ( "Email address does not contain " + AT_SIGN );
18   }
19
20   public String getHost( )
21   {
22     int index = email.indexOf( AT_SIGN );
23     return email.substring( index + 1, email.length( ) );
24   }
25 }
```

Description

We coded the constructor at lines 10–18. We test if the constructor's parameter, *email*, contains the character *AT_SIGN* (a constant equal to the @character) at line 13. If it does, we proceed normally and initialize the instance variable *email* at line 14. If it does not, we throw an *IllegalEmailException* with the appropriate message at lines 16–17. In addition to the constructor, we coded the *getHost* method at lines 20–24. The *getHost* method returns the substring comprising the characters of *email* after *AT_SIGN*. Thus, for an email address of *myEmailAddress@yahoo.com*, the *getHost* method will return *yahoo.com*.

Now that we have built our own exception class and a class including a method that *throws* that exception, we are ready to use them in a client program. This is identical to using a predefined Java exception. **Example 11.22** shows our *EmailChecker* class.

Example 11.22 The *EmailChecker* Class

```
 1 /* The EmailChecker class
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6
 7 public class EmailChecker
 8 {
 9   public static void main( String [ ] args )
10   {
11     Scanner scan = new Scanner( System.in );
12     System.out.print( "Enter your email address > " );
13     String myEmail = scan.next( );
14     try
15     {
16       EmailAddress address = new EmailAddress( myEmail );
17       System.out.println( "Your host is " + address.getHost( ) );
18     }
19     catch ( IllegalEmailException iee )
20     {
21       System.out.println( iee.getMessage( ) );
22     }
23   }
24 }
```

Description

We ask the user to input an email address, *myEmail*, at lines 12–13. We then try to instantiate the *EmailAddress* object *address* at line 16, passing *myEmail* to the constructor. If *myEmail* does not contain the @ character, our *EmailAddress* constructor *throws* an *IllegalEmailException*, which we *catch* at line 19. In this *catch* block, we print the message the *EmailAddress* constructor sent to the *IllegalEmailException* constructor. If *myEmail* contains the @ character, we continue executing inside the *try* block. **Figure 11.24** shows two runs of this example; the first generates the exception, the second completes without generating an exception.

Figure 11.24 Two Sample Runs of Example 11.22

Description

CODE IN ACTION

Within the online resources, you will find a movie with a step-by-step illustration of *try* and *catch* blocks. Click on the link to start the movie.

CHAPTER REVIEW

11.14 Chapter Summary

- Java provides exception classes so that unexpected, illegal operations at run time can be trapped and handled. This provides the programmer with a tool to keep the program running instead of terminating.
- When calling a constructor or method that *throws* a checked exception, we must use *try* and *catch* blocks; otherwise, the code will not compile.
- For calls to a constructor or method that *throws* an unchecked exception *try* and *catch* blocks are optional. If *try* and *catch* blocks are not used, the exception will be caught at run time by the Java Virtual Machine.
- When a *try* block assigns a value to a variable and that variable is used after the *try/catch* block, the variable must be initialized before the *try* block is entered.
- A variable defined inside a *try* block is local to that block.
- The *java.io* package contains classes for input and output operations.
- In order to read from a file, that file must exist; otherwise, a *FileNotFoundException* will be thrown.
- When we open a file for writing, the file is created if it does not exist. If the file already exists, the contents of the file are deleted.

- When we open a file for appending, the file is created if it does not exist. If the file already exists, we start writing at the end of the file.
- The *Scanner* class in the *java.util* package is helpful in parsing a *String* consisting of fields separated by one or more delimiters.
- A *Record* class provides a very simple way to write a class whose only purpose is to store data.
- The *FileWriter* and *PrintWriter* classes provide functionality to write primitive data types to a text file.
- The *Stream* interface includes functionality to perform aggregate sequential and parallel operations on a collection of elements.
- We can use the *Path* and *Files* classes to convert file contents to a *Stream*. An *ArrayList* can also be converted to a *Stream*.
- Many methods of the *Stream* interface accept one parameter whose type is from a functional interface. In this case, we can use a lambda expression when calling such a method.
- We can use the *URL*, *InputStream*, and *Scanner* classes in order to read data from a remote resource.
- Data in remote sites are often formatted using XML or JSON. The *org.json* package includes classes, such as *JSONObject* and *JSONArray*, that provide the functionality to parse a JSON string.
- Objects can be written to a file; they must be instantiated from a class that *implements* the *Serializable* interface.
- The *Serializable* interface has no methods; therefore, no additional methods need to be implemented in a class that *implements* the *Serializable* interface.
- The *FileOutputStream* and *ObjectOutputStream* classes provide functionality to write objects to a file.
- To avoid writing class data to a file of objects, declare the data as *static* or *transient*, where appropriate.
- *The FileInputStream* and *ObjectInputStream* classes provide the functionality to read objects from a file.

- The *readObject* method returns the object read as an *Object* class reference. That object reference must be type cast to the appropriate class.
- To define our own exception, we create a class that extends an existing exception class. This class will consist of a constructor that accepts a message and passes the message to the superclass constructor.
- The method that will generate the exception includes the *throws* clause in the method header. If the invalid condition is detected, the method *throws* a new object of the user-defined exception.

11.15 Exercises, Problems, and Projects

11.15.1 Multiple Choice Exercises

1. Why are *try/catch* blocks useful?

    - They can replace selection statements, thus saving CPU time.
    - *try/catch* blocks enable programmers to attempt to recover from illegal situations and continue running the program.

4. Some methods that *throw* an exception require *try* and *catch* blocks, while some do not.

    - true
    - false

7. What keyword is found in the header of a method that could detect an error and generate an appropriate exception?

    - *throw*
    - *throws*
    - *exception*
    - *exceptions*

12. When coding a *try* and *catch* block, it is mandatory to code a *finally* block.

    - true
    - false

15. Most input- and output-related classes can be found in the package

- *java.file*
- *java.inputoutput*
- *java.io*
- *java.readwrite*

20. If we open a file for reading and the file does not exist,

    - there is a compiler error.
    - an exception is thrown.
    - the file will be created automatically.

24. When we open a file for writing,

    - we will be adding data at the end of the file.
    - the contents of the file, if any, will be deleted.
    - there is a run-time error if the file does not exist.

28. When we open a file for appending,

    - we will be adding data at the end of the file.
    - the contents of the file, if any, will be deleted.
    - there is a run-time error if the file does not exist.

32. What is the keyword for a class whose purpose is only to store data?

    - Object
    - Record
    - Data

36. What method can we use to convert an *ArrayList* to a *Stream*?

    - *convert*
    - *stream*
    - *toStream*

40. Which interface must be implemented by a class whose objects will be written to a file directly?

   - none
   - *Serializable*
   - *IO*
   - *Object*

11.15.2 Reading and Understanding Code

1. Assuming the file *words.txt* holds the following data:
   CS1 Java Illuminated
   what is the output of this code sequence:
   a. if the file is found?
   b. if the file is not found?

```
 try
 {
   Scanner file = new Scanner( new File( "words.txt" ) );

   String result = "";

   while ( file.hasNext( ) )
   {
     String s = file.next( );

     result += s;
     result += " AND ";
   }
   System.out.println( "result is " + result );
   file.close( );

 }
catch ( FileNotFoundException fnfe )
{
   System.out.println( "Unable to find words.txt" );
}
catch ( IOException ioe )
{
   ioe.printStackTrace( );
}
```

   Description

2. What is the output of this code sequence?

```
Scanner parse = new Scanner( "A B C D" );
while ( parse.hasNext( ) )
   System.out.print( parse.next( ) );
```

Description

3. What is the output of this code sequence?

```
Scanner parse = new Scanner( "AA:BB:CC" );
parse.useDelimiter( ":" );
while ( parse.hasNext( ) )
    System.out.println( parse.next( ) );
```

Description

4. What is the output of this code sequence?

```
Scanner parse = new Scanner( "oneANDtwoANDthreeANDfour" );
parse.useDelimiter( "AND" );
while ( parse.hasNext( ) )
   System.out.println( parse.next( ) );
```

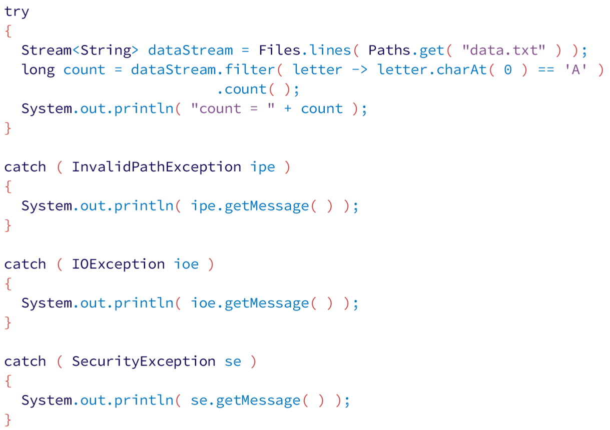
Description

For Questions 16, 17, 18, and 19, you should assume that the file *data.txt* contains the following text:

```
A
B
C
A
B
A
```

Description

1. What is the output of this code sequence?



```
try
{
  Stream<String> dataStream = Files.lines( Paths.get( "data.txt" ) );
  long count = dataStream.filter( letter -> letter.charAt( 0 ) == 'A' )
                         .count( );
  System.out.println( "count = " + count );
}

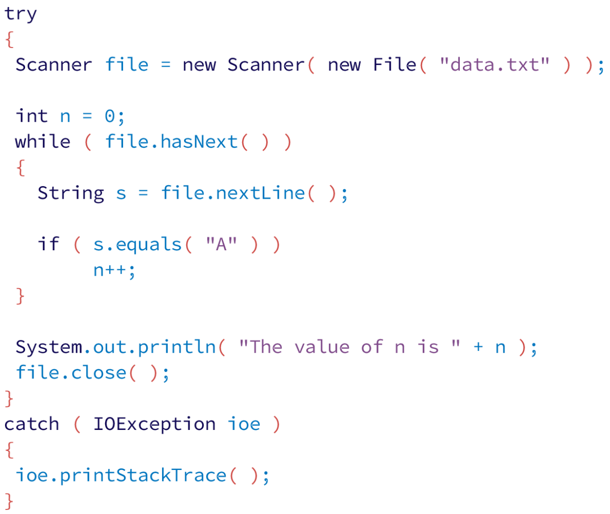
catch ( InvalidPathException ipe )
{
  System.out.println( ipe.getMessage( ) );
}

catch ( IOException ioe )
{
  System.out.println( ioe.getMessage( ) );
}

catch ( SecurityException se )
{
  System.out.println( se.getMessage( ) );
}
```

Description

2. What is the output of this code sequence?



```
try
{
 Scanner file = new Scanner( new File( "data.txt" ) );

 int n = 0;
 while ( file.hasNext( ) )
 {
   String s = file.nextLine( );

   if ( s.equals( "A" ) )
        n++;
 }

 System.out.println( "The value of n is " + n );
 file.close( );
}
catch ( IOException ioe )
{
 ioe.printStackTrace( );
}
```

Description

3. What is the output of this code sequence?

```
try
{
  Scanner file = new Scanner( new File( "data.txt" ) );

  while ( file.hasNext( ) )
  {
    String s = file.nextLine( );
    if ( s.equals( "A" ) )
         System.out.println( "Excellent" );
    else if ( s.equals( "B" ) )
         System.out.println( "Good" );
    else
         System.out.println( "Try to do better" );
  }
  file.close( );
}
catch ( IOException ioe )
{
  ioe.printStackTrace( );
}
```

Description

4. What is the output of this code sequence?

```
try
{
 Scanner file = new Scanner( new File( "data.txt" ) );

 String s = "";
 while ( file.hasNext( ) )
 {
   s = file.nextLine( );
 }

 if (  s.equals( "A" ) )
   System.out.println( "Nice finish" );
  file.close( );
 }
 catch ( IOException ioe )
 {
   ioe.printStackTrace( );
 }
```

Description

5. The file *data.txt* contains the following text:

```
CS1
```

What does the file *data.txt* contain after this code sequence is executed?

```
try
{
 FileWriter fw = new FileWriter( "data.txt", true );
 PrintWriter pw = new PrintWriter( fw );

 pw.println( "Java Illuminated" );
 pw.close( );
}
catch ( IOException ioe )
{
 ioe.printStackTrace( );
}
```

Description

6. The file *data.txt* contains the following text:

```
CS1
```

What does the file *data.txt* contain after this code sequenced is executed?

```
try
{
 FileWriter fw = new FileWriter( "data.txt", false );
 PrintWriter pw = new PrintWriter( fw );

 String s = "ABCDEFGH";

 for ( int i = 0; i < s.length( ); i++ )
 {
   if ( i % 2 == 0 )
     pw.print( s.charAt( i ) );
 }
 pw.println( );
 pw.close( );
}
catch ( IOException ioe )
{
 ioe.printStackTrace( );
}
```

Description

7. The file *data.txt* contains the following text:

```
CS1
```

What does the file contain after the following code sequence is executed?

```
try
{
 FileWriter fw = new FileWriter( "data.txt", true );
 PrintWriter pw = new PrintWriter( fw );

 for ( int i = 0; i < 5; i++ )

     pw.println( i );
  pw.close( );
 }
 catch ( IOException ioe )
 {
   ioe.printStackTrace( );
 }
```

Description

8. What does the file *data.txt* contain after the following code sequence is executed?

```
try
{
 FileWriter fw  = new FileWriter( "data.txt", false );
 PrintWriter pw = new PrintWriter( fw );

 int s = 0;
 for ( int i = 0; i < 5; i++ )
 {
   s += i;
 }
 pw.print( "The result is " );
 pw.print( s );
 pw.close( );
}
catch ( IOException ioe )
{
  ioe.printStackTrace( );
}
```

Description

11.15.3 Fill In the Code

1. This code segment reads a file named *data.txt* that contains one data item per line, and outputs only the data items that are integers. Hint: You may need to use nested *try* and *catch* blocks.

```
String s = "";
int n = 0;
try
{
   Scanner file = new Scanner( new File( "data.txt" ) );
   while ( file.hasNext( ) )
   {
      s = file.nextLine( );
      // your code goes here
   }
}
catch ( IOException ioe )
{
 ioe.printStackTrace( );
}
```

Description

2. This code retrieves the "*C* " in the string "*A-B-C-D*" using *Scanner* and outputs it:

```
Scanner parse = new Scanner( "A-B-C-D" );
parse.useDelimiter( "-" );
String s = "";
// your code goes here

System.out.println( s );
```

Description

For Questions 26–29, you should assume that the file *data.txt* contains the following:

Java Illuminated: Programming Is Not A Spectator Sport

Description

3. This code sequence reads the first two lines of the file *data.txt* and outputs them to the console.

```
try
{
  Scanner file = new Scanner( new File( "data.txt" ) );
  // your code goes here
```

Description

4. This code sequence reads the file *data.txt* and outputs the lowest *String* in lexicographic order to the console. Assume that *data.txt* contains one word per line.

```
try
{
  Stream<String> dataStream = Files.lines( Paths.get( "data.txt" ) );
  // your code goes here

}
catch ( InvalidPathException ipe )
{
  System.out.println( ipe.getMessage( ) );
}
catch ( IOException ioe )
{
  System.out.println( ioe.getMessage( ) );
}
catch ( SecurityException se )
{
  System.out.println( se.getMessage( ) );
}
```

Description

5. This code sequence reads the file *data.txt*, concatenates all the lines with a space between them, and outputs them as:

```
Java Illuminated: Programming Is Not A Spectator Sport
```

```
try
{
  Scanner file = new Scanner( new File( "data.txt" ) );

  String result = "";
  // your code goes here

}
catch ( IOException ioe )
{
  ioe.printStackTrace( );
}
```

Description

6. This code sequence reads the file *data.txt* and outputs only the lines that start with the *String* “*Sp*”. Assume that we do not know the contents of the file before reading it.
For the current example, the output will be:

```
Spectator
Sport

try
{
  Scanner file = new Scanner( new File( "data.txt" ) );

  String result = "";
  // your code goes here

}
catch ( IOException ioe )
{
  ioe.printStackTrace( );
}
```

Description

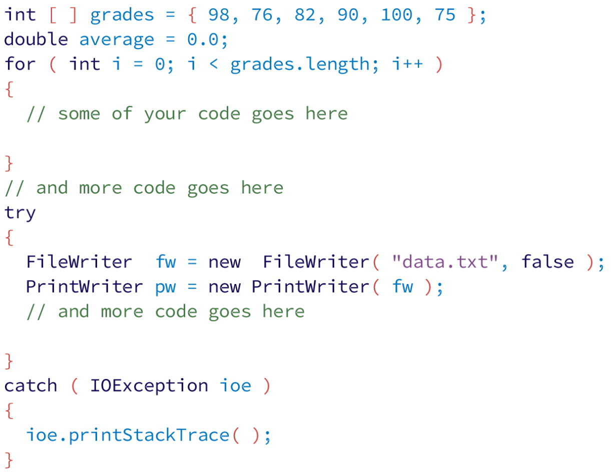
7. This code sequence loops through the array *grades* and writes all its elements to the file *data.txt*, one per line:

```
int [ ] grades = { 98, 76, 82, 90, 100, 75 };
try
{
  FileWriter fw = new FileWriter( "data.txt", false );
  // your code goes here

}
// and your code continues here
```

Description

8. This code sequence loops through the array *grades*, calculates the average, and writes the average to the file *data.txt*:



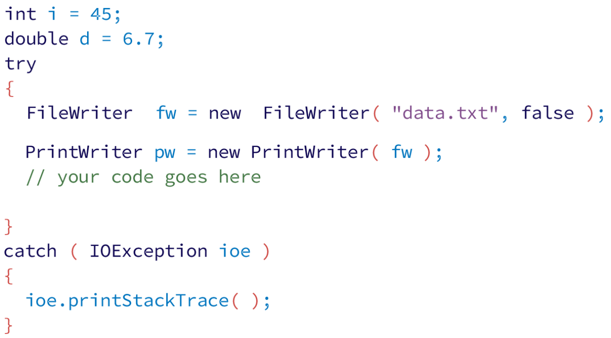
```
int [ ] grades = { 98, 76, 82, 90, 100, 75 };
double average = 0.0;
for ( int i = 0; i < grades.length; i++ )
{
  // some of your code goes here

}
// and more code goes here
try
{
  FileWriter  fw = new  FileWriter( "data.txt", false );
  PrintWriter pw = new PrintWriter( fw );
  // and more code goes here

}
catch ( IOException ioe )
{
  ioe.printStackTrace( );
}
```

Description

9. This code sequence writes the values of the variables *i* and *d* to the file *data.txt*, one line at a time.



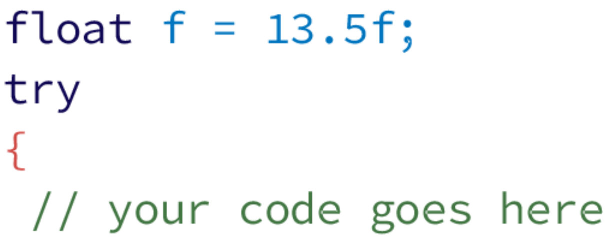
```
int i = 45;
double d = 6.7;
try
{
  FileWriter  fw = new  FileWriter( "data.txt", false );

  PrintWriter pw = new PrintWriter( fw );
  // your code goes here

}
catch ( IOException ioe )
{
  ioe.printStackTrace( );
}
```

Description

10. This code sequence appends the value of the variable *f* to the file *data.txt*:



```
float f = 13.5f;
try
{
  // your code goes here
```

Description

11.15.4 Identifying Errors in Code

1. Where is the error in this code sequence?

   ```
   Scanner parse = new Scanner( "1 2 3" );
   int i = parse.next( );
   ```

   Description

2. Where is the error in this code sequence?

   ```
   try
   {
     Scanner file = new Scanner( new File( "data.txt" ) );
     String s = file.nextLine( );
   }
   catch ( ArithmeticException ae )
   {
     System.out.println( ae.getMessage( ) );
   }
   ```

   Description

3. Where is the error in this code sequence?

   ```
   try
   {
     Scanner file = new Scanner( new File( "data.txt" ) );
     file.write( "Hello" );
   }
   catch ( IOException ioe )
   {
     ioe.printStackTrace( );
   }
   ```

   Description

11.15.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

1. You coded the following in the class *Test.java*:

```
import java.io.IOException;
import java.io.File;
import java.util.Scanner;
public class Test
{
  public static void main( String [ ] args )
  {
      try // line 9
      {

            Scanner file = new Scanner( new File( "data.txt" ) );

            String stringRead = file.nextLine( );
            System.out.println( stringRead );
      }
  }
}
```

Description

At compile time, you get the following error:

```
Test.java:9: error: 'try' without 'catch', 'finally' or resource
declarations
   try    // line 9
   ^
1 error
```

Description

Explain what the problem is and how to fix it.

2. You coded the following in the class *Test.java*:

```
import java.io.IOException;
import java.io.File;
import java.util.Scanner;

public class Test
{
  public static void main( String [ ] args )
  {
      try
      {
       Scanner file = new Scanner( new File( "data.txt" ) );

       String stringRead = file.nextLine( );
      }
      catch ( IOException ioe )
      {
       ioe.printStackTrace( );
      }
      System.out.println( "string read: " + stringRead );
      // line above is 19
   }
}
```

Description

At compile time, you get the following error:

```
Test.java:19: error: cannot find symbol
   System.out.println( "string read: " + stringRead );
                                         ^
symbol:   variable stringRead
location: class Test
1 error
```

Explain what the problem is and how to fix it.

3. You coded the following in the class *Test.java*:

```
import java.io.IOException;
import java.io.File;
import java.util.Scanner;
public class Test
{
  public static void main( String [ ] args )
  {
    String stringRead;
    try
    {
     Scanner file = new Scanner( new File( "data.txt" ) );

     stringRead = file.nextLine( );
    }
    catch ( IOException ioe )
    {
     ioe.printStackTrace( );
    }
    System.out.println( "string read: " + stringRead );
    // line above is line 21
 }
}
```

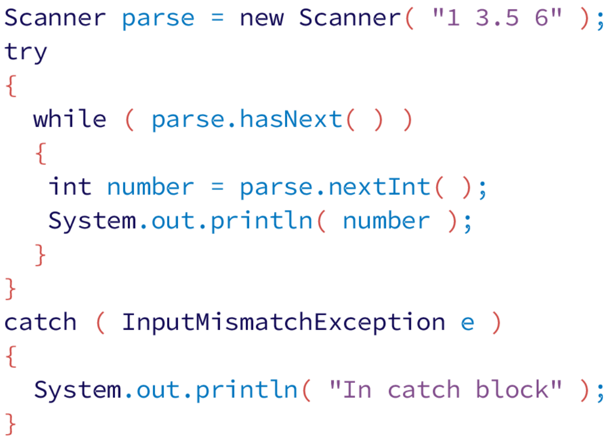
At compile time, you get the following error:

```
Test.java:21: error: variable stringRead might not have been
initialized
System.out.println( "string read: " + stringRead );
                                      ^
1 error
```

Description

Explain what the problem is and how to fix it.

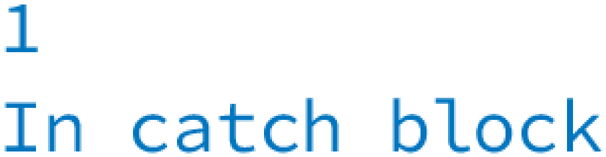
4. You coded the following in the class *Test.java*:



```
Scanner parse = new Scanner( "1 3.5 6" );
try
{
  while ( parse.hasNext( ) )
  {
   int number = parse.nextInt( );
   System.out.println( number );
  }
}
catch ( InputMismatchException e )
{
  System.out.println( "In catch block" );
}
```

Description

The code compiles and runs, but the result is:

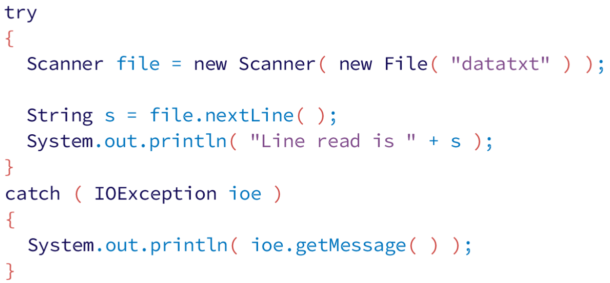


```
1
In catch block
```

Description

Explain why the *catch* block executes and change the data so that all the numbers are processed.

5. In order to read from the file *data.txt*, you coded the following in the *Test.java* class:



```
try
{
  Scanner file = new Scanner( new File( "datatxt" ) );

  String s = file.nextLine( );
  System.out.println( "Line read is " + s );
}
catch ( IOException ioe )
{
  System.out.println( ioe.getMessage( ) );
}
```

Description

The code compiles and runs, but here is the output:

```
datatxt (The system cannot find the file specified)
```

Description

Explain what the problem is and how to fix it.

6. You coded the following in the class *Test.java*:

```
import java.io.*;

public class Test
{
 public static void main( String [ ] args )
 {
   FileWriter fw = new FileWriter( "data.txt", false );
   PrintWriter pw = new PrintWriter( fw );

   pw.println( "hi" );
   pw.close( );
 }
}
```

Description

At compile time, you get the following error:

```
Test.java:7: error: unreported exception IOException; must be
caught or declared to be thrown
   FileWriter  fw = new  FileWriter ( "data.txt", false);
                    ^
1 error
```

Description

Explain what the problem is and how to fix it.

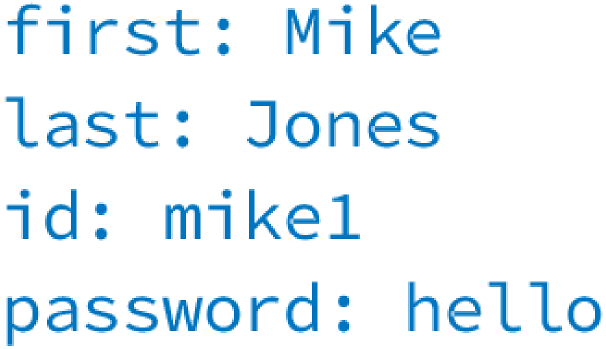
11.15.6 Write a Short Program

1. Write a program that reads a file and writes a copy of the file to another file with line numbers inserted.
2. In Internet programming, programmers receive parameters via a query string, which looks like a *String* with fields separated by the “&” character. Each field typically has a metadata part that identifies the data followed by an equals sign and then the data. An example of a query string is:

```
first=Mike&last=Jones&id=mike1&password=hello
```

Description

Using *Scanner* at least once, parse a query string and output each field on a different line after replacing the equal sign with a colon followed by a space. For example, for the preceding sample query string, the output should be:



```
first: Mike
last: Jones
id: mike1
password: hello
```

Description

3. Write a program that reads a file that contains only one line; output all the characters, one character per line.
4. Write a program that reads a file and counts how many lines it contains.
5. Write a program that reads a text file that contains a grade (for instance, 87) on each line. Calculate and print the average of the grades.
6. Write a program that reads a text file and writes to a file every line of the file separated by a blank line.
7. Modify Example 11.15 and output to the console the number of movies that start with a given character. Allow the user to input a character and output the number of movies that start with that character.
8. Often websites display the visitor count ("You are visitor number 5246"). Write a program that reads a file that holds the visitor count, outputs it, and updates the file, incrementing the visitor count by 1.

9. Often on websites, the beginning of an article is displayed followed by the word more and several dots (as in *more*…). Write a graphical application that reads the first two lines of a file, and displays them inside a window, adding the word *more* in blue followed by three dots.

11.15.7 Programming Projects

1. Design a class that checks if a *String* is made of tokens of the same data type (for this, you may only consider four data types: *boolean, int, double*, or *char*). This class has two instance variables: the *String* of data and its delimiter. Other than the constructor, you should include a method, *checkTokens,* that takes one parameter, representing the data type expected (for example, 0 could represent *boolean*, 1 could represent *int*, 2 could represent *double*, and 3 could represent *char*). The method returns *true* if all the tokens in the *String* are of the specified data type; otherwise, it returns *false*.
2. We are interested in checking the number of times a given word (for example, the word *secret*) appears in a file. You should assume that lines do not wrap, that is, a line does not continue on the next line. Warning: You could have letters arranged like *secsecret*. Design a class that encapsulates that idea. Test it with a client program.
3. Design a class that checks if the contents of two text files are identical and, if not, determines how many lines are different. Lines are different if they differ in one or more characters. Test your class with a client program.

4. Design a class that encapsulates the contents of a text file. Include the following methods in your class: *numberOfLinesInFile*, *longestLineInFile* (the line number of the line containing the maximum number of characters), *shortestLineInFile*, and *averageNumberOfCharactersPerLine*. Test your class with a client program.
5. Alter Example 11.7 so that *Scanner* will use a comma and semicolon as delimiters. Hint: you will need to use a *Pattern*.
6. A file contains web addresses, one on each line. Design a class that encapsulates the concept of counting the number of college addresses (contains *.edu*), government addresses (contains *.gov*), business addresses (contains *.com*), organization addresses (contains *.org*), or other addresses. Test your class with a client program.
7. In cryptograms, each character is encoded into another. If

the text is long enough, one can, as a strategy, use the frequency of occurrence of each character. The most frequently occurring character will likely be the code for an *e*, because *e* is the most frequently used letter of the English alphabet. Design a class that attempts to determine the relative frequency of each letter by reading a file and keeping track of the number of times each of the 26 English alphabet characters appears. Also provide methods, such as *highestFrequencyCharacter* and *lowestFrequencyCharacter*. Test your class with a client program.

8. Design a class that calculates statistics on data in a file. We expect the file to contain grades represented by integer values, one per line. If you encounter a value that is not an integer, you should throw an exception, print a message to the console, skip that value, and continue processing. Store the grades that you read in an *ArrayList* so that all the grades are available for retrieval. You should also have, as a minimum, methods that return the grade average, the highest grade, the lowest grade, and ones that return all the grades as an array of letter grades. Test your class with a client class.
9. Write a *Record* class encapsulating the concept of a home, assuming that it has the following attributes: the number of rooms, the square footage, and whether it has a basement. Write a client program that creates five *Home* objects, writes them to a file as objects, then reads them from the file as objects, outputs a description of each object using the *toString* method, and outputs the number of *Home* objects. When reading the objects, you should assume that you do not know the number of objects in the file.

10. Using *Streams*, output the number of the following in a Java file: constructors, *public* variables or methods, *private* variables or methods, *static* variables or methods. Assume that the words *public*, *private*, and *static* can appear at most once per line. Also output if the number of opening curly braces is equal to the number of closing curly braces. Also assume that there can be only one opening or closing curly brace per line at the most.

11.15.8 Technical Writing

1. Are exceptions a good thing or a bad thing? Argue both sides.
2. With respect to writing objects to and reading objects from a file, discuss the importance of documenting your code well.

11.15.9 Group Project (for groups of 2, 3, or more students)

1. A friend of yours owns two houses at Football City, the site of the next Super Bowl. Your friend wants to rent those two houses for the Friday, Saturday, and Sunday of the Super Bowl weekend. House #1 has 3BR (3 bedrooms), 3BA (3 baths), and house #2 has 1BR, 1BA.

   For this project, concurrency is not an issue; you should assume that two customers will never access your system at exactly the same time. You should also assume that the management-sid014"TX">This friend has asked you to build a file-based reservation system enabling the following:

   A. Management-side software:

   Your friend controls the rental price and may change it every day. He/she sends you a change file every day; this file may be empty, in which case there are no pricing changes. If the file is not empty, pricing has changed (for one or more houses, or for one or more days). You are in charge of this project, and therefore, you are in charge of specifying the file format; however, this must be a simple text file because your friend is not a computer person.

You do not have to simulate the act of sending the file by your friend; you should assume that the file is a text file in your directory and that you only need to read the data.

Your management-side software needs to read this file and update a different file, with which you control the reservation system. You can create your own design for the structure of that file. Of course, prices for existing reservations cannot be changed.

Finally, your management-side software should write to a file the status of the reservations; that is, which house is rented to whom, when, and for what price.

B. Customer-side software:

The customer-side software allows a customer to make a reservation. You should prompt the customer for a possible reservation, offering whatever house is available, when, and at what price. Do not offer a customer a house that is already rented.

In this simple version, a customer makes and pays for the reservation at the same time. Also, a reservation cannot be cancelled. When a reservation is made, the customer-side software automatically updates the file controlling the reservations.

Introduction

Small problems are easier to solve than big ones, with or without the help of a computer. For example, it is easy to see that 14 is a multiple of 7, but determining if 12,348 is a multiple of 7 requires some thinking . . . or a well-programmed computer.

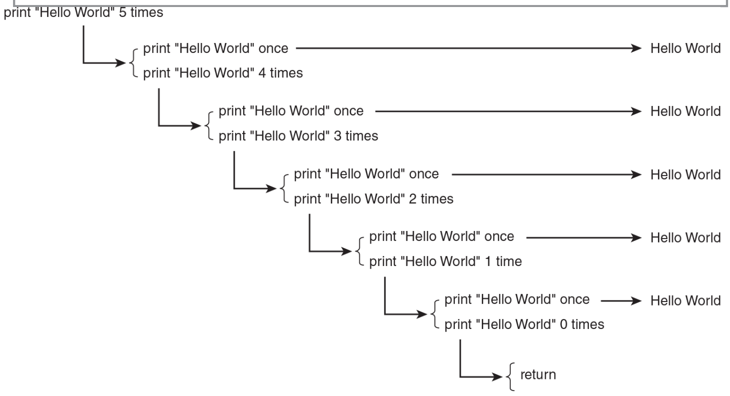
If we knew that 12,341 is a multiple of 7, then it would be easy to determine that 12,348 is also a multiple of 7, because 12,348 is simply 12,341 + 7. But then, it is not that easy to determine that 12,341 is a multiple of 7. But again, if we knew that 12,334 is a multiple of 7, then it would be easy to determine that 12,341 is also a multiple of 7, because 12,341 is simply 12,334 + 7. Well, if we keep subtracting 7 from the current number, eventually, either we will arrive at 0, which means that 12,348 is a multiple of 7, or we will arrive at a number less than 7 but not 0, which means that 12,348 is not a multiple of 7. Thus, we have reduced a large problem to a small problem that is easy to solve.

The idea of **recursion** is to reduce the size of a problem at each step so that we eventually arrive at a very small, easy-to-solve problem. That easy-to-solve problem is called the **base case**. The formula that reduces the size of the problem is called the **general case**. The general case takes us from solving a bigger problem to solving a smaller problem.

A method that uses recursion calls itself. In other words, in the body of a **recursive method**, there is a call to the method itself. The arguments passed are smaller in value (that is, they get us closer to the base case) than the original arguments. The recursive method will keep calling itself with arguments that are smaller and smaller in value, until eventually we reach the base case.

Any problem that can be solved recursively can also be solved using a loop, or iteration. Often, however, a recursive solution to a problem provides simpler, more elegant, and more compact code than its iterative counterpart.

```
Hello World
Hello World
Hello World
Hello World
Hello World
```



print "Hello World" 5 times
print "Hello World" once
print "Hello World" 4 times
Hello World
print "Hello World" once
print "Hello World" 3 times
Hello World
print "Hello World" once
print "Hello World" 2 times
Hello World
print "Hello World" once
print "Hello World" 1 time
Hello World
print "Hello World" once
print "Hello World" 0 times
Hello World
return

12.1 Simple Recursion: Identifying the General and Base Cases

When designing a recursive solution for a problem, we need to do two things:

- define the base case
- define the rule for the general case

For example, if we want to print “Hello World” 100 times, we can do the following:

- print “Hello World” once
- print “Hello World” 99 times

Note that we do two things: First, we print “Hello World” once, which is easy to do. Then we reduce the size of the remaining problem to printing “Hello World” 99 times. In order to print “Hello World” 99 times, we print “Hello World” once, then we print “Hello World” 98 times. Continuing the same approach, to print “Hello World” 98 times, we print “Hello World” once, then we print “Hello World” 97 times, and so on. Eventually, we will reach a point where we print “Hello World” once, then print “Hello World” 0 times. Printing “Hello World” 0 times is an easy-to-solve problem; we simply do nothing. That is our base case for this problem.

Thus, our general approach to printing “Hello World” *n* times (where *n* is greater than 0) is to print “Hello World” once, and then print “Hello World” *n* 2 1 times. As we reduce the number of times we print “Hello World,” we will eventually reach 0, the base case. This condition is easy to detect. Thus, we can solve the large problem by reducing the problem to smaller and smaller problems until we find a problem that we know how to solve.

The following pseudocode illustrates the approach for our recursive method.

```
void printHelloWorldNTimes( int n )
{
   if ( n is greater than 0 )
   {
       print "Hello World"
       printHelloWorldNTimes( n - 1 )
   }
   // else do nothing
}
```

Description

When *n* is greater than 0, we will execute the body of the *if* statement, printing “Hello World” once, then printing it *n* 2 1 times. This is the general case for this problem. We can see that we are going from a problem of size *n* (print “Hello World” *n* times) to a problem of size (*n* 2 1) (print “Hello World” *n* 2 1 times).

When *n* is 0 (or less), we do nothing; that is, the call to *printHelloWorldNTimes* with an argument of 0 does not generate any action. This is the base case, and this is when the recursive calls will end.

Example 12.1 shows this method.

Example 12.1 Recursively Printing “Hello World” *n* Times

```
 1  /* Printing Hello World n times using recursion
 2     Anderson, Franceschi
 3  */
 4
 5  public class RecursiveHelloWorld
 6  {
 7    public static void main( String [ ] args )
 8    {
 9       // print "Hello World" 5 times using our recursive method
10       printHelloWorldNTimes( 5 );
11    }
12
13    // the recursive method
14    public static void printHelloWorldNTimes( int n )
15    {
16     if ( n > 0 )
17     {
18      // print "Hello World" once
19      System.out.println( "Hello World" );
20
21      // now print "Hello World" ( n - 1 ) times
22      printHelloWorldNTimes( n - 1 );
23     }
24     // if n is 0 or less, do nothing
25    }
26  }
```

Description

We coded the *printHelloWorldNTimes* method from line 13 to line 25. That method prints “Hello World” *n* times, where *n* is an *int*, the only parameter of the method. We test at line 16 for the general case: *n* is greater than 0. There is no *else* clause: if *n* is 0 or less, we have reached the base case and the method does nothing.

The code for the general case is executed at lines 18–22. At line 19, we print “Hello World” once. At line 22, we make a recursive call to the *printHelloWorldNTimes* method in order to print “Hello World” (*n* 2 1) times. The method calls itself, but with an argument that is 1 less than its argument *n*.

SOFTWARE ENGINEERING TIP

If the method does nothing in the base case, it is important to document that fact to show when the recursive calls will end.

On line 10, we call the *printHelloWorldNTimes* method, passing the argument 5. Because *main* is *static*, it can call only *static* methods; therefore, we need to define our *printHelloWorldNTimes* method as *static*. In general, recursive methods can be defined as *static* or *nonstatic*.

Figure 12.1 shows the output of Example 12.1. As we can see, “Hello World” is indeed printed five times. **Figure 12.2** illustrates how the recursive calls are executed and the output resulting from the calls.

12.2 Recursion with a Return Value

In the preceding example, we coded a very simple method. Now let’s look at some examples that are a little more complex, with recursive methods that return a value.

In a value-returning method, the *return* statement can include a call to another value-returning method, as in:

```
public static int multiplyAbsoluteValueBy3( int n )
{
   return ( 3 * Math.abs( n ) );
}
```

Description

In this case, the *multiplyAbsoluteValueBy3* method cannot return its value until the *abs* method returns a value, allowing the expression in the *return* statement to be fully evaluated.

The same principle applies to a value-returning method that is recursive. The return value of the recursive method often consists of an expression that includes a call to the method itself.

Thus, in the general case of the method, we could see code like:

```
  return ( expression including a recursive call to the method );
```

Description

Each execution of the recursive method must wait to return its value until its recursive call to the method returns a value. When the base case is reached, the method simply returns a value without making another recursive call. At that point, the method that invoked the method with the base case argument receives its return value, which allows that method to return a value to its caller, and so on, until the method is able to return a value to the initial caller. In this way, the return values unravel up to the initial caller.

To see how this works, let's look at an example of a recursive method that returns a value.

12.2.1 Computing the Factorial of a Number

We will define a recursive method to compute and return the factorial of a positive integer.

The factorial of a positive number is defined as follows:

$$\text{factorial}(n) = n! = n * (n-1) * (n-2) * (n-3) * \ldots * 2 * 1$$

Description

The factorial of a negative number is not defined. The factorial of 0, by convention is 1.

$$\text{factorial}(0) = 0! = 1$$

Description

Let's define the base case and the general case for computing the factorial of a number.

In order to define the rule for the general case, we need to find a relationship between the problem at hand (computing the factorial of a number *n*), and a smaller, similar problem, involving, for example, (*n* 2 1), (*n* 2 2), or other smaller values of *n*. So, here we will try to establish a relationship between factorial(*n*) and factorial(*n* 2 1), factorial(*n* 2 2), and so on.

Let's first examine what the value of factorial(*n* 2 1) is. Applying the preceding formula, we get:

$$\text{factorial}(n-1)=(n-1)!=(n-1)*(n-2)*(n-3)*\ldots*2*1$$

Description

As we can see from the preceding formulas, there is a very simple relationship between factorial(*n*) and factorial(*n* 2 1):

$$\text{factorial}(n)=n*\text{factorial}(n-1)$$

Description

This is the relationship we will use for the formulation of the general case.

Using this formula, at each step we reduce the size of the problem (measured by the value of the input *n*) from *n* to (*n* 2 1). In order to compute factorial(*n*), we will call the factorial method with the argument (*n* 2 1) and multiply the returned value by *n*. The call to the factorial method with the argument (*n* 2 1) will generate a recursive call to the factorial method with argument (*n* 2 2), until eventually we generate a recursive call to the factorial method with the argument 0. We know how to compute factorial (0): by convention, it is 1. That is our base case and we have reached it. We will return 1, which will allow the unraveling of the recursive method calls until we solve the original problem, factorial(*n*).

Example 12.2 shows the code for calculating a factorial recursively. In order to keep things simple, we will also return 1 if the argument sent to the method is negative. However, we are careful in documenting our method to emphasize that the argument should be greater than or equal to 0. If we do not want to return anything when a negative argument is passed to the method, we would need to throw an exception, because the method is a value-returning method.

Example 12.2 Computing a Factorial Using Recursion

```
 1 /* Computing the factorial of a number using recursion
 2    Anderson, Franceschi
 3 */
 4
 5 public class RecursiveFactorial
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     // compute factorial of 5 and output it
10     System.out.println( "Factorial( 5 ) is "
11                          + factorial( 5 ) );
12   }
13
14   /** recursive factorial method
15   *   @param    n  a positive integer
16   *   @return      the factorial of n
17   */
18   public static int factorial( int n )
19   {
20     if ( n <= 0 ) // base case
21       return 1;
22     else                // general case
23       return ( n * factorial( n - 1 ) );
24   }
25 }
```

Description

Here is how our *factorial(int n)* method will work:

- Base case: if *n* is negative or 0, the method returns 1
- General case: if *n* is greater than 0, the method returns *n* * *factorial*(*n* 2 1)

At lines 10–11, we make the initial call to the *factorial* method and print the result. We simply compute the factorial of 5. We can modify the example to prompt the user for another value.

We coded the *factorial* method at lines 14–24. The *factorial* method takes an *int* parameter named *n*, and returns the factorial of *n* as an *int*. At line 20, we test if *n* is less than or equal to 0. If that is true, we have reached the base case, and the *factorial* method returns 1. If *n* is greater than 0, the code skips to line 23, where we have coded the general case. We make a recursive call to the *factorial* method with an argument of (*n* 2 1). The value returned by that recursive call is then multiplied by *n* and the result is returned.

Figure 12.3 shows the output of Example 12.2.

Figure 12.3 Output of Example 12.2

Description

We can verify that factorial(5) is 120. Indeed,

$$5! = 5 * 4 * 3 * 2 * 1 = 120$$

Description

To illustrate how recursive method calls are processed and their values are returned, let's modify Example 12.2 to include some output statements inside the *factorial* method. In this way, we can trace the recursive calls.

The JVM manages method calls using a **stack**. When a method is called, the JVM places the method's arguments and the caller's return address in a **frame** on the stack in a last-in, first-out order. Each method invocation adds another frame to the top of the stack. When a method completes and returns to the caller, its frame is removed from the top of the stack and is discarded. To help us trace the processing of recursive calls, we will use the *StackWalker* class, introduced in Java 9, which allows us to display the current contents of the stack at each invocation of the recursive method.

Example 12.3 is similar to Example 12.2 except that we have added statements to trace these features.

Example 12.3 Tracing Recursive Calls of the *factorial* Method

```java
/* Tracing the calculation of the factorial
   of a number using recursion
   Anderson, Franceschi
*/
import java.util.List;
import java.util.stream.Collectors;

public class RecursiveFactorialWithStackTrace
{
  public static void main( String [ ] args )
  {
    // compute factorial of 5 and output it
    System.out.println( "\nFactorial( 5 ) is "
                      + factorial( 5 ) );
  }

  /** recursive factorial method
  *   @param   n  a positive integer
  *   @return   the factorial of n
  */
  public static int factorial( int n )
  {
    List<StackWalker.StackFrame> stack = StackWalker.getInstance( )
             .walk( s -> s.skip(1).collect( Collectors.toList( ) ) );

    System.out.println( "factorial( " + n + " ) called" );
    System.out.println( "\tCurrent Stack" );
    for ( StackWalker.StackFrame f : stack )
      System.out.println( "\t\t" + f.getLineNumber( ) + " "
                                 + f.getMethodName( ) );

    if ( n == 0 )  // base case
    {
      System.out.println( "\nBase case detected\n" );

      System.out.println( "factorial( " + n + " ) returning 1" );
      System.out.println( "\tCurrent Stack"  );
      for ( StackWalker.StackFrame f : stack )
        System.out.println( "\t\t" + f.getLineNumber( ) + " "
                                   + f.getMethodName( ) );

      return 1;
    }
    else        // general case
    {
      int factorialNMinus1 = factorial( n - 1 );

      System.out.println( "factorial( " + n + " ) returning "
                           + n + " * " + factorialNMinus1 );
      System.out.println( "\tCurrent Stack"  );
      for ( StackWalker.StackFrame f : stack )
        System.out.println( "\t\t" + f.getLineNumber( ) + " "
                                   + f.getMethodName( ) );

      return ( n * factorialNMinus1 );
    }
  }
}
```

Description

- each call to the factorial method and its argument
- the detection of the base case and the value returned at that point
- the expression that evaluates to the return value
- the current stack at each method invocation

The *factorial* method is coded at lines 17–57.

When the method begins executing, we capture the current state of the stack into a *List* of *StackWalker.StackFrame* elements at lines 23–24. We get the current stack by calling the *getInstance* method of the *StackWalker* class. We then call the *walk* method, also in the *StackWalker* class, which creates a **stream** of stack frames. Streams, introduced in Java 8, are sequences of elements to which aggregate functions can be applied. The *walk* method, using a lambda expression, then traverses the stream, calling the *Stream collect* method, which calls on the *Collectors' static toList* method to accumulate the stack frames into a list. We skip the first frame, (*skip(1)*), because the first frame represents the method call to create the list.

The *StackWalker* class is in *java.lang*, so we do not need an *import* statement. On lines 5–6, we import the *List* interface and the *Collectors* class from *java.util* and *java.util.stream*, respectively.

At line 26, we output a message indicating that the *factorial* method has been called, along with the parameter value. When the base case is detected, we output a message indicating that the method has reached the base case and report its return value (lines 34–36). For the general case, we output the expression that will be returned by the method (lines 48–49). At each of these places, we also output the current state of the stack, displaying for each stack frame the line number from which the method was called and the name of the method. On lines 27–30 we output the stack when the *factorial* method starts executing. On lines 37–40 we output the stack when the method has detected the base case and is returning a known value (1), and on lines 50–53 we output the stack after the method makes a recursive call in the general case.

Figure 12.4 shows the output of Example 12.3. We can see the recursive calls to the *factorial* method with the value of the argument being reduced by 1 until the base case, 0, is reached. At that point, each recursively called method, in turn, returns a value to its caller until the initial invocation of the method returns the value 120. We also see that each time we detect the general case, another invocation of the *factorial* method is added to the stack. Once the base case is reached, the *factorial* methods on the stack start returning their value, and as they complete, the frame for their method invocation is removed from the stack.

Figure 12.4 The Trace of the *factorial* Method (*continues*)

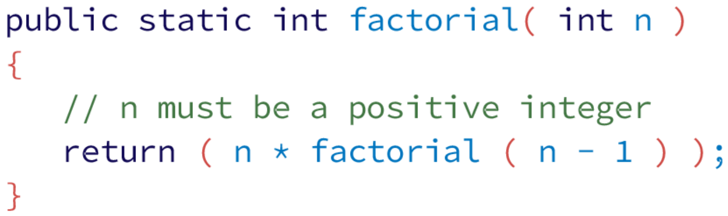
Description

Identifying the base case is critical. If a recursive method never reaches a base case, the method continues calling itself indefinitely, causing the JVM to continue placing frames on the stack until memory for the stack is full. At this time, the JVM generates a *StackOverflowError*, which terminates the program.

COMMON ERROR TRAP

Failure to code the base case will result in a run-time error.

For example, if we did not code the base case in our *factorial* method, the method would look like the following:



```
public static int factorial( int n )
{
   // n must be a positive integer
   return ( n * factorial ( n - 1 ) );
}
```

Description

When the method is called, the recursive calls keep being made because the base case is never reached. This eventually generates a *StackOverflowError*. **Figure 12.5** shows the first few lines of output from a run of Example 12.2 (the *RecursiveFactorial* class) with lines 20 to 22 commented out.

Figure 12.5 The First Few Lines of a Run of Example 12.2 If the Base Case Is Not Coded

Description

12.2.2 Computing the Greatest Common Divisor

A common algebra problem is to calculate the greatest common divisor, or **gcd**, of two positive integers. The gcd is the greatest positive integer that divides evenly into both numbers.

For example, consider 50 and 20. We can figure in our head that 5 divides evenly into both numbers, but so does 10. Since we can't find a number greater than 10 that divides evenly into both numbers, 10 is the gcd of 50 and 20.

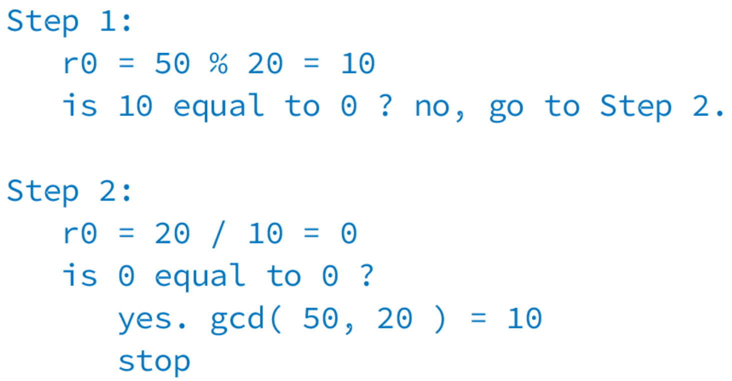
It is easy to guess the gcd of two small numbers, but it is more difficult to guess the gcd of two large numbers, such as 474 and 162. The following Euclidian algorithm finds the gcd of two positive integers *a* and *b*. This algorithm derives from the fact that the gcd of two integers *a* and *b* (with *a* > *b*) is the same as the gcd of *b* and the remainder of *a* / *b*.

```
Step 1:
  r0 = a % b
  if ( r0 is equal to 0 )
      gcd ( a, b ) = b
      stop
  else
      go to step 2

Step 2:
  repeat step 1 with b and r0, instead of a and b.
```

Description

Let's run the algorithm on our first example, 50 and 20. We substitute 50 for *a* and 20 for *b*.



```
Step 1:
    r0 = 50 % 20 = 10
    is 10 equal to 0 ? no, go to Step 2.

Step 2:
    r0 = 20 / 10 = 0
    is 0 equal to 0 ?
        yes. gcd( 50, 20 ) = 10
        stop
```

Description

Therefore, the gcd of 50 and 20 is 10.

Let's now run the algorithm on our second example, 474 and 162.

The remainder of 474 divided by 162 is 150
150 is not equal to 0
so we take the remainder of 162 divided by 150, which is 12
12 is not equal to 0
so we take the remainder of 150 divided by 12, which is 6
6 is not equal to 0
so we take the remainder of 12 divided by 6, which is 0
0 is equal to 0
so the gcd of 474 and 162 is 6

Let's go back to our algorithm and look at Step 1 as a method taking two parameters, *a* and *b*. Step 2 is a method call to Step 1 with two different parameters, *b* and *r*0. It is very simple to calculate *r*0, since *r0* is the remainder of the division of *a* by *b*. Using the modulus operator, *r*0 is *a % b*. Therefore, this algorithm can easily be coded as a recursive method.

Let's call the two parameters of the method, *dividend* and *divisor*, in that order.

When the remainder of the division of *dividend* by *divisor* is 0, we have reached the base case and the method returns *divisor*. The general case is when the remainder of the division of *dividend* by *divisor* is not 0. The method then calls itself with *divisor* and the remainder of the division of *dividend* by *divisor*.

Example 12.4 shows the code for the recursive implementation of the greatest common divisor solution.

Example 12.4 Computing the GCD of Two Integers Using Recursion

```
 1 /* Computing the greatest common divisor using recursion
 2    Anderson, Franceschi
 3 */
 4
 5 public class RecursiveGCD
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     // compute and output gcd of 474 and 162
10     System.out.println( "The GCD of " + 474 + " and "
11                          + 162 + " is " + gcd( 474, 162 ) );
12   }
13
14   /** recursive gcd method
15   *   @param    dividend  the first strictly positive integer
16   *   @param    divisor   the second strictly positive integer
17   *   @return             the gcd of dividend and divisor
18   */
19   public static int gcd( int dividend, int divisor )
20   {
21     if ( dividend % divisor == 0 )     // base case
22       return divisor;
23     else                               // general case
24       return ( gcd ( divisor, dividend % divisor ) );
25   }
26 }
```

Description

We make the call to the *gcd* method at lines 10–11 with arguments 474 and 162 and output the result.

The *gcd* method is coded from lines 14–25. The method header shows that the *gcd* method takes two *int* parameters named *dividend* and *divisor*, and returns an *int*, the greatest common divisor of *dividend* and *divisor*. At line 21, we check for the base case by testing if the remainder of the integer division of *dividend* by *divisor* is 0. If so, the *gcd* method returns *divisor* without making another recursive call.

If the remainder is not 0, we are in the general case, so we make a recursive call at line 24 with the arguments *divisor* and the remainder of the division (*dividend % divisor*). We return the value returned by that call.

Figure 12.6 shows the output of Example 12.4.

Figure 12.6 Output of Example 12.4

Description

As we did with the recursive *factorial* method, let's modify Example 12.4 to include some output statements inside the *gcd* method in order to trace the recursive calls.

The *gcd* method in **Example 12.5** (lines 16–60) is the same as the *gcd* method in Example 12.4, except that each time the method is called, we print the parameter values and result of the modulus operation (lines 27–29) to verify that the method is correctly detecting the general and base cases. We also print a message when the base case is reached (lines 37–38). At lines 49–51, we output the value returned by the method in the general case. As in Example 12.3, at each of these places, we also output the current state of the stack (lines 30–33, 39–42, and 53–56), displaying for each stack frame the line number from which the method was called and the name of the method.

Example 12.5 Tracing the Recursive Calls of the *gcd* Method

```java
/* Computing the greatest common divisor using recursion
   Anderson, Franceschi
*/
import java.util.List;
import java.util.stream.Collectors;

public class RecursiveGCDWithStackTrace
{
  public static void main( String [ ] args )
  {
    // compute gcd of 474 and 162 and output it
    System.out.println( "\nThe GCD of " + 474 + " and "
                         + 162 + " is " + gcd( 474, 162 ) );
  }

  /** recursive gcd method with trace
   *   @param    dividend   the first strictly positive integer
   *   @param    divisor    the second strictly positive integer
   *   @return              the gcd of dividend and divisor
  */
  public static int gcd( int dividend, int divisor )
  {
    List<StackWalker.StackFrame> stack = StackWalker.getInstance( )
           .walk( s -> s.skip(1).collect( Collectors.toList( ) ) );

    System.out.print( "gcd( " + dividend + ", " + divisor + " )" );
    System.out.println( "   " + dividend + " % " + divisor + " = "
                         + ( dividend % divisor ) );
    System.out.println( "\tCurrent stack" );
    for ( StackWalker.StackFrame f : stack )
      System.out.println( "\t\t" + f.getLineNumber( )
                            + " " + f.getMethodName( ) );

    if ( dividend % divisor == 0 )  // base case
    {
      System.out.println( "\nbase case reached, returning "
                           + divisor );
      System.out.println( "\tCurrent stack" );
      for ( StackWalker.StackFrame f : stack )
        System.out.println( "\t\t" + f.getLineNumber( )
                            + " " + f.getMethodName( ) );

      return divisor;
    }
    else                           // general case
    {
      int temp = gcd( divisor, dividend % divisor );
      System.out.println( "gcd( " + divisor + ", "
                          + ( dividend % divisor )
                          + " ) returning " + temp );

      System.out.println( "\tCurrent stack" );
      for ( StackWalker.StackFrame f : stack )
        System.out.println( "\t\t" + f.getLineNumber( )
                            + " " + f.getMethodName( ) );

      return temp;
    }
  }
}
```

Description

Figure 12.7 shows the output of Example 12.5. We can see the recursive calls all the way to the base case, and the return value from each recursive call. We also see that each time we detect the general case, we call the *gcd* method recursively, and the current method is added to the stack because the current method cannot complete until the invoked method returns. Once the base case is reached, the *gcd* methods on the stack start returning their value. One by one each method completes and its stack frame is removed from the stack. Note that the return value stays the same throughout the process. Such a recursive method is called **tail recursive** because the method does no further processing when the recursive call returns.

Figure 12.7 The Trace of the *gcd* Method

Description

CODE IN ACTION

```
C( 5, 2 ) = 10
```

12.3 Recursion with Two Base Cases

Recursive formulations can be more complex than the examples we have discussed. The general case can involve more than one recursive call, with different arguments. This, in turn, means that we can have more than one base case.

Suppose we are playing a networked video game online. There are *n* players who would like to play. Unfortunately, that game can be played with only *p* players. We will make the assumption that *p* is an integer between 0 and *n* (for instance, *n* could be 100 and *p* could be 8). Otherwise, we simply cannot play the game.

Our problem is to determine how many different ways we can choose *p* players from among *n* players. We will call that number *Combinations(n, p)*.

The math formula for *Combinations*(*n, p*) is:

$$Combinations(n, p) = n!/((n - p)! * p!)$$

Our goal here is to come up with a recursive solution to the problem and thus to code *Combinations*(*n, p*) recursively.

There are some obvious cases to consider. If we have the same number of players as the number who can play the game, then *p* equals *n*, and we pick all the players. There is only one way to do that, so *Combinations*(*n, n*) = 1.

If the game requires no players, then *p* equals 0, and we do not pick any players. Again, there is only one way to do that, so *Combinations*(*n*, 0) = 1.

But what is the answer in the general case where the value of *Combinations*(*n, p*) may not be so obvious?

One way to look at that problem is as follows:

Among these *n* potential players, let’s focus on one player in particular. We will call that player Louis. We can either pick Louis or not pick Louis. Therefore, the total number of possibilities of picking *p* players among *n* potential players is equal to the sum of the following two numbers:

- the number of possibilites of picking *p* players, including picking Louis, among *n*
- the number of possibilities of picking *p* players, without picking Louis, among *n*

If we pick Louis, then we will have to choose (*p* 2 1) more players. But we cannot pick Louis again, so there are only (*n* 2 1) potential players left. The number of such possibilities is *Combinations(n 2 1, p 2 1)*.

If we do not pick Louis, then we still have to choose *p* players. But since we are not picking Louis, there are only (*n* 2 1) potential players left. The number of such possibilities is *Combinations(n 2* 1*, p)*.

Therefore, we can write the following recursive formula:

```
Combinations( n, p ) = Combinations( n - 1, p - 1 )
                       + Combinations( n - 1, p )
```

Description

If we look at the two terms on the right side of the preceding formula, we can see that:

- In the first term, both parameters, *n* and *p*, have been decreased by 1.
- In the second term, one parameter, *n*, has been decreased by 1, while *p* is unchanged.

Therefore, solving the problem of computing *Combinations*(*n, p*) using this formula translates into solving two similar, but smaller, problems. That is our general case.

Our next concern is to decide what the base case or cases are. In other words, as we apply the preceding formula repeatedly, when will we reach an easy-to-solve problem? Since we have two recursive terms on the right side of the formula, we will have two base cases.

Let's look at the first term, *Combinations*(*n – 1, p – 1*). We can see that both *n* and *p* decrease by 1 at the same time. When we start, *p* is greater than or equal to 0 and less than or equal to *n*. Therefore, as we keep applying the formula and concentrate on the first term, we can see that *p* will eventually reach 0, and that *p* will reach 0 before *n* does. As discussed earlier, *Combinations*(*n*, 0) = 1, because there is only one way to pick 0 players from a set of *n* players—do not pick any. This is one base case.

Let's now look at the second term, *Combinations*(*n* – 1, *p*). We can see that *n* decreases by 1 while *p* is unchanged. We know that *p* must be less than or equal to *n* (we cannot pick more than *n* players among *n* players). As *n* decreases and *p* does not, *n* will eventually reach *p*. As discussed earlier, *Combinations*(*n, n*) = 1, because there is only one way to pick *n* players among *n* players—pick them all. This is our other base case.

Example 12.6 shows the code for this example.

Example 12.6 Computing Combinations Recursively

```
/* Computing the number of combinations
   of picking p objects among n, using recursion
   Anderson, Franceschi
*/

public class RecursiveCombinations
{
  public static void main( String [ ] args )
  {
    // compute and output number of combinations
    System.out.println( "C( 5, 2 ) = "
                         + combinations( 5, 2 ) );
  }

  /** recursive combinations method
  *   @param    n a positive number
  *   @param    p a positive number, less than or equal to n
  *   @return   the number of combinations of choosing p among n
  */
  public static int combinations( int n, int p )
  {
    if ( p == 0 )           // base case # 1
      return 1;
    else if ( n == p )      // base case # 2
      return 1;
    else                    // general case
      return ( combinations( n - 1, p - 1 )
              + combinations( n - 1, p ) );
  }
}
```

Description

In this example, we use the *combinations* method to compute the number of ways of picking 2 players from among 5.

We call the *combinations* method with arguments, 5 and 2, and output the returned value at lines 11–12.

The *combinations* method is coded at lines 15–29. The method header, at line 20, shows that the *combinations* method takes two *int* parameters, the number of players (*n*) and the number of players to select (*p*). The return value, an *int*, is the number of combinations of picking *p* players among *n*.

At line 22, we test for the first base case (*p* == 0). If true, we return 1. If *p* is not equal to 0, we test for the second base case (*n* is equal to *p*). If that is *true*, we return 1. If *p* is not equal to 0 and *n* is not equal to *p*, then we are in the general case and the code skips to lines 27–28. We make two recursive calls to the *combinations* method. The first recursive call is with arguments *n* – 1 and *p* – 1. The second recursive call is with arguments *n* – 1 and *p*. We add the values returned by these two recursive calls and return the result.

The output of Example 12.6 is shown in **Figure 12.8**.

Figure 12.8 Output of Example 12.6

Description

We can verify that our algorithm is correct. As discussed earlier,

$$Combinations(n,p) = n!/\,((\,n-p\,)!*p!)$$

Description

Thus,

$$Combinations(\,5,2\,) = 5!/\,(\,3!*2!) = 10$$

Description

Those of us with a mathematics background can verify that

```
Combinations( n, p ) = Combinations( n - 1, p - 1 ) +
                       Combinations( n - 1, p )
```

Description

that is,

```
n! / ( ( n - p )! * p! ) = ( n - 1 )! / ( ( n - p )! * ( p - 1 )! )
                          + ( n - 1 )! / ( ( n - 1 - p )! * p! )
```

Description

What happens if we code for only one base case when there are two or more base cases?

COMMON ERROR TRAP

There can be more than one base case. Failing to take into account all base cases can result in a *StackOverflowError* at run time.

When the method is called, the recursive calls will continue to be made, because the missing base cases will never be detected. This will eventually generate a *StackOverflowError*.

           here
```

Your result: "able was i here i saw elba" is not a palindrome

The correct result: "able was i here i saw elba" is not a palindrome

12.4 Programming Activity 1: Checking for a Palindrome

In this activity, you will work with recursion to perform this function:

Code a recursive method to determine if a *String* is a palindrome.

A palindrome is a word, phrase, or sentence that is symmetrical; that is, it is spelled the same forward and backward. Examples are “otto,” “mom,” “madam,” and “able was I ere I saw elba.”

How can we determine, using recursion, whether a *String* is a palindrome?

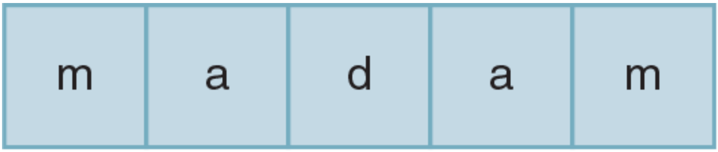
If the *String* has two or more characters, we can check if the first and last characters are identical. If they are not identical, then the *String* is not a palindrome. That is a base case.

If the first and last characters are identical, then we need to check if the substring comprised of all the characters between the first and last characters is a palindrome. That is the general case.

If the *String* is a palindrome, each recursive call will reduce the size of the argument—that is, the number of characters in the argument *String*—by 2. Eventually, the recursive calls will result in a *String* argument consisting of 0 or 1 character. Both are trivial palindromes. That is our second base case. Note that we will reach this base case only if the *String* is a palindrome. Indeed, if the *String* is not a palindrome, the recursive calls will detect the first base case as soon as the first and last characters of the *String* argument are different, and the recursive method will return *false*.

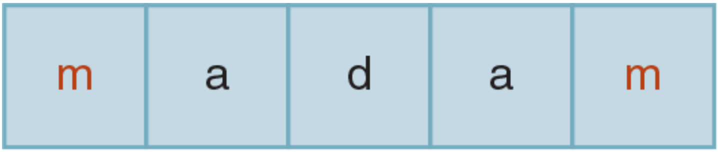
For example, to check if “madam” is a palindrome, we take the following steps.

Here is the original *String*:



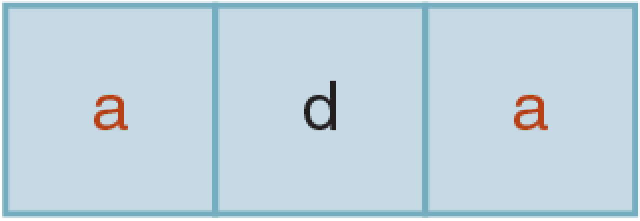
m	a	d	a	m

We compare the first and last characters.



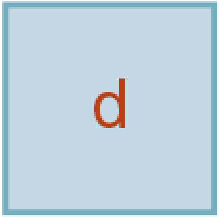
m	a	d	a	m

They are equal, so we now check the substring comprised of the characters between the first and last characters. Again, we compare the first and last characters of this substring.



a	d	a

They are equal, so we now check the substring comprised of the characters between the first and last characters.

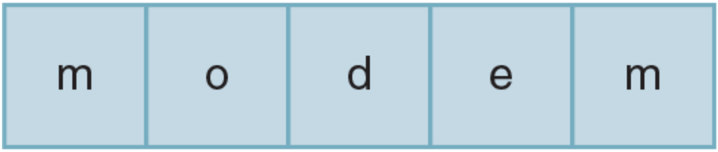


d

There is only one character in this substring, so we have reached our second base case. The *String* “madam” is a palindrome.

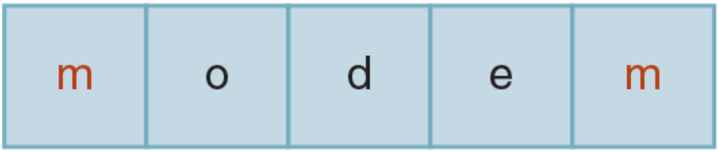
Let’s now check if “modem” is a palindrome.

Here is the original *String*:



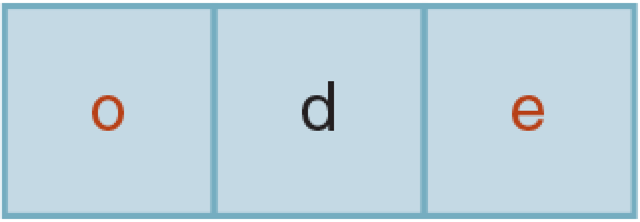
m	o	d	e	m

We compare the first and last characters.



m	o	d	e	m

They are equal, so we now check the substring comprised of the characters between the first and last characters. Again, we check the first and last characters.



o	d	e

They are not equal, so we have reached the first base case. The *String* “modem” is not a palindrome.

Instructions

In this chapter's Programming Activity 1 folder, you will find the source files needed to complete this activity. Copy all of the files to a folder on your computer. Note that all files should be in the same folder.

Open the *PalindromeDrawing.java* source file. Searching for five asterisks (*****) in the source code will position you to the location where you will add your code. In this task, you will fill in the code inside the *recursivePalindrome* method to determine if a *String* representing a word or a sentence is a palindrome. The method returns *true* if the *String* is a palindrome, *false* if the *String* is not a palindrome. **Example 12.7** shows the section of the *PalindromeDrawing* source code where you will add your code.

Example 12.7 Location of Student Code in *PalindromeDrawing*

```
public boolean recursivePalindrome( String pal )
{
  // ***** Student writes the body of this method *****

  // Using recursion, determine if a String representing
  // a word or a sentence is a palindrome
  // If it is, return true, otherwise return false

  // We call the animate method inside the body of this method
  // The call to animate is already coded below

  animate( pal );

  //
  // Student code starts here
  //

  return true; // replace this dummy return statement

  //
  // End of student code - PA 1
  //
}
```

Description

The framework will animate your code so that you get some feedback on the correctness of your code. It will display the argument *String* passed to the recursive method at each recursive call of that method. Your result will be displayed in red and the correct result will be displayed in green.

To test your code, compile *PalindromeDrawing.java* and run *PalindromeApplication*. When the program begins, you will see a text box in which to enter a word or a sentence, as shown in **Figure 12.9**.

Figure 12.9 Opening Window

Description

Click “check” to animate your code.

If you enter an empty *String* or a *String* with more than 26 characters, the text box will display “enter 1–26 characters”. This part is already coded for you.

Figure 12.10 shows the output if you enter “able was I ere I saw elba.” We can see the argument *String* of our recursive method shrinking by two characters at each recursive call until we reach a base case.

Figure 12.10 Sample Final Screen for Programming Activity 1 When a Palindrome Is Found

Description

If you insert an extra “h” into the preceding phrase, and enter “able was I here I saw elba,” which is not a palindrome, the final result of your animation is shown in **Figure 12.11**. When the argument *String* of our recursive method becomes “here,” the recursive calls stop and the method returns *false*.

Figure 12.11 Sample Final Screen for Programming Activity 1 When a Palindrome Is Not Found

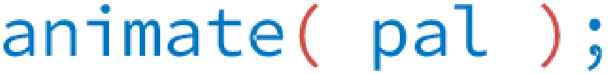
Description

Task Instructions

Inside the method *recursivePalindrome* of class *PalindromeDrawing* write the code to solve the palindrome problem:

- The *recursivePalindrome* method header has already been coded for you. Write the code to check if the parameter of the method, *pal*, is a palindrome. Return *true* if it is, *false* if it is not. Your method should be recursive; that is, it should call itself. We have provided a dummy *return* statement so that the code will compile. You should replace the dummy statement with your appropriate *return* statement.

- Be sure your code ignores case differences; that is, Otto and Racecar are indeed palindromes.
- The call to the *animate* method has already been written for you. It should be the first statement in the body of the method and is simply:



```
animate( pal );
```

Troubleshooting

If your method implementation does not animate or animates incorrectly, check these items:

- Check the feedback on the output to see if your code gives the correct result.
- Verify that you coded the base cases correctly.
- Verify that you coded the general case and its corresponding recursive call correctly.

DISCUSSION QUESTIONS

1. What are the base cases for this method?
2. Is this method tail recursive?
3. What happens if you do not code one of the base cases?

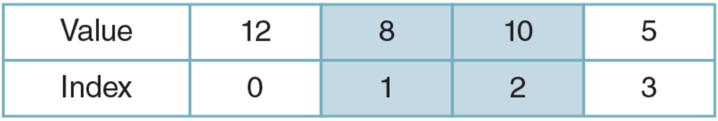
```
total = 35
```

```
sum called with index 0
sum called with index 1
sum called with index 2
sum called with index 3
sum called with index 4
total = 35
```

12.5 Simple Recursion on an Array

When coding a recursive method that performs an aggregate operation on an array, we typically define that method as performing that operation on a subarray.

We can define a subarray of an array with two integers: a starting index and an ending index for that subarray. For example, a starting index of *1* and an ending of *2* define a subarray of two elements as shown here:

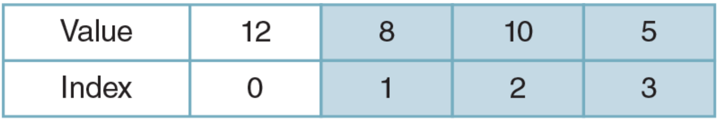


Value	12	8	10	5
Index	0	1	2	3

Description

Above, a starting index of *0* and an ending index of *3* would define a subarray that is the whole array.

In many problems, it is enough to define the subarray with just a starting index; in this case, the implicit ending index is the last index of the array. For example, a starting index of *1* defines a subarray of three elements as shown here:



Value	12	8	10	5
Index	0	1	2	3

Description

Above, a starting index of *0* would define a subarray that is the whole array.

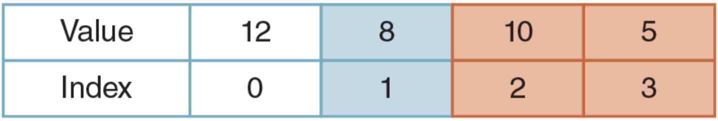
Thus, we can define the general case as follows:

1. Process the first element of the subarray
2. Process the remaining subarray

For a first element to exist, the subarray must not be empty; thus, the base case is when the subarray is empty. That happens when the starting index is equal to the length of the array; that is, it is *1* beyond the last index of the array.

For example, if we want to compute the sum of the elements of a subarray, we can do it as follows:

Sum = first element + sumof the elements of the remaining subarray



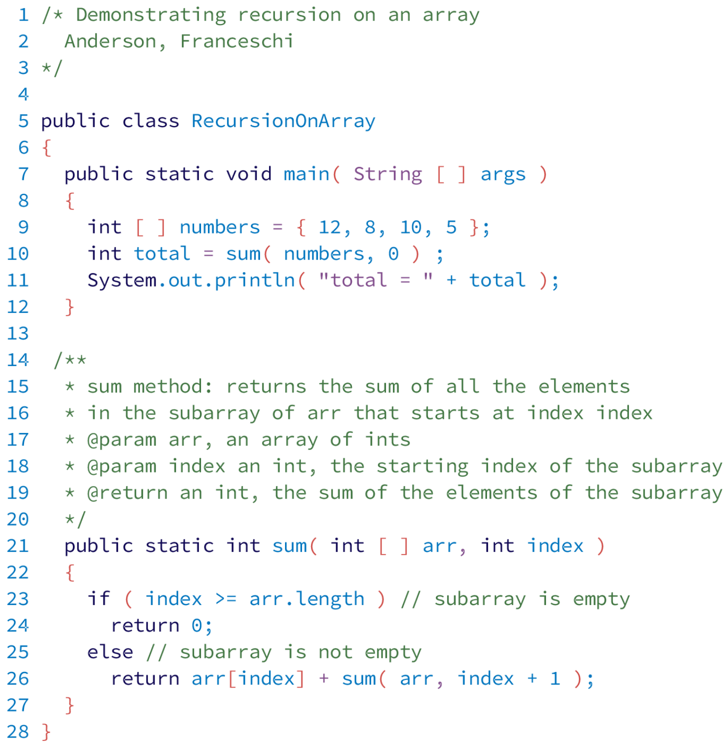
Value	12	8	10	5
Index	0	1	2	3

Description

In the array above, the sum of the elements of the subarray starting at index 1 is equal to element at index 1 (8) plus the sum of the elements of the subarray starting at index 2 (10 + 5). Eventually, the remaining subarray is empty and the sum of the elements of that empty subarray is *0*.

Example 12.8 shows a recursive method computing the sum of the elements of an array of integers (lines 14–27). The *index* parameter (line 21) represents the starting index of the subarray of *arr*, the other parameter of *sum*, that the *sum* method operates on. At line 23, we test if the subarray is empty and return *0* if it is. If the subarray is not empty, we return the sum of its first element and the sum of the remaining subarray at line 26. In the *main* method, at line 10, we call *sum* on the whole array *numbers*, that is, the subarray that starts at index *0*. The output is shown in **Figure 12.12**.

Example 12.8 Summing the Elements of an Array Using Recursion



```
 1 /* Demonstrating recursion on an array
 2    Anderson, Franceschi
 3 */
 4
 5 public class RecursionOnArray
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     int [ ] numbers = { 12, 8, 10, 5 };
10     int total = sum( numbers, 0 ) ;
11     System.out.println( "total = " + total );
12   }
13
14  /**
15   * sum method: returns the sum of all the elements
16   * in the subarray of arr that starts at index index
17   * @param arr, an array of ints
18   * @param index an int, the starting index of the subarray
19   * @return an int, the sum of the elements of the subarray
20   */
21   public static int sum( int [ ] arr, int index )
22   {
23     if ( index >= arr.length ) // subarray is empty
24       return 0;
25     else // subarray is not empty
26       return arr[index] + sum( arr, index + 1 );
27   }
28 }
```

Description

Figure 12.12 Output of Example 12.8

If we want to trace all the recursive calls to *sum*, we can add the following statements before line 23:

```
System.out.println( "sum called with index " + index );
```

Description

Figure 12.13 shows the resulting output when we make the original call: *sum(numbers, 0)*. The original call and the last call are highlighted.

Figure 12.13 Output of Example 12.8 with Tracing Added

Description

```
Enter a value to search for > 7
7 found at index 2
```

```
Enter a value to search for > 34
34 not found
```

12.6 Binary Search: A Recursive Solution

We can use a binary search algorithm to search a sorted array for a given value.

Let’s look at how we can define a recursive solution to this problem. We will assume that the array is sorted in ascending order.

Again, we need to define the base cases and the general case, and the general case must reduce the size of the problem.

When searching for a value in an array, we have two possible outcomes:

- We find the value and return its array index.
- We do not find the value and return –1.

Overall, our strategy is this. First, we will look at the middle element of the array. If the value of the middle element is the value we are looking for, we will return its index. That is our first base case.

If the value of the middle element is greater than the value we are looking for, then the value we are looking for cannot be found in elements with array indexes higher than the index of the middle element. Therefore, we will continue our search in the lower half of the array only. We will do that by making a recursive call to our search method, specifying the lower half of the original array as the subarray to search.

Similarly, if the value of the middle element is lower than the value we are looking for, then the value we are looking for cannot be found in elements with array indexes lower than the index of the middle element. Therefore, we will continue our search in the upper half of the array only. We will do that by making a recursive call to our search method, specifying the upper half of the original array as the subarray to search. That is our formulation for the general case.

As we continue searching, the size of the subarray that we search will shrink with every recursive call. Indeed, every recursive call cuts the size of the subarray we search in half. In this recursive algorithm, not only does the size of the problem decrease with each recursive call, but it also decreases by a large amount.

If the value we are looking for is not in the array, the part of the array that we are searching will continue shrinking until it is empty. At that point, we know that we will not find our value in the array. We have reached our other base case, and we return –1.

Example 12.9 shows the code for a recursive binary search.

Example 12.9 Searching an Array Sorted in Ascending Order

```
 1 /* Searching a sorted array using recursion
 2    Anderson, Franceschi
 3 */
 4
 5 import java.util.Scanner;
 6
 7 public class RecursiveBinarySearch
 8 {
 9   public static void main( String [ ] args )
10   {
11     // define an array sorted in ascending order
12     int [ ] numbers = { 3, 6, 7, 8, 12, 15, 22, 36, 45,
13                         48, 51, 53, 64, 69, 72, 89, 95 };
14
15     Scanner scan = new Scanner( System.in );
16     System.out.print( "Enter a value to search for > " );
17     int value = scan.nextInt( );
18
19     int index = recursiveBinarySearch
20                 ( numbers, value, 0, numbers.length - 1 );
21     if ( index != -1 )
22       System.out.println( value + " found at index " + index );
23     else
24       System.out.println( value + " not found" );
25   }
26
27   /** recursiveBinarySearch method
28   *   @param    arr   the array sorted in ascending order
29   *   @param    key   the value to search for in the subarray
30   *   @param    start the subarray's first index
31   *   @param    end   the subarray's last index
32   *   @return   the array index at which key was found,
33   *             or -1 if key was not found
34   */
35   public static int recursiveBinarySearch
36                ( int [ ] arr, int key, int start, int end )
37   {
38     if ( start <= end )
39     {
40       // look at the middle element of the subarray
41       int middle = ( start + end ) / 2;
42
43       if ( arr[middle] == key )      // found key, base case
44         return middle;
45       else if ( arr[middle] > key )  // look lower
46         return recursiveBinarySearch( arr, key, start, middle - 1 );
47       else                           // look higher
48         return recursiveBinarySearch( arr, key, middle + 1, end );
49     }
50     else                             // key not found, base case
51       return -1;
52   }
53 }
```

Description

We coded the *recursiveBinarySearch* method at lines 27–52. That method takes four parameters: *arr*, the array we are searching; *key*, the value we are searching for; and *start* and *end*, which represent, respectively, the first and last index of the subarray of *arr* that we should search.

At line 38, we test if the subarray we are searching contains at least one element. If it does not, we have reached a base case and we know that we will not find *key*. Thus, we return −1 in the *else* clause at line 51. If the subarray has at least one element, we assign the index of the middle element of the subarray to *middle* at line 41. We then compare the array element at index *middle* to *key* at line 43. If they are equal, we have reached the other base case (we have found *key*) so we return *middle* at line 44.

If the array element at index *middle* is greater than *key*, we call the *recursiveBinarySearch* method with the subarray consisting of all elements with values lower than *middle* (from *start* to *middle* − 1) at line 46. If the array element at index *middle* is smaller than *key*, then we call the *recursiveBinarySearch* method with the subarray consisting of all elements with values higher than *middle* (from *middle* + 1 to *end*) at line 48. In both cases, whatever is returned by the recursive call is returned by the method.

In *main*, we begin by instantiating our array to search. Note that the values are in ascending order (lines 12–13). We then prompt the user for the search key and make the call to the recursive binary search method, passing the entire array as the subarray to search (lines 19–20). We output the result of our search at lines 21–24.

Figure 12.14 shows the output from Example 12.9 when the key value is found, and when the key value is not found.

Figure 12.14 Two Runs of Example 12.9

Description

Let’s run the preceding example on the value 7 in order to illustrate the various recursive calls and the case where the value is found.

Here is the array *numbers*, sorted in ascending order:

Description

We calculate the index *middle* by adding the indexes *start* and *end*, then dividing by 2. Thus, when the *recursiveBinarySearch* method is first called, *middle* is 8.

The element at index 8 (45) is greater than 7, so we call the *recursiveBinarySearch* method, searching the left subarray, highlighted here.

Description

The index *middle* is now calculated to be 3 ((0 + 7)/2).

The element at index 3 (8) is greater than 7, so we call the *recursiveBinarySearch* method, searching the left subarray, highlighted here.

Description

The index *middle* is now calculated to be 1 ((0 + 2)/2).

The element at index 1 (6) is smaller than 7, so we call the *recursiveBinarySearch* method, searching the right subarray, highlighted here.

Description

The index *middle* is now calculated to be 2 ((2 + 2)/2).

The element at index 2 (7), is equal to 7. We have found the value and return its index, 2.

Let’s now run the preceding example on the value 34 in order to illustrate the various recursive calls and the base case when the value is not found.

Here is the array *numbers* again:

Description

The index *middle* when the *recursiveBinarySearch* method is first called is 8 ((0 + 16)/2).

The element at index 8 (45) is greater than 34, so we call the *recursiveBinarySearch* method, searching the left subarray highlighted here.

Description

The index *middle* is now calculated to be 3 ((0 + 7)/2).

The element at index 3 (8) is smaller than 34, so we call the *recursiveBinarySearch* method, searching the right subarray, highlighted here.

Description

The index *middle* is now calculated to be 5 ((4 + 7)/2).

The element at index 5 (15) is smaller than 34, so we call the *recursiveBinarySearch* method, searching the right subarray, highlighted here.

Description

The index *middle* is now calculated to be 6 ((6 + 7)/2).

The element at index 6 (22) is smaller than 34, so we call the *recursiveBinarySearch* method, searching the right subarray, highlighted here.

Description

The index *middle* is now calculated to be 7 ((7 + 7)/2).

The element at index 7 (36) is larger than 34, so we call the *recursiveBinarySearch* method, searching the left subarray. However, that left subarray is empty. We have not found 34, so we return –1.

12.7 Programming Activity 2: The Towers of Hanoi

A well-known problem that lends itself to an elegant recursive formulation is the Towers of Hanoi. Here it is:

- There are three towers, which we can represent as the source tower, the temporary tower, and the destination tower.
- We have a stack of *n* disks piled on the source tower; all the disks have a different diameter. The largest disk is at the bottom and the smallest disk is at the top.
- The goal is to transfer all the disks, one at a time, to the destination tower using all three towers for help. No larger disk can be placed on top of a smaller one.

The recursive solution to the problem for the general case (*n* >= 1) is as follows:

1. Transfer the top (*n* – 1) disks from the source tower to the temporary tower.
2. Transfer the one remaining disk (the largest) from the source tower to the destination tower.
3. Transfer the (*n* – 1) disks from the the temporary tower to the destination tower.

The base case, when *n 5* 0 (there are 0 disks to transfer), is to do nothing.

The first and third operations are simply recursive calls using a smaller number of disks (*n* – 1) than the original problem.

In the case of *n 5* 5, **Figures 12.15–12.18** illustrate the recursive solution and formulation. In the figures, the left, middle, and right towers represent the source, temporary, and destination towers, respectively.

Description

Figure 12.18 Position After Step 3

Description

In this activity, you will work with recursion to perform the following function:

Code a recursive method to solve the Towers of Hanoi problem

Instructions

In this chapter's Programming Activity 2 folder, you will find the source files needed to complete this activity. Copy all of the files to a folder on your computer. Note that all files should be in the same folder.

Open the *HanoiDrawing.java* source file. Searching for five asterisks (*****) in the source code will position you to the code section where you will add your code. In this task, you will fill in the code inside the *recursiveTOfH* method to solve the Towers of Hanoi problem. **Example 12.10** shows the section of the *HanoiDrawing* source code where you will add your code.

Example 12.10 Location of Student Code in *HanoiDrawing*

```
public void recursiveTOfH( int numDisks, int fromTower,
                           int toTower, int useTower )
{
   // ***** Student writes the body of this method *****
   //
   // Using recursion, transfer numDisks disks from the tower
   // fromTower to the tower toTower using the tower
   // useTower

   // The disks are numbered as follows: if we started with n disks,
   //   the disk at the top is disk # 1
   //   and the disk at the bottom is disk # n

   // We call the moveDisk method inside the body of this method

   // The moveDisk method moves one disk and takes 3 arguments:
   //   an int, representing the disk number to be moved
   //   an int, representing the tower to move the disk from
   //   an int, representing the tower to move the disk to
   // So if these three variables are:
   //   diskNumber, fromTower, and toTower
   //   then the call to moveDisks will be:

   //   moveDisk( diskNumber, fromTower, toTower );

   if ( numDisks > 0 )
   {
    // Student code starts here
    // 1. Move ( numDisks - 1 ) disks from fromTower
    //   to useTower using toTower
    // 2. Move one disk from fromTower to toTower
    //   Print a message to the screen, then
    //   call moveDisk in order to animate.

    // 3. Move ( numDisks - 1 ) disks from useTower to toTower
    //   using fromTower

   }

   // Base case: 0 disks to move ==> do nothing
   //
   // end of student code
   //
 }
```

Description

The framework will animate your code so that you get some feedback on the correctness of your code. It will display the disks being moved from one tower to another until the whole set of disks has been moved from the left tower to the right tower. Code to enforce the rules has already been written.

To test your code, compile *HanoiDrawing.java* and run *HanoiApplication*; when the program begins, a text box will allow you to enter the number of disks as shown in **Figure 12.19**.

Figure 12.19 Opening Window

Description

Click “run” to animate your code.

If you enter an integer less than 1 or greater than 9, the program will use a default value of 4. If you enter 5, as shown in Figure 12.19, the first screen will be as shown in Figure 12.15. **Figure 12.20** shows an intermediate position as you run your code.

Figure 12.20 An Intermediate Position in the Animation

Description

Task Instructions

- In the file *HanoiDrawing.java* the *recursiveTOfH* method header is:

```
public void recursiveTOfH( int numDisks, int fromTower,
                           int toTower, int useTower )
```

Description

- This method takes four parameters: *numDisks*, representing the number of disks to be moved, and 3 *ints* representing the tower to move the disks from, the tower to move the disks to, and the tower to use to accomplish that task of moving *numDisks* disks from tower *fromTower* to tower *toTower*. For instance, with five disks, our method call in the *main* method is:

```
recursiveTOfH( 5, 0, 2, 1 );
```

Description

- The preceding method call is interpreted as: move 5 disks from tower 0 to tower 2, using tower 1 as a temporary holding tower.

- Your code goes in three places, all of them inside the *if* statement.

    1. First, you need to move all the disks except the bottom one from the *fromTower* (source tower, “left tower” on the figures) to the *useTower* (temporary tower, “middle tower” on the figures) using the *toTower* (“destination tower, right tower” on the figures). You do this by calling *recursiveTOfH* with the appropriate arguments.
    2. Then, you need to move the bottom disk from the *fromTower* (source tower, “left tower” on the figures) to the *toTower* (destination tower, “right tower” on the figures). To track your progress, output the move to the command line (“Move disk *x* from tower *y* to tower *z*”). You also need to call the *moveDisk* method so that the code animates. The API of *moveDisk* is explained in Example 12.10.
    3. Finally, you need to move all the disks from the *useTower* (temporary tower, “middle tower” on the figures) to the *toTower* (destination tower, “right tower” on the figures). Again, you call *recursiveTOfH*.

For example, if you run your program with three disks, and assuming the towers are labeled 0, 1, and 2 from left to right, the command line output of your method should read something like:

```
Move disk 1 from tower 0 to tower 2
Move disk 2 from tower 0 to tower 1
Move disk 1 from tower 2 to tower 1
Move disk 3 from tower 0 to tower 2
Move disk 1 from tower 1 to tower 0
Move disk 2 from tower 1 to tower 2
Move disk 1 from tower 0 to tower 2
```

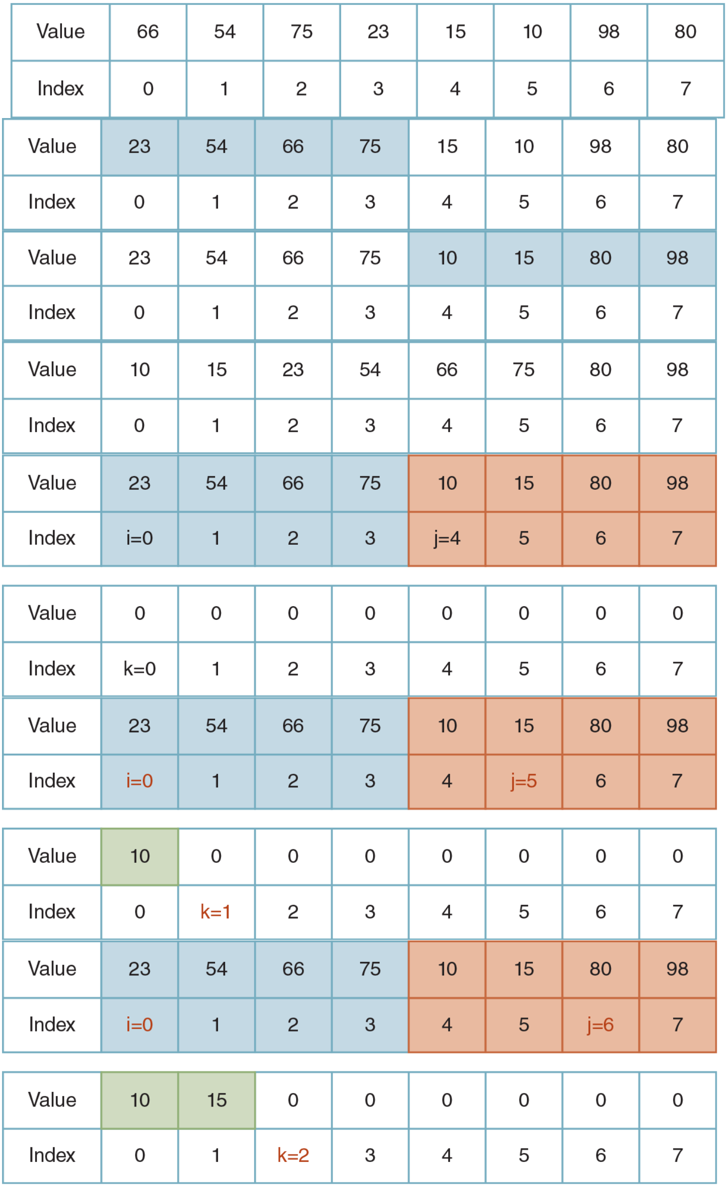
Troubleshooting

If your method implementation does not animate or animates incorrectly, check these items:

- Check the feedback on the output to see if your code violates the rules.
- Verify that you coded the first recursive call correctly.
- Verify that you coded the second recursive call correctly.

DISCUSSION QUESTIONS

1. What is the base case for the method?
2. As the number of disks increases, what happens to the time it takes for the method to run?



Value	66	54	75	23	15	10	98	80
Index	0	1	2	3	4	5	6	7

Value	23	54	66	75	15	10	98	80
Index	0	1	2	3	4	5	6	7

Value	23	54	66	75	10	15	80	98

12.8 Merge Sort

Selection sort, insertion sort, and bubble sort (discussed earlier in this text) all involve a double loop to sort an array. Two other sorting algorithms are **Merge Sort** and **Quick Sort**. They both use recursion. We study Merge Sort first. In the general case, it works as follows:

- Step 1: Merge sort the left half of the array (this is a recursive call)
- Step 2: Merge sort the right half of the array (this is a recursive call)
- Step 3: Merge the two sorted half arrays

For example, we will use merge sort to sort the following array:

Description

Step 1 is calling merge sort to sort the left half of the array;

after step 1, the array now looks like:

Description

Step 2 is calling merge sort to sort the right half of the array; after step 2, the array now looks like:

Description

At this point, the left and right halves of the array are sorted. In step 3, we merge them together so that the whole array is now sorted.

Description

To do so, we loop through all the elements of the left and right subarrays in parallel fashion, comparing them two at a time and placing them in the resulting sorted array. In doing so, we use three indices:

- i is the index of the value that we are processing in the left subarray
- j is the index of the value that we are processing in the right subarray
- k is the index, in the resulting sorted array, of the value that we are placing

That sequence is illustrated as follows. At the beginning, i is 0 (the first index of the left subarray, j is 4 (the first index of the right subarray), and k is 0 (the first index of the resulting array).

Description

We now process the elements at index i = 0 (23) and j = 4 (10). 10 is smaller, so we place 10 at index k (0) in the resulting array and increment j by 1 (to 5) and k by 1 (to 1).

Description

We now process the elements at index i = 0 (23) and j = 5

(15). 15 is smaller, so we place 15 at index k (1) in the resulting array and increment j by 1 (to 6) and k by 1 (to 2).

Description

We now process the elements at index i = 0 (23) and j = 6 (80). 23 is smaller, so we place 23 at index k (2) in the resulting array and increment i by 1 (to 1) and k by 1 (to 3).

Description

We now process the elements at index i = 1 (54) and j = 6 (80). 54 is smaller, so we place 54 at index k (3) in the resulting array and increment i by 1 (to 2) and k by 1 (to 4).

Description

We now process the elements at index i = 2 (66) and j = 6 (80). 66 is smaller, so we place 66 at index k (4) in the resulting array and increment i by 1 (to 3) and k by 1 (to 5).

Description

We now process the elements at index i = 3 (75) and j = 6 (80). 75 is smaller, so we place 75 at index k (5) in the resulting array and increment i by 1 (to 4) and k by 1 (to 6).

Description

At this point, i, which has value 4, has gone past the last index (3) of the left half of the array. We have finished processing all the values of the left half of the array. We loop through the remaining values of the right half of the array and place them in the same order (since they are already sorted) in the resulting array, which is now full and sorted.

Description

In this example, we finished processing the left half of the array first. In general, we do not know which half of the array we will finish processing first. That does not matter. Once we know that we finished processing one half of the array, we can simply loop through both halves of the array and place their elements in the resulting array in order. One of the two halves is empty; that loop will not execute.

At each recursive call, we call merge sort to sort a subarray within the original array. As the recursive calls are made, the sizes of the subarrays are getting smaller and smaller. Eventually, we end up making a recursive call on a subarray of only one element; that is the base case. There is nothing to do; a subarray of only one element is automatically sorted. Note that if the original array is empty, then there is nothing to do either.

A subarray of the original array is defined by two parameters: its starting index and its ending index. For example, a starting index of 2 and ending index of 3 define the subarray made up of the values 75 and 23, as shown below:

Description

Example 12.11 shows the implementation of merge sort (lines 16–37). In the general case (lines 28–34), we make a recursive call to sort the left half of the array (lines 29–30), then make another recursive call to sort the right half of the array (lines 31–32), and then call *merge* (lines 33–34) to merge the two halves. The *merge* method is shown at lines 39 to 94. We declare and instantiate a new array, *temp*, of the same size as the original array at line 54. At lines 59 to 73, we place the elements of the two halves of the array into the new array until one half of the array is fully processed. Note that we do not know which half that is. At lines 75 to 81, we flush the remaining elements of the left half of the array into *temp*, if necessary. At lines 83 to 89, we flush the remaining elements of the right half of the array into *temp*, if necessary. At lines 91 to 93, we copy the elements of *temp* back to the original array.

Example 12.11 Sorting an Array of Integers Using Merge Sort

```
/* Sorting an array using merge sort
  Anderson, Franceschi
*/

public class MergeSort
{
  public static void main( String [] args )
  {
    int [] numbers = { 66, 54, 75, 23, 15, 10, 98, 80 };
    mergeSort( numbers, 0, numbers.length - 1 );
    for ( int i = 0; i < numbers.length; i++ )
      System.out.print( numbers[i] + " " );
    System.out.println( );
  }

 /**
  * mergeSort method: sorts the subarray of arr
  * (from index start to index end, both included)
  * in ascending order
  * @param arr, an array of ints
  * @param start an int, the starting index of the subarray
  * @param end an int, the ending index of the subarray
  */
  public static void mergeSort( int [] arr, int start, int end )
  {
    if ( start < end ) // general case
    {
      int middle = ( start + end ) / 2;
      // sort the left part of the array
      mergeSort( arr, start, middle );
      // sort the right part of the array
      mergeSort( arr, middle + 1, end );
      // merge the 2 parts
      merge( arr, start, middle, middle + 1, end );
    }
    // else, base case, empty or 1 element array, already sorted
  }

 /**
  * merge method: merges, in ascending order,
  * the two subarrays of arr defined as follows:
  * left subarray: between indexes start1 and end1, both included
  * right subarray: between indexes start2 and end2, both included
  * @param arr, an array of ints
  * @param start1 an int, the starting index of the left subarray
  * @param end1 an int, the ending index of the left subarray
  * @param start2 an int, the starting index of the right subarray
  * @param end2 an int, the ending index of the right subarray
  */
  public static void merge( int [] arr, int start1, int end1,
                                        int start2, int end2 )
  {
    // merge the 2 sides into a temp array
    int [] temp = new int[arr.length]; // temporary array
    int i = start1;
    int j = start2;
    int k = start1;

    // generate merged subarray until one side is done
    while ( i <= end1 && j <= end2 )
    {
      if ( arr[i] < arr[j] )
      {
        temp[k] = arr[i];
        i++;
      }
      else
      {
        temp[k] = arr[j];
        j++;
      }
      k++;
    }

    // flush left subarray if necessary
    while ( i <= end1 )
    {
      temp[k] = arr[i];
      i++;
      k++;
    }

    // flush right subarray if necessary
    while ( j <= end2 )
    {
      temp[k] = arr[j];
      j++;
      k++;
    }

    // write back temp into arr
    for ( i = start1; i <= end2; i++ )
      arr[i] = temp[i];
  }
}
```

Description

At lines 9 to 13 of the *main* method, we call *mergeSort* to sort an array of integers. **Figure 12.21** shows the output of Example 12.11.

Figure 12.21 Output of Example 12.11

Description

If we want to trace all the recursive calls to *mergeSort* and the ensuing calls to *merge*, we can add the following statements after line 25 and after line 52, respectively:

```
System.out.println("mergeSort( " + start + ", " + end + " ) called");
System.out.println("merge( " + start1 + ", " + end1
                      + ", " + start2 + ", " + end2 + " ) called");
```

Description

Figure 12.22 shows the resulting output when we make the original call: *mergeSort(numbers, 0, 7)*. The calls resulting from step 1, step 2, and step 3 (as they apply to the whole array) are highlighted.

Figure 12.22 Output of Example 12.11 with Tracing Added

Description

We will later study the running time of merge sort and compare it to the running times of selection sort, insertion sort, and bubble sort.

12.9 Quick Sort

Quick sort, like merge sort, also uses recursion. In the general case, it works as follows:

- Step 1: Use one array element, called the pivot, to partition the array into two parts, left and right. All the elements on the left side are smaller than the pivot, and all the elements on the right side are greater than or equal to the pivot.
- Step 2: Quick sort the left part of the array (this is a recursive call)
- Step 3: Quick sort the right part of the array (this is a recursive call)

We use quick sort to sort the following array:

Description

In step 1, we partition the array around one of the array elements called the pivot. Because we have no information about the array, the easiest way is to choose the first element of the array, here 66, as the pivot. The *partition* method, coded at lines 37 to 59 of **Example 12.12**, moves the pivot element somewhere in the array and reorganizes the array as follows:

Example 12.12 Sorting an Array of Integers Using Quick Sort

```java
/* Sorting an array using quick sort
   Anderson, Franceschi
*/

public class QuickSort
{
  public static void main( String [] args )
  {
    int [] numbers = { 66, 54, 75, 23, 15, 10, 98, 80 };
    quickSort( numbers, 0, numbers.length - 1 );
    for ( int i = 0; i < numbers.length; i++ )
      System.out.print( numbers[i] + " " );
    System.out.println( );
  }

  /**
  * quickSort method: sorts the subarray of arr
  * (from index start to index end, both included)
  * in ascending order
  * @param arr, an array of ints
  * @param start an int, the starting index of the subarray
  * @param end an int, the ending index of the subarray
  */
  public static void quickSort( int [] arr, int start, int end )
  {
    if ( end > start ) // general case, >= 2 elements
    {
      int pivotIndex = partition( arr, start, end );
      // quick sort left subarray
      quickSort( arr, start, pivotIndex - 1 );
      // quick sort right subarray
      quickSort( arr, pivotIndex + 1, end );
    }
    // else, 0 or 1 element ==> subarray is sorted, do nothing
  }

  /**
  * partition method: partitions the subarray of arr
  * (from index start to index end, both included)
  * around the pivot, arr[start]
  * @param arr, an array of ints
  * @param start an int, the starting index of the subarray
  * @param end an int, the ending index of the subarray
  */
  public static int partition( int [] arr, int start, int end )
  {
    int j = start;
    int pivot = arr[start];
    for ( int i = start + 1; i <= end; i++ )
    {
      if ( arr[i] < pivot )
      {
        j++;
        swap( arr, i, j );
      }
    }
    swap( arr, start, j );
    return j;
  }

  /**
  * swap method: swaps the elements of arr
  * at index i and index j
  * @param arr, an array of ints
  * @param i an int, a valid index of arr
  * @param j an int, a valid index of arr
  */
  public static void swap( int [] arr, int i, int j )
  {
    int temp = arr[i];
    arr[i] = arr[j];
    arr[j] = temp;
  }
}
```

Description

Description

For this example, this is what the array will look like after the partition method executes:

Description

The array elements left of the pivot (10, 54, 23, and 15) are all smaller than the pivot.

The array elements right of the pivot (75, 98, 80) are all greater than or equal to the pivot.

The pivot is in its final position. The elements left of the pivot and right of the pivot are not sorted. Note that the pivot can end up being anywhere, including in the first or last position. Ideally, we would want the pivot to be in the middle of the array so that the array is partitioned evenly. However, there is no guarantee of that happening.

After calling quick sort to sort the left side of the array (step 2), the array now looks like:

Description

After calling quick sort to sort the right side of the array (step 3), the array is now sorted and looks like:

Description

Below is a sequence showing the execution of *partition* when originally called.

The pivot is 66, the first element of the array, start is 0, and end is 7. The indexes i and j are equal to 1 and 0, respectively.

Description

The element at index i, 54, is less than 66, so we increment j by 1 and swap the elements at indexes i (1) and j (1), which, in this case, is a no-op.

Description

In the second iteration of the loop (i = 2), we compare 75, the element at index 2, with 66, the pivot. 75 is not smaller than 66, so we do nothing.

Description

In the third iteration of the loop (i = 3), we compare 23, the element at index 3, with 66, the pivot. 23 is smaller than 66, so we increment j by 1 and swap the elements at indexes i and j, that is, 3 and 2.

Description

Note that the index j tracks the index of the last element of the left side of the array, which contains all the elements less than the pivot.

In the fourth iteration of the loop (i = 4), we compare 15, the element at index 4, with 66, the pivot. 15 is smaller than 66, so we increment j by 1 and swap the elements at indexes i and j, that is, 4 and 3.

Description

In the fifth iteration of the loop (i = 5), we compare 10, the element at index 5, with 66, the pivot. 10 is smaller than 66, so we increment j by 1 and swap the elements at indexes i and j, that is, 5 and 4.

Description

In the sixth iteration of the loop (i = 6), we compare 98, the element at index 6, with 66, the pivot. 98 is not smaller than 66, so we do nothing.

Description

In the seventh and last iteration of the loop (i = 7), we compare 80, the element at index 7, with 66, the pivot. 80 is not smaller than 66, so we do nothing.

Description

After the loop, we swap the elements at index 0 (the value of start) and 4 (the value of j) so that the pivot, 66, is placed exactly between the left side of the array (all those elements are less than the pivot) and the right side of the array (all those elements are greater than or equal to the pivot).

Description

Example 12.12 shows the implementation of quick sort (lines 16 to 35). The *quickSort* method sorts a subarray of its array parameter, *arr*. Like with merge sort, a subarray of the original array is defined by two parameters: its starting index and its ending index. Thus, the *quickSort* method sorts the subarray of *arr* whose elements are between the *start* and *end* indices, both included. At line 10, we sort the array *numbers* by specifying a *start* value of 0 and an *end* value of *numbers.length – 1*, identifying the whole array *numbers* as the subarray.

In the general case (lines 28–32), we first partition the array at line 28. Note that the *partition* method returns an integer, the index of the pivot after *partition* has finished executing. In this example, when *partition* is first called on the whole array, the index returned by *partition* is 4. That value is used in the two recursive calls to *quickSort* at lines 30 and 32. We make a recursive call to sort the left part of the array (lines 29–30), then make another recursive call to sort the right part of the array (lines 31–32).

The *partition* method is coded at lines 37 to 59. The pivot is defined, at line 48, as the first element of the subarray being sorted. At lines 49 to 56, we use a loop to partition the subarray using the pivot, but without moving the pivot. At line 57, we swap the pivot with the last element of the left part of the array. At this point, the pivot has moved to its final position. All the elements on the left side of the pivot are smaller than the pivot, and all the elements on the right side of the pivot are greater than or equal to the pivot.

At line 10 of the *main* method, we call *quickSort* to sort an array of integers named *numbers*, and output the sorted array at lines 11 to 12. **Figure 12.23** shows the output of Example

12.12.

Figure 12.23 Output of Example 12.12

Description

If we want to trace all the recursive calls to *quickSort* and the ensuing calls to *partition*, we can add the following statements after line 25 and after line 46, respectively:

```
System.out.println("quickSort( " + start + ", " + end + " ) called");
System.out.println("partition( " + start + ", " + end + " ) called");
```

Description

Figure 12.24 shows the resulting output when we make the original call: *quickSort(numbers, 0, 7)*. The calls resulting from step 1, step 2, and step 3 are highlighted.

Figure 12.24 Output of Example 12.12 with Tracing Added

Description

We will study the running time of quick sort and compare it to the other sorting algorithms we have studied later.

12.10 Recursion Versus Iteration

Recursion and iteration are different approaches to solving a problem.

- A recursive function is implemented using decision constructs (e.g., *if/else* statements) and repeatedly calls itself.
- An iterative function is implemented with looping constructs (e.g., *while* or *for* statements) and repeatedly executes the loop.

Most programmers would not use recursion to print “Hello World” *n* times; they would simply use the following *for* loop:

```
for ( int i = 0; i < n; i++ )
      System.out.println( "Hello World" );
```

Similarly, a factorial method can easily be coded using iteration.

However, other problems, such as the Towers of Hanoi and the binary search, are more easily coded using recursion rather than iteration.

SOFTWARE ENGINEERING TIP

Readability and maintenance are important considerations when coding a method. If running times are equivalent and a recursive implementation is easier to understand than the equivalent iterative implementation, choose recursion over iteration; otherwise, iteration is generally preferred.

Often, the recursive solution to a problem is more elegant and easier to understand than an equivalent iterative solution. The main difficulty in coding a recursive method is the problem-solving part. The implementation, using Java or any other programming language, is easier than the equivalent code that uses iteration.

Another consideration when deciding to use recursion or iteration is the efficiency of the method at execution time. This is called the running time of the method, and is often measured in order of magnitude as a function of the size of the input.

For instance, for the Hello World example, the input is *n*. Using iteration, we will execute the loop *n* times, and the test condition of the *for* statement will be executed ($n + 1$) times. When the running time of a method can be expressed as *n* multiplied by a constant value ($n \times c$), we say that the order of magnitude of its running time is *n*; we say it is "big-Oh" of *n* or $O(n)$.

Using recursion, and considering Example 12.1, the *printHelloWorldNTimes* method will call itself *n* times before reaching the base case ($n = 0$), for which the method does nothing. At each recursive call, the method performs a small and finite number of operations: it tests for *n* being greater than 0, and then prints "Hello World" once before calling itself; so it performs two operations before calling itself. Since it calls itself *n* times overall, the approximate running time of the method is 2 * *n*, and therefore the order of magnitude of its running time is also $O(n)$ (orders of magnitude ignore constant factors).

So in this case, the running times of iteration and recursion are of the same order of magnitude. However, the overhead associated with all the recursive method calls will add to the running time. That will make recursion slower than iteration, which is often the case.

CHAPTER REVIEW

12.11 Chapter Summary

- The idea of recursion is to convert or reduce a bigger problem to a smaller, similar problem. The relationship between the bigger problem and the smaller problem is called the general case.
- By reducing the size of a problem to a smaller problem recursively, we eventually arrive at a small problem that is easy to solve. That small problem is called the base case.
- Solving a problem using recursion typically involves coding a recursive method.
- A recursive method
    - can be a *static* method or an instance method,
    - can take 0, 1, or more parameters, and
    - can be a *void* or a value-returning method.
- A recursive method calls itself.
- Problem solving using recursion involves two steps: generating a recursive formulation of the problem for the general case, and solving the base case(s).
- There can be one or more base cases.

- Most base cases are simple, but some can be more complex.
- Most general cases are simple, but some can be more complex.
- A recursive method calls itself repeatedly until a base case is reached.
- A recursive method typically includes an *if/else* statement that tests for the base case.
- If the recursive method does not test for the base case, calling the method will typically result in a stack overflow run-time error.
- Recursion is typically an alternative to iteration. The coding of a recursive method is typically compact and elegant. However, a recursive method may not be as efficient as its iterative equivalent.

12.12 Exercises, Problems, and Projects

12.12.1 Multiple Choice Exercises

1. A recursive method

   - is always a *static* method.
   - is never a *static* method.
   - may or may not be *static*.

5. A recursive method

   - is always a method with a *void* return value.
   - is always a value-returning method.
   - can be either of the above.

9. When formulating a recursive solution, what should we consider?

   - base cases and general case
   - base cases only
   - general case only

13. A recursive method

    - is a method containing a loop.
    - calls itself.
    - is part of the *java.recursion* package.

17. When coding a class that includes a recursive method, we need to import the *java.recursion* package.

    - true
    - false

20. If the base case of a recursive method is not taken into account when coding the method, the likely outcome is

    - a compiler error.
    - a run-time error.
    - no error.

24. If there are several base cases in a recursive method, omitting the code for one of them will result in

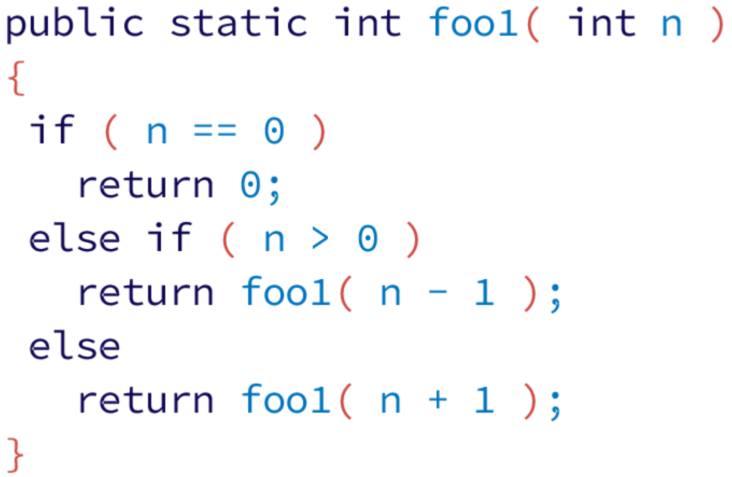
    - a compiler error.
    - a run-time error.
    - no error.

28. If a recursive method makes a recursive call with the same argument that it was passed, the likely outcome is

    - a compiler error.
    - a run-time error.
    - no error.

12.12.2 Reading and Understanding Code

For Questions 9 to 11, consider the following method:



```
public static int foo1( int n )
{
  if ( n == 0 )
    return 0;
  else if ( n > 0 )
    return foo1( n - 1 );
  else
    return foo1( n + 1 );
}
```

Description

1. What is the value of *i* after the following code is executed?

```
int i = foo1( 0 );
```

Description

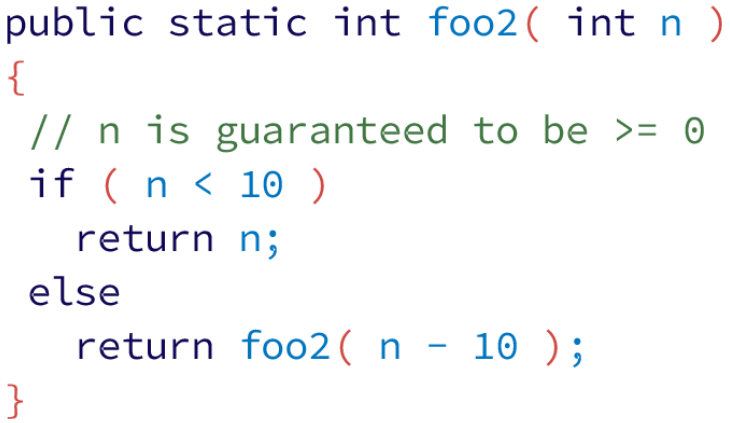
2. What is the value of *i* after the following code is executed?

```
int i = foo1( 4 );
```

Description

3. What does the *foo1* method do?

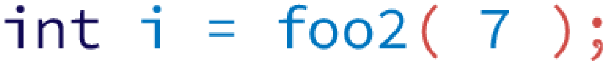
For Questions 12 to 15, consider the following method:



```
public static int foo2( int n )
{
 // n is guaranteed to be >= 0
 if ( n < 10 )
   return n;
 else
   return foo2( n - 10 );
}
```

Description

1. What is the value of *i* after the following code is executed?



```
int i = foo2( 7 );
```

Description

2. What is the value of *i* after the following code is executed?

```
int i = foo2( 13 );
```

Description

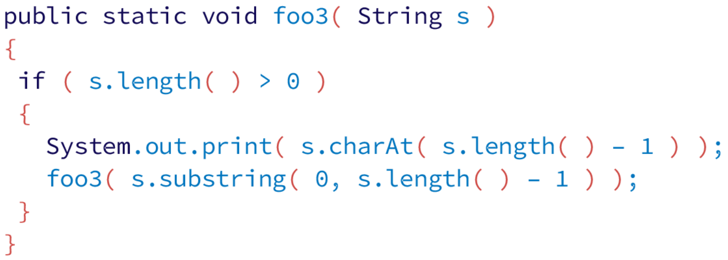
3. What is the value of *i* after the following code is executed?

```
int i = foo2( 65 );
```

Description

4. What does the *foo2* method return when the argument is a positive integer?

For Questions 16 to 19, consider the following method:



```
public static void foo3( String s )
{
 if ( s.length( ) > 0 )
 {
   System.out.print( s.charAt( s.length( ) - 1 ) );
   foo3( s.substring( 0, s.length( ) - 1 ) );
 }
}
```

Description

1. What is the output of the following code?

```
foo3( "" );
```

2. What is the output of the following code?

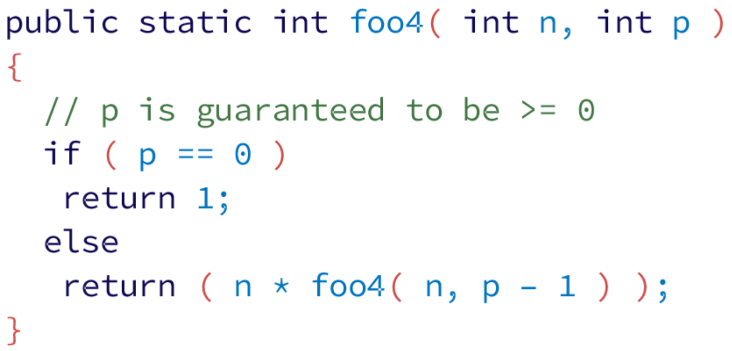
```
foo3( "Hi" );
```

3. What is the output of the following code?

```
foo3( "Hello" );
```

4. What does the *foo3* method do?

For Questions 20 to 23, consider the following method:



```
public static int foo4( int n, int p )
{
  // p is guaranteed to be >= 0
  if ( p == 0 )
   return 1;
  else
   return ( n * foo4( n, p - 1 ) );
}
```

Description

1. What is the value of *i* after the following code is executed?

```
int i = foo4( 6, 0 );
```

Description

2. What is the value of *i* after the following code is executed?

```
int i = foo4( 5, 1 );
```

Description

3. What is the value of *i* after the following code is executed?

```
int i = foo4( 4, 3 );
```

Description

4. What does the *foo4* method return as a function of its two parameters, *n* and *p*?

12.12.3 Fill In the Code

1. This recursive method returns the number of times a given character is found in a *String*.

```
public static int foo( String s, char c )
{
  if ( s.length( ) == 0 )
    return 0;
  else
  {
    // your code goes here

  }
}
```

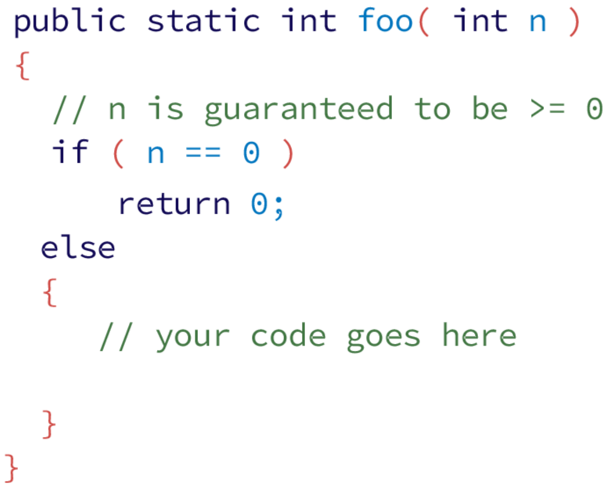
   Description

2. This recursive method returns “even” if the length of a given *String* is even, and “odd” if the length of the *String* is odd.

```
public static String foo( String s )
{
  if ( s.length( ) == 0 )
      return "even";
  else if ( s.length( ) == 1 )
      return "odd";
  else
       // your code goes here
}
```

   Description

3. This recursive method returns the sum of all the integers from 0 to a given number.

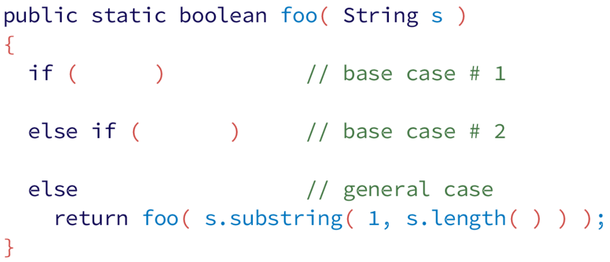


```
public static int foo( int n )
{
  // n is guaranteed to be >= 0
  if ( n == 0 )
     return 0;
 else
 {
    // your code goes here

 }
}
```

Description

4. This recursive method returns *true* if its *String* parameter contains the characters *A* and *B* in consecutive locations; otherwise, it returns *false*.



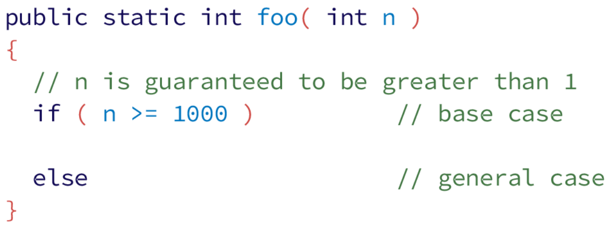
```
public static boolean foo( String s )
{
  if (      )           // base case # 1

  else if (       )     // base case # 2

  else                  // general case
    return foo( s.substring( 1, s.length( ) ) );
}
```

Description

5. This recursive method squares a number until the result is greater than or equal to 1000, then returns the result. For instance, *foo(10)* returns 10000, *foo(6)* returns 1296, and *foo(1233)* returns 1233.



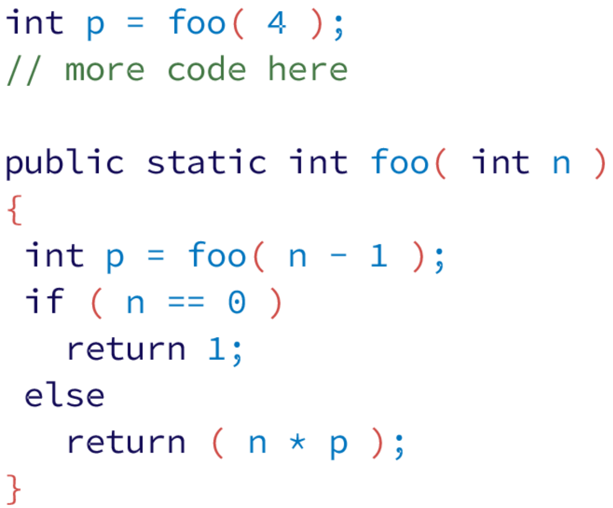
```
public static int foo( int n )
{
  // n is guaranteed to be greater than 1
  if ( n >= 1000 )          // base case

  else                      // general case
}
```

Description

12.12.4 Identifying Errors in Code

1. You coded the following in the file *Test.java*. Where is the error?



```
int p = foo( 4 );
// more code here

public static int foo( int n )
{
 int p = foo( n - 1 );
 if ( n == 0 )
   return 1;
 else
   return ( n * p );
}
```

   Description

2. You coded the following method. Where is the error?

```
public static double foo( int n )
{
 if ( n == 0 )
   return 1.0;
 else if ( n < 0 )
   return foo( n - 1 );
 else
   return foo( n + 1 );
}
```

Description

3. You coded the following method. Where is the error?

```
public static boolean foo( int n )
{
 // n is guaranteed to be >= 0
 if ( n == 0 )
   return true;
 else
   foo( n - 1 );
}
```

Description

4. You coded the following method. Where is the error?

```
public static boolean foo( int n )
{
 // n is guaranteed to be >= 0
 if ( n == 0 )
   return true;
 else
   return foo( n );
}
```

Description

12.12.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

1. You coded the following in the file *Test.java*:

```
// inside main
System.out.println( foo( 5 ) );
// more code here

public static int foo( int n )
{
 return ( n * foo( n - 1 ) );  // line 15
}
```

   Description
   The code compiles, but when it runs, you get the following output:

```
Exception in thread "main" java.lang.StackOverflowError
at Test.foo(Test.java:15)
at Test.foo(Test.java:15)
at Test.foo(Test.java:15)
....
```

   Description
   Explain what the problem is and how to fix it.

2. You coded the following in the file *Test.java*:

```
// inside main
System.out.println( foo( 5 ) );
// more code here

public static int foo( int n )
{
 if ( n == 0 )
   return foo( 0 );  // line 15
 else
   return ( n * foo( n - 1 ) );
}
```

Description

The code compiles, but when it runs, you get the following output:

```
Exception in thread "main" java.lang.StackOverflowError
at Test.foo(Test.java:15)
at Test.foo(Test.java:15)
at Test.foo(Test.java:15)
....
```

Description

Explain what the problem is and how to fix it.

3. You coded the following in the file *Test.java*:

```
// inside main
System.out.println( foo( 5 ) );
// more code here

public static int foo( int n ) // line 9
{
 if ( n == 0 )
   return 1;
 else
   System.out.println( n * foo( n - 1 ) );
}         // line 15
```

Description

At compile time, you get the following error:

```
Test.java:15: error: missing return statement
}        // line 15
^
1 error
```

Description

Explain what the problem is and how to fix it.

4. You coded the following in the file *Test.java*:

```
// inside main
System.out.println( foo( 5 ) );
// more code here

public static int foo( int n )
{
 if ( n == 0 )
   return 1;
 else
   return ( foo( n ) * ( n - 1 ) );
}
```

Description

The code compiles, but when it runs, you get the following message, repeated many times, before finally stopping:

```
Exception in thread "main" java.lang.StackOverflowError
     at Test.foo(Test.java:15)
     at Test.foo(Test.java:15)
     at Test.foo(Test.java:15)
```

Description

Explain what the problem is and how to fix it.

5. You coded the following in the file *Test.java*:

```
// inside main
System.out.println( foo( "Hello" ) ); // line 6
// more code here
public static int foo( String s )     // line 9
{
 if ( s.length( ) == 0 )
   return 0;
 else
   return ( 1 +
        foo( s.substring( 0, s.length( ) - 2 ) ) ); // line 15
   }
```

Description

The code compiles, but when it runs, you get the following output:

```
Exception in thread "main" java.lang.StringIndexOutOfBoundsException: begin 0,
end -1, length 1
   at java.base/java.lang.String.checkBoundsBeginEnd(String.java:4601)
   at java.base/java.lang.String.substring(String.java:2704)
   at Test.foo(Test.java:15)
   at Test.foo(Test.java:15)
   at Test.foo(Test.java:15)
   at Test.main(Test.java:6)
```

Description

Explain what the problem is and how it happens.

6. You coded the following in the file *Test.java*:

```
// inside main
System.out.println( foo( "Hello" ) ); // line 6
// more code here

public static int foo( String s ) // line 9
{
 if ( s.length( ) == 0 ) // line 11
   return 0;
 else
 {
    String temp = null;
    if ( s.length( ) > 1 )
         temp = s.substring( 0, s.length( ) - 1 );
    return ( 1 + foo( temp ) ); // line 18
 }
}
```

Description

The code compiles, but when it runs, you get the following output:

```
Exception in thread "main" java.lang.NullPointerException:
Cannot invoke "String.length( )" because <parameter1> is
null
        at Test.foo(Test.java:11)
        at Test.foo(Test.java:18)
        at Test.foo(Test.java:18)
        at Test.foo(Test.java:18)
        at Test.foo(Test.java:18)
        at Test.foo(Test.java:18)
        at Test.main(Test.java:6)
```

Description

Explain what the problem is and how to fix it.

12.12.6 Write a Short Program

1. Using recursion, write a program that takes a word as an input and outputs that word backward.
2. Using recursion, write a program that keeps prompting the user for a word containing a $ character. As soon as the user inputs a word containing the $ character, you should output that word and your program will terminate.
3. Using recursion, write a program that takes a word as an input and outputs that word with all characters separated by a space.
4. Using recursion, write a program that takes a word as an input and outputs the number of times the letter *a* is found in that word.
5. Using recursion, write a program that takes an integer value as an input and outputs the Fibonacci value for that number. The Fibonacci value of a number is defined as follows:

   ```
   Fib( 1 ) = 1
   Fib( 2 ) = 1
   Fib( n ) = Fib ( n - 1 ) + Fib( n - 2 ) for n >= 3
   ```

   Description
6. Using recursion, write a program that takes a positive number as an input and keeps dividing that number by 3 until the result is less than 1, at which time output that result.
7. Using recursion, write a program that takes 10 numbers as inputs and outputs the minimum of these numbers.
8. Using recursion, write a program that takes 10 words representing Internet addresses as inputs and outputs the number of words containing .edu.
9. Rewrite Example 12.9, *RecursiveBinarySearch*, using an array sorted in descending order.

12.12.7 Programming Projects

1. Write a class with just one instance variable, a *String* representing a binary number. Write a recursive method taking only one parameter that converts that binary number to its decimal equivalent. Your program should include a client class to test your class.
2. Write a class with just one instance variable, an *int*. Your constructor should take an *int* as its only parameter. Write a recursive method that checks if that *int* is a multiple of 5. Your program should include a client class to test your class.
3. Write a class with just one instance variable, a *String* representing some HTML code. Your constructor should take a file name as its only parameter (you will need to make up some sample HTML files to test your program). Write a recursive method returning the number of occurrences of a specified character in the HTML *String*. Your program should include a client class to test your class. In particular, call the recursive method to check whether the sample files contain an equal number of < and > characters.
4. Write a class with just one instance variable, a *String* representing a password. Write a recursive method to check if the password contains at least one character that is a digit (0 to 9). Your program should include a client class to test your class.
5. Write a class with two instance variables, representing the same password. Write a recursive method that checks if both passwords are equal. Your program should include a client class to test your class.

6. Write a class with two instance variables, representing an old password and a new password. Write a recursive method that returns the number of places where the two passwords have different characters. The passwords can have different lengths. Write another, nonrecursive method returning whether the two passwords are sufficiently different. The method takes an *int* parameter indicating the minimum number of differences that qualify the passwords as being sufficiently different. Your program should include a client class to test your class.
7. Write a class with just one instance variable, an integer array. Your constructor should take an integer array as its only parameter. Write a recursive method that returns the sum of all elements in the array. Your program should include a client class to test your class.
8. Write a class with just one instance variable, an integer array. Your constructor should take an integer array as its only parameter. Write a recursive method that returns the maximum value of all the elements in the array. Your program should include a client class to test your class.
9. Write a class with the functionality of checking a list of names to determine whether the same name is present in two consecutive locations. The method solving that problem should be recursive. Your program should include a client class to test your class.
10. A professor has a policy to give at least one A in his or her class. Write a class that encapsulates that idea, including a recursive method checking for at least one A in a set of grades. Your program should include a client class to test your class.
11. Write a class with just one instance variable, an array

representing grades between 0 and 100. Your constructor should take an array as its only parameter. Write a recursive method that returns the average of all grades. Your program should include a client class to test your class.

12. Write a class with just one instance variable, an *int*. Your constructor should take an *int* as its only parameter. Write a recursive method that converts that *int* to a *String* representing that number in binary. Your program should include a client class to test your class.
13. Write a class potentially representing a *String* of binary digits (0s and 1s). Your constructor should take a *String* as its only parameter (that *String* may contain only 0s and 1s, or it may not). Write a recursive method that checks whether that *String* contains 0s and 1s only. Write another recursive method that converts that *String* to its decimal equivalent. Your method should be different from the one in Exercise 48: it should take two parameters, the *String* representing the binary number, and an *int* representing an exponent. Your program should include a client class to test your class.
14. Add a *static* method to the *Rational* class that is discussed and implemented earlier in the book. That *static* method sorts an array of *Rational* objects in ascending order using merge sort. Add some code in the main to test your method.
15. Add a *static* method to the *Auto* class that is discussed and implemented earlier in the book. That *static* method sorts an array of *Auto* objects in ascending order using quick sort. *Auto* objects are sorted in alphabetical order using their *model* instance variable. Add some code in the main

to test your method.

16. Write a class that includes a recursive method that converts a prefix arithmetic expression to an infix arithmetic expression. You should assume that a prefix arithmetic expression uses this syntax:
operator integerl integer2 integer3 …
The corresponding infix arithmetic expression is:

integer1 operator integer2 operator integer3 …

The operator can be +, –, *, or /.
For example, with this prefix arithmetic expression:

$$-6\ 123\ 45$$

your method should return the following infix arithmetic expression:

$$6 - 123 - 45$$

And for this prefix arithmetic expression:

$$+76543\ 12\ 4\ 5\ 6\ 7$$

Your method should return the following infix arithmetic expression:

$$76543 + 12 + 4 + 5 + 6 + 7$$

For simplicity, assume that there is just one space between the operator and the first integer and between the integers. Look up the documentation for the *Matcher* and *Pattern* classes and regular expressions. Your program should include a client class to test your program.

12.12.8 Technical Writing

1. Think of an example of a problem, different from the chapter problems, which can be solved by an iterative formulation and a recursive formulation. Discuss which one you would prefer to code and why.

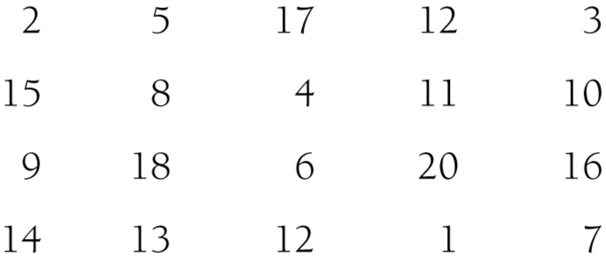
12.12.9 Group Projects (for a group of 1, 2, or 3 students)

1. Consider a rectangular grid of integers. We are interested in computing recursively the largest sum of any path from a top position to a bottom position. A valid path is defined as follows:

    - It should start at a number in the top row and end at a number in the bottom row.
    - It should include a number in every row.
    - From row *i* to row (*i* + 1), a valid path can be created:

- down vertically (in the same column)
- down diagonally one column to the left (if possible)
- down diagonally one column to the right (if possible)

For instance, let’s assume we have the following rectangle of numbers:



2	5	17	12	3
15	8	4	11	10
9	18	6	20	16
14	13	12	1	7

Note: Your program should accept any positive number at any spot within the rectangle.
Examples of valid paths are:
2 → 8 → 18 → 14
17 → 4 → 18 → 14
5 → 4 → 20 → 12
In this example, the path generating the largest sum is:
17 → 11 → 20 → 12 for a total of 17 + 11 + 20 + 12 = 60
Your program should accept from the user a rectangle of integers; to keep it simple, you can limit the size of the rectangle to a maximum of 10 columns by 20 rows. Your program should, recursively, compute and output the path that generates the largest sum.

Introduction

As our programs execute, we often need a means to organize data in memory. Arrays are a convenient method to store multiple variables of the same data type. *ArrayLists* improve on arrays by dynamically expanding, as needed.

In fact, arrays and *ArrayLists* are just two examples of **data structures**, which are methodologies a program uses to store its data in memory.

An *ArrayList* dynamically adjusts its size by increasing its capacity whenever it runs out of space. In fact, in many cases, the capacity exceeds the space needed to hold our elements. Then memory is allocated but not used. Obviously, this is not an efficient use of memory space.

However, *ArrayLists* are useful in some situations, such as reading data from a file, where we don’t know in advance how many items we will need to store in memory. Once the data is read, we know that the size of the *ArrayList* will not change further, so we can trim the capacity of the *ArrayList* to its current size using the *trimToSize* method, thus releasing the unused memory.

In other situations, however, the number of data items may dynamically increase or decrease as the program executes. For these cases, we need a data structure that efficiently grows and shrinks as items are added and removed.

A new data structure that we will illustrate in this chapter is the **linked list**, which can expand (or shrink) one object at a time, keeping the size of the list to a minimum at all times. An advantage, then, of linked lists is that they do not consume unnecessary memory.

13.1 Linked Lists

13.1.1 Linked-List Concepts and Structure

A **linked list** can be thought of as a chain of linked nodes.

A **node** is an object with two attributes:

- data—The data can be a primitive data type (for example, an *int*), or it can be a reference to an object of a specified class.
- the location of the next node in the chain—We say that a node “**points to**” or “**refers to**” the next node.

Figure 13.1 shows how we can visualize a node containing the integer value 5. The arrow points to the next node in the list.

Figure 13.1 A Node

Description

In the last node of the list, the location of the next node contains the value *null*, to indicate that there are no more nodes in the list.

Figure 13.2 illustrates a linked list of four video game players.

The object data stored at each node has the following attributes: the player's ID, the player's name, and the name of the player's favorite game.

Figure 13.2 A Linked List

Description

From the standpoint of program design, this linked list can be implemented using three classes:

- a *Player* class, encapsulating a player
- a *PlayerNode* class, encapsulating a node
- a *PlayerLinkedList* class, encapsulating the linked list

In the *Player* class, we will have three instance variables:

- an *int* storing the user ID of the player
- a *String* storing the name of the player
- a *String* storing the name of the player's favorite game

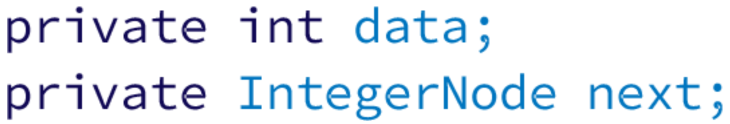
Often, a node class is designed in a general manner to store a generic *Object*. Implementing a list of generic *Objects* has the advantage of reusability; indeed, we could instantiate the list with any type of *Object* we want. In this chapter, we will first implement a linked list of the primitive type, *int*, then a linked list of *Player* objects, and then a linked list of generic *Objects*.

In the *IntegerNode* class, we have two instance variables:

- an *int*
- an *IntegerNode* object reference, representing the next node

Thus, the *IntegerNode* class is defined using an object reference of its own type. Indeed, one of its instance variables is an *IntegerNode* object reference.

We define our two instance variables using the following statements:



```
private int data;
private IntegerNode next;
```

Description

Based on this definition of the *IntegerNode* class, we need only one instance variable in the linked-list class, a reference to the first node, which we call the **head** of the linked list. Indeed, the first node will give us access to the second node, which in turn will give us access to the third node, and so on, until we reach the last node. We will know when we have reached the end of the linked list, because the reference to the next *IntegerNode* will have the value *null*.

Often, linked-list classes have another instance variable that holds the number of items in the linked list. Although the number of items can be calculated by looping through and counting all the nodes in the linked list, it is convenient to store the number of items as an instance variable. So our *IntegerLinkedList* class, encapsulating the linked list, will have two instance variables:

- an *IntegerNode* object reference, named *head*, representing the first node of the linked list
- an *int*, named *numberOfItems*, representing the number of items in the linked list

SOFTWARE ENGINEERING TIP

Include an instance variable in the linked-list class to store the number of items in the list for quick and direct access to that information as needed.

13.1.2 Linked-List Basics

Example 13.1 shows our *IntegerNode* class:

Example 13.1 The *IntegerNode* Class

```java
/* The IntegerNode class
   Anderson, Franceschi
*/

public class IntegerNode
{
  private int data;
  private IntegerNode next;

  /** default constructor
  *   sets data to 0, and next to null
  */
  public IntegerNode( )
  {
    data = 0;
    next = null;
  }

  /** overloaded constructor
  *   @param data data value
  */
  public IntegerNode( int data )
  {
    setData ( data );
    next = null;
  }

  /** accessor for data
  *   @return    the value of the node
  */
  public int getData( )
  {
    return data;
  }

  /** accessor for next
  *   @return   the reference to the next node
  */
  public IntegerNode getNext( )
  {
    return next;
  }

  /** mutator for data
  *   @param    data   the new value for the node
  *   @return  a reference to this object
  */
  public IntegerNode setData( int data )
  {
    this.data = data;
    return this;
  }

  /** mutator for next
  *   @param next the new value for next
  *   @return a reference to this object
  */
  public IntegerNode setNext( IntegerNode next )
  {
    this.next = next;
    return this;
  }
}
```

Description

The code for this class is straightforward. We code two constructors at lines 10 to 26. Both of these constructors set the value of *next* to *null*. This will be the desired action when a node is created. However, to allow a client (which will be the linked-list class) to reset the value of *next* as the list expands and shrinks, we provide the *setNext* method.

13.1.3 Methods of a Linked List

For our class encapsulating a linked list, we need to consider the following issues:

- We do not want client programs to change the head node of our list. Thus, we will not provide an accessor or a mutator for the head node.
- Client programs should not be able to change the number of items in the list. Only the methods of the class should update the number of items as we insert or delete items in the list. Thus, we will provide an accessor for the number of items in the list so that the client can view the number of items, but no mutator.

With a linked list, there is some basic functionality that we need to provide, such as

- insert an item,
- delete an item, and
- list, in order, all the items in the list, and return that list as a *String*.

Table 13.1 shows the APIs of the *insert*, *delete*, and *toString* methods.

IntegerLinkedList Methods

Methods of the *IntegerLinkedList* Class	
Return value	**Method name and argument list**

`void`	`insert( int value )` inserts *value* at the beginning of the list.
`boolean`	`delete( int value )` removes the first item on the list that is equal to *value* and returns *true*. If there is no such item on the list, the method returns *false*.
`String`	`toString( )` returns a *String* representation of the list.

Description

In our linked list of *ints*, we do not store the *ints* in any predetermined order. Thus, there are only two logical places to insert a node: at the beginning and at the end of the list. Inserting at the end will consume CPU time, since we will have to loop through all nodes in the list to find the end. So we have decided to insert at the beginning of the linked list because it is easier and faster. Unless we run out of memory, it will always be possible to insert a new node at the beginning of a list, so our *insert* method has a *void* return value.

Other options for implementing a linked list include providing methods to insert at the end of the list, or at a specified position in the list, or at a position before or after a node containing a specified value or object.

When inserting a new *int*, our *insert* method performs the following steps:

1. Instantiate a new node containing the *int* to be inserted.
2. Attach that node at the beginning of the list; that is, make that node point to the previous head node. If the list originally was empty, that is, *head* has the value *null*, then the *next* field of the new node is given the value *null*.
3. Indicate that the new node is now the head of the list; that is, make *head* point to the new node.
4. Increase the number of items in the list by 1.

Figures 13.3a to **13.3d** illustrate the first three steps.

Figure 13.3a Inserting: Our Original Linked List

Description

Figure 13.3b Step 1: The New Node Is Instantiated

Description

Figure 13.3c Step 2: The New Node Has Been Attached to the Beginning of the List

Description

Figure 13.3d Step 3: *head* Now Points to the New Node

Description

There are many alternatives for deleting an item from a linked list. We can delete the first element or the last item, or delete an item based on specified criteria. Such a criterion can be the value of the item, or it can be the position of an item in the list. We will implement one *delete* method only: one that deletes an item based on its value.

In order to delete an item, we will traverse the list searching for an item whose value matches a specified value passed as the argument of the *delete* method. **Traversing** a list means looping through the nodes in the list, one after the other, starting at the first node. If we find such an item, we will remove it from the list and return *true*. If we do not find the item, we will return *false*.

There are three possible outcomes when searching for such an item:

1. Such an item can be found and is located somewhere after the head node.
2. Such an item can be found and is located at the head node. Special care must be taken here. There will be a change in the head node of the list and our code will need

to handle that.

3. Such an item cannot be found. In this case, no deletion can take place, and we will return *false*.

In the first case, when the node to delete is located after the first node in the list, we need to connect the node before the deleted node (the “previous” node) to the node after the deleted node. To do this, we replace the previous node’s *next* field with the *next* field of the deleted node. Thus, as we traverse the list, we need to keep track of the previous node, as well as the current node. To do this, we maintain two node references, *previous* and *current*.

Once we have located the node to delete and it is not the first node of the list, we perform the following steps:

1. Set the *next* field in the *previous* node to the *next* field in the node to be deleted (*current*).
2. Decrease the number of items in the list by 1.

The *current* node becomes unreachable and is therefore a candidate for garbage collection.

Figures 13.4a and **13.4b** illustrate deleting a node with the value 8, which is located somewhere in the middle of the list.

Figure 13.4a The List Before Deleting the Item Whose Value Is 8

Description

Figure 13.4b The *previous* Node Is Connected to the Node After *current*, Deleting the Item Whose Value Is 8

Description

When the node to delete is the head node, we need to make the node pointed to by the deleted node the new *head* of the list. Thus, we perform the following steps:

1. Assign the *next* field of the *current* node to *head*.

2. Decrease the number of items in the list by 1.

Figures 13.5a and **13.5b** illustrate deleting the first node in the list.

Figure 13.5a Before Deleting the Item Whose Value Is 7

Description

Figure 13.5b After Updating *head*, the First Node in the List Is Deleted

Description

Example 13.2 shows our *IntegerLinkedList* class.

Example 13.2 The *IntegerLinkedList* Class

```java
/* The IntegerLinkedList class
   Anderson, Franceschi
*/

public class IntegerLinkedList
{
  private IntegerNode head;
  private int numberOfItems;

  /** default constructor
  *   constructs an empty list
  */
  public IntegerLinkedList( )
  {
    head = null;
    numberOfItems = 0;
  }

  /** accessor for numberOfItems
  *   @return   numberOfItems
  */
  public int getNumberOfItems( )
  {
    return numberOfItems;
  }

  /** insert method
  *   @param  value   data to insert
  *    inserts node at head
  */
  public void insert( int value )
  {
    IntegerNode nd = new IntegerNode( value );
    nd.setNext( head );
    head = nd;
    numberOfItems++;
  }

  /** delete method
  *   @param    value    the value to delete
  *   @return   true if value was deleted from the list, false otherwise
  */
  public boolean delete( int value )
  {
    IntegerNode current = head;
    IntegerNode previous = null;
    while ( current != null
           && current.getData( ) != value )
    {
      previous = current;
      current = current.getNext( );
    }

    if ( current == null ) // not found
         return false;
    else
    {
      if ( current == head )
        head = head.getNext( ); // delete head
      else
        previous.setNext( current.getNext( ) );

      numberOfItems--;
      return true;
    }
  }

  /** toString
  *   @return    values in list separated by a space
  */
  @Override
  public String toString( )
  {
    String listString = "";
    IntegerNode current = head;
    for ( int i = 0; i < numberOfItems; i++ )
    {
      listString += current.getData( ) + " ";
      current = current.getNext( );
    }
    return listString;
  }
}
```

Description

The default constructor (lines 10–17) initializes the *head* and *numberOfItems* instance variables to *null* and 0, respectively. The *insert* method, coded from lines 27 to 37, inserts a node containing its parameter *value* at the beginning of the list. At line 33, we create a new node, *nd*, with the data *value*. At line 34, we connect *nd* to the first node in the list by setting its *next* field to the current head of the list. At line 35, we assign the new node, *nd*, to *head*, making it the first node in the linked list. Figures 13.3a to 13.3d illustrate the impact on the list of lines 33–35. At line 36, we increment *numberOfItems* to reflect the addition of a node to the list.

The *delete* method, coded from lines 39 to 66, returns *true* if the deletion is successful and *false* if the deletion is not successful.

Using a *while* loop at lines 47–52, we walk through, or traverse, the list searching for a node containing *value*, our *delete* method's parameter. At lines 45 and 46, we declare and initialize two *IntegerNode* references, which we will use to track the current and previous nodes as we traverse the list. Because each node points only to the next node in the list, we can traverse the list in a forward direction only. Once we have reached a node, we do not have a way to backtrack to the previous node. Thus, as we traverse the list, we must remember the previous node because we will need to change the value of its next node. We update *previous* and *current* at lines 50–51 by assigning *current* to *previous*, then moving *current* to the next node in the list by calling the *getNext* method.

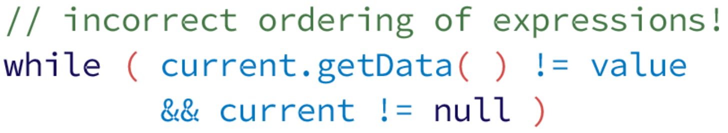
Once we find *value*, we will connect *previous* to the *IntegerNode* after *current*. If we have reached the end of the list —that is, *current* is *null* (line 47)—or if we have found *value* (line 48), we are ready to either return *false* or delete the node by updating the links in our list. At that point, we exit the *while* loop and skip to line 54.

COMMON ERROR TRAP

When traversing a list, always test if a node reference is *null* before calling a method using that reference. Failure to do so might result in a *NullPointerException* at run time. More generally, when coding a linked-list method, always pay attention to the possibility of an object reference being *null* before using that reference to call a method.

Note that the order of the expressions in the *while* loop condition is critical. Expressions in a compound condition are evaluated left to right, so (*current != null*) is evaluated first. If this expression is *false* (that is, *current* is *null*), then the whole *while* loop condition cannot evaluate to *true*, so the second expression is not evaluated. This is important because the second expression uses *current* to call the *getData* method. If *current* is *null*, the evaluation of the second expression would generate a *NullPointerException*. In this way, we are taking advantage of Java's short-circuit evaluation of logical AND operations.

Thus, if we reversed the order of the expressions in the *while* loop condition, as shown here,



```
// incorrect ordering of expressions!
while ( current.getData( ) != value
          && current != null )
```

Description

reaching the end of the list would always generate a *NullPointerException*.

At line 54, we test whether *current* is *null*, because a *null* value indicates that we exited the *while* loop because the list is empty or we reached the end of the list without finding *value*. Either way, the deletion is unsuccessful and we return *false* at line 55.

If *current* is not *null*, we have found *value*. We update the list and return *true* at lines 58–64. If *current* is the head node, we found *value* at the beginning of the list, so we need to update the *head* instance variable. In this case, we assign the node after *head* to *head* at line 59. Note that if there was only one element in the list before the deletion, *head* becomes *null* (at this point the list will be empty). Figures 13.5a and 13.5b show the impact of executing line 59 on the list (before and after).

If *current* is not the head node, we skip to line 61 where we set the node pointed to by *previous* to be the node after *current*. At this point, *current* is no longer part of the linked list.

At line 63, we decrement *numberOfItems*, to reflect that we now have one fewer item in the list. Finally, at line 64, we return *true*. Figures 13.4a and 13.4b show the impact of executing line 61 on the list (before and after).

Our last method, *toString*, is at lines 68–82. Our *toString* method traverses the list and returns a *String* containing the data from each item in the list. A *toString* method traversing the list is especially useful at the debugging stage, when we want to verify that we have properly added or deleted an element. We can test our code by calling *toString* before and after such operations.

13.1.4 Testing a Linked-List Class

Like any class that we design, we want to test the class before using it in a program. In particular, we should test two important methods: *insert* and *delete*. Furthermore, we want to test all possible scenarios.

SOFTWARE ENGINEERING TIP

There are many ways to code the deletion of a node in the list. Try to write code that is easy to read and maintain.

Considering our *insert* method, which always inserts at the head of the list, we want to test a minimum of two situations:

- inserting into an empty list
- inserting into a nonempty list

As we will see later in the chapter, there are other types of linked lists and their *insert* methods may require more test cases than the ones previously mentioned.

After each insertion, we can use the *toString* method to verify that the items were inserted correctly.

For the *delete* method, we should test the following scenarios:

- attempting to delete from an empty list
- deleting an item in the middle of the list
- deleting an item stored in the head node
- deleting an item stored in the last node in the list

- attempting to delete an item not in the list

After each deletion, we can use the *toString* method to check that the items were deleted correctly.

Example 13.3 shows a client program that tests the *IntegerLinkedList* class.

Example 13.3 The *IntegerLinkedListTest* Class

```
/* The IntegerLinkedListTest class
   Anderson, Franceschi
*/

public class IntegerLinkedListTest
{
  public static void main( String [ ] args )
  {
    // construct empty IntegerLinkedList
    IntegerLinkedList numbers = new IntegerLinkedList( );
    System.out.println( "Number of items in the list: "
     + numbers.getNumberOfItems( ) + "\n" + numbers.toString( ) );

    numbers.insert( 7 ); // insert in empty list
    System.out.println ( "Number of items in the list: "
     + numbers.getNumberOfItems( ) + "\n" + numbers.toString( ) );

    numbers.insert( 2 ); // insert in list with one item
    System.out.println( "Number of items in the list: "
     + numbers.getNumberOfItems ( ) + "\n" + numbers.toString( ) );

    numbers.insert( 5 ); // insert in list with two items
    System.out.println( "Number of items in the list: "
     + numbers.getNumberOfItems( ) + "\n" + numbers.toString( ) );

    if ( ! numbers.delete( 8 ) )     // unsuccessful - not in list
       System.out.println( "8 could not be deleted:" );

    if ( numbers.delete( 2 ) )       // successful
       System.out.println( "2 was successfully deleted:" );
    System.out.println( "Number of items in the list: "
       + numbers.getNumberOfItems( ) + "\n" + numbers.toString( ) );

    if ( numbers.delete( 7 ) )       // successful
       System.out.println( "7 was successfully deleted:" );
    System.out.println( "Number of items in the list: "
       + numbers.getNumberOfItems( ) + "\n" + numbers.toString( ) );

    if ( numbers.delete( 5 ) )       // successful
       System.out.println( "5 was successfully deleted:" );
    System.out.println( "Number of items in the list: "
       + numbers.getNumberOfItems( ) + "\n" + numbers.toString ( ) );

    if ( ! numbers.delete( 8 ) )     // unsuccessful - empty list
       System.out.println( "8 could not be deleted:" );
    System.out.println( "Number of items in the list: "
       + numbers.getNumberOfItems( ) + "\n" + numbers.toString ( ) );
  }
}
```

Description

In this example, we instantiate the *IntegerLinkedList numbers* object at line 10, then traverse the empty list at lines 11–12.

SOFTWARE ENGINEERING TIP

Testing all the methods in a linked list is critical to avoid errors at run time. Try to test all possible scenarios of all methods.

We successively insert 7, 2, and 5 and traverse *numbers* after each insertion at lines 14–24.

After that, we test our *delete* method. At line 26, we attempt to delete the value 8; we know this will fail, as the output in **Figure 13.6** shows.

Figure 13.6 Output of Example 13.3

Description

We then delete in the middle of the list at line 29, at the end of the list at line 34, and at the beginning of the list (actually the only item left at that point) at line 39. Another attempt to delete is made at line 44, but at that time the list is empty, which causes us to execute line 45, as shown in Figure 13.6.

CODE IN ACTION

Within the online resources, you will find a movie with a step-by-step illustration of linked-list methods. Click on the link to start the movie.

id: 5          name: Ajay      game: Sonic

Player deleted: id: 5          name: Ajay      game: Sonic
Number of items in the list: 0

7 not found: cannot be deleted
```

13.2 Linked Lists of Objects

Our next step is to design and code a linked list of objects, for example, *Player* objects, described earlier in the chapter.

Since each node in our list will store a *Player* reference, we start by defining our *Player* class, shown in **Example 13.4**.

Example 13.4 The *Player* Class

```java
/* The Player Class
   Anderson, Franceschi
*/

public class Player
{
 private int id;
 private String name;
 private String game;

 /** constructor
 * @param id    player's id
 * @param name  player's name
 * @param game  player's game
 */
 public Player( int id, String name, String game )
 {
    setID( id );
    setName( name );
    setGame( game );
 }

 /** accessor for id
 * @return   id
 */
 public int getID( )
 {
    return id;
 }

 /** accessor for name
 * @return name
 */
 public String getName( )
 {
    return name;
 }

 /** accessor for game
 * @return game
 */
 public String getGame( )
 {
    return game;
 }

 /** mutator for Id
 * @param id  new value for id
 * @return    a reference to this object
 */
 public Player setID( int id )
 {
   this.id = id;
   return this;
 }

 /** mutator for name
 * @param name  new value for name
 * @return      a reference to this object
 */
 public Player setName( String name )
 {
    this.name = name;
    return this;
 }

 /** mutator for game
 * @param game  new value for game
 * @return      a reference to this object
 */
 public Player setGame( String game )
 {
    this.game = game;
    return this;
 }

 /** equals method
 *  @param o reference to object to compare to this object
 *  @return  true if o is a Player object
 *   and id, name, and game are equal in both objects; false otherwise
 */
 @Override
 public boolean equals( Object o )
 {
   if (  ! ( o instanceof  Player ) )
       return false;
   else
   {
       Player  objPlayer = ( Player ) o;
       return ( id == objPlayer.id && name.equals( objPlayer.name )
              && game.equals( objPlayer.game ) );
   }
 }

 /** toString method
 *  @return  String representation of Player object
 */
 @Override
 public String toString( )
 {
    return ( "id: " + id + "\tname: "
             + name + "\tgame: " + game );
 }
}
```

Description

The code for this class is straightforward. We declared the three instance variables, along with a constructor, accessors and mutators, and the standard *equals* and *toString* methods.

Example 13.5 shows our *PlayerNode* class:

Example 13.5 The *PlayerNode* Class

```java
/* The PlayerNode class
   Anderson, Franceschi
*/

public class PlayerNode
{
 private Player player;
 private PlayerNode next;
 /** default constructor
 * initializes player and next references to null
 */
 public PlayerNode( )
 {
    player = null;
    next = null;
  }

  /** overloaded constructor
  * @param  player
  * initializes player reference to player reference to Player object
  */
  public PlayerNode( Player player )
  {
    setPlayer( player );
    next = null;
  }

  /** accessor for player
  * @return player
  */
  public Player getPlayer( )
  {
    return player;
  }

  /** accessor for next
  * @return next
  */
  public PlayerNode getNext( )
  {
    return next;
  }

  /**  mutator for player
  *  @param player  new Player reference
  *  @return        a reference to this object
  */
  public PlayerNode setPlayer( Player player )
  {
    this.player = player;
    return this;
  }

  /**  mutator for next
  *  @param next  new reference to next PlayerNode
  *  @return      a reference to this object
  */
  public PlayerNode setNext( PlayerNode next )
  {
    this.next = next;
    return this;
  }
}
```

Description

The code for this class is similar to the code of the *IntegerNode* class. The overloaded constructor allows the client to set the *Player* object, while the default constructor sets the reference for the *Player* object to *null*.

13.2.1 A Linked-List Shell

For our class encapsulating a linked list of *Player* objects, we need to consider the following issues:

- We anticipate having many linked-list classes. Therefore, it makes sense to set up a linked-list superclass from which our more specialized linked-list classes will inherit.
- We provide some basic utility methods, but we omit methods to insert or delete nodes in the list, because those methods will have different names and implementations, depending on the functionality of a given subclass.
- We do not intend to instantiate objects from our superclass; thus, we declare our superclass *abstract*.

Example 13.6 shows our *abstract ShellLinkedList* class. This class defines methods that will be common to all subclasses. For example, in addition to the default constructor and the accessor for the number of items in the list, we provide a method to determine whether the list is empty and a *toString* method that can be used to print each node in the list. We declare both instance variables as *protected* so that our linked-list subclasses inherit the head and number of items in the list.

Example 13.6 The *ShellLinkedList* Class

```java
/* The ShellLinkedList class
   Anderson, Franceschi
*/

public abstract class ShellLinkedList
{
  protected PlayerNode head;
  protected int numberOfItems;

  /**  constructor
  *  sets head to null and numberOfItems to 0
  */
  public ShellLinkedList( )
  {
    head = null;
    numberOfItems = 0;
  }

  /**  accessor for numberOfItems
  *   @return    numberOfItems
  */
  public int getNumberOfItems( )
  {
    return numberOfItems;
  }

  /** isEmpty method
  * @return  true if no items in list; false otherwise
  */
  public boolean isEmpty( )
  {
    return ( numberOfItems == 0 );
  }

  /** toString method
  * @return the contents of the list
  */
  @Override
  public String toString( )
  {
    String listString = "";
    PlayerNode current = head;
    while ( current != null )
    {
      listString += current.getPlayer( ).toString( ) + "\n";
      current = current.getNext( );
    }
    return listString;
  }
}
```

Description

SOFTWARE ENGINEERING TIP

Do not include a mutator method for the number of items. Only the linked-list class should alter the number of items as items are inserted or deleted. Including a mutator method for the number of items could allow the client to corrupt its value.

Table 13.2 shows the APIs of *ShellLinkedList* constructor and methods.

***ShellLinkedList* Constructor and Methods**

Constructor and Methods of the *abstract ShellLinkedList* Class

Class	**Constructor and argument list**
`ShellLinkedList`	`ShellLinkedList( )` constructs an empty list
Return value	**Method name and argument list**
`int`	`getNumberOfItems( )` returns the number of items in the list
`boolean`	`isEmpty( )` returns *true* if the list contains 0 items, *false* otherwise
`String`	`toString( )` returns the contents of every node in the list

Description

SOFTWARE ENGINEERING TIP

Do not provide an accessor or mutator for the head node instance variable of the linked list. This will protect the head node from being accessed or changed outside the class.

SOFTWARE ENGINEERING TIP

Choose names for instance variables and methods that illustrate their function within the data structure. Your class will be easier for others and yourself to understand at maintenance time.

SOFTWARE ENGINEERING TIP

Provide a *toString* method that traverses the list. This is helpful in testing the other methods of the class. In particular, traversing the list after calling the insert or delete methods can verify that an item was correctly added or removed.

We coded the method *isEmpty* at lines 27 to 33. It returns *true* if the list is empty, *false* otherwise.

The *toString* method, at lines 35–49, traverses the linked list until it reaches the end of the list, where *current* will be *null*.

13.2.2 Generating an Exception

Now that we have a shell class for a linked list, we want to add some methods to perform operations on the linked list, such as inserting or deleting elements.

An issue may arise with the return value of the *delete* method. When deleting a node, we want to return the item that we are deleting. Indeed, we want to be able to delete a node based on the value of one or more of the fields of the object stored at that node, that is, the value of one or more of the instance variables of the *Player* class. For example, if the client wants to delete the first *Player* on the list with an ID of 5, we would then return that *Player* object to the client. If the list is empty or we cannot find a *Player* with ID 5, we do not want to return *null* because the client likely will attempt to use the returned object reference, which would generate a *NullPointerException*. A solution to this problem is to *throw* an exception when we are unable to delete the requested node. To do this, we create our own exception class, *DataStructureException*, which we use throughout this chapter.

It is good practice to define our own exception class as a subclass of another exception class. This way, our class inherits the existing functionality of the exception class, which simplifies coding the new class: we need to code only the constructor.

Example 13.7 shows our *DataStructureException* class, which *extends* the *NoSuchElementException* class, which is in the *java.util* package.

Example 13.7 The *DataStructureException* Class

```
 1 /* The DataStructureException Class
 2    Anderson, Franceschi
 3 */
 4 import java.util.NoSuchElementException;
 5
 6 public class DataStructureException extends NoSuchElementException
 7 {
 8   /** constructor
 9   * @param s error message
10   */
11   public DataStructureException( String s )
12   {
13      super( s );
14   }
15 }
```

Description

The constructor for the class is coded at lines 8 to 14; it simply takes a *String* parameter and passes it to the superclass constructor. When one of our methods detects an error situation, such as an attempt to delete from an empty list, we will *throw* the exception using a statement like the following:

```
throw new DataStructureException( "Some error message here" );
```

Description

The message we pass to the constructor will identify the type of error we detected.

The header of any method that *throws* the *DataStructureException* will add a *throws* clause, as in the following template:

```
accessModifier dataType methodName( parameter list )
                              throws DataStructureException
```

Description

The *NoSuchElementException* class inherits from *RuntimeException*, and thus is not a checked exception. This means that the client does not need to use *try/catch* blocks when invoking any method that could throw a *DataStructure-*

Exception. Nevertheless, we will always use *try/catch* blocks so that when a *DataStructureException* occurs, the client will see our custom message and can better understand the source of the problem.

Now we are ready to expand our shell linked-list class with more meaningful methods.

13.2.3 Other Methods of a Linked List

In addition to our *insert* and *delete* methods, we also provide the functionality to retrieve, or **peek** at, the contents of a node, without deleting it.

Table 13.3 shows the APIs of the *insert*, *delete*, and *peek* methods.

PlayerLinkedList Methods

Methods of the *PlayerLinkedList* Class

Return value	Method name and argument list
`void`	`insert( Player p )` inserts *Player p* at the beginning of the list.
`Player`	`delete( int searchID )` returns and removes the first *Player* in the list with an ID equal to *searchID*. If there is no such *Player* in the list, the method throws a *DataStructureException*.
`Player`	`peek( int searchID )` returns the first *Player* on the list whose ID is equal to *searchID*. If there is no such *Player* in the list, the method throws a *DataStructureException*.

Description

Again, we will insert at the beginning of the list and our *insert* method has a *void* return value; our insert method works in the same manner as the insert method for a list of *ints*.

Our *delete* method will also delete a node based on specific criteria. With our list of *ints*, the criterion was simply the value of an item; here, the criterion can be the value of one (or several) instance variables of an item. We will implement one *delete* method only: one that deletes an item based on a specified value of its *id* field. The implementation of a *delete* method that deletes an item based on a specified value of its *name* or *game* field is similar.

If we find such an item, we will remove it from the list and return a reference to that item. When deleting from a list of *ints*, it made sense to return a *boolean* value rather than the value of the item, because we already knew the value of the item since it was passed as a parameter to the method. Here, we delete a node based on the value of the *id* field of an object, so we do not know the values of the other fields of that object. Thus, it makes sense to return an object reference rather than just *true* or *false*. If the item cannot be found, we will *throw* a *DataStructureException*.

Otherwise, the mechanics of deleting a node within the list, whether that node is the *head* node or is in the middle of the list, are exactly the same as with our linked list of *ints*.

Example 13.8 shows our *PlayerLinkedList* class. This class *extends* and inherits the functionality of our *ShellLinkedList* class; thus *head* and *numberOfItems* are inherited instance variables.

Example 13.8 The *PlayerLinkedList* Class

```java
/* The PlayerLinkedList class
   Anderson, Franceschi
*/

public class PlayerLinkedList extends ShellLinkedList
{

  /** default constructor
  *   calls constructor of ShellLinkedList class
  */
  public PlayerLinkedList( )
  {
    super( );
  }

  /** insert method
  *   @param      p    Player object to insert
  */
  public void insert( Player p )
  {
    // insert as head
    PlayerNode pn = new PlayerNode( p );
    pn.setNext( head );
    head = pn;
    numberOfItems++;
  }

  /** delete method
  *   @param      searchID    id of Player to delete
  *   @return    the Player deleted
  */
  public Player delete( int searchID )
                           throws DataStructureException
  {
   PlayerNode current = head;
   PlayerNode previous = null;
   while ( current != null
           && current.getPlayer( ).getID( ) != searchID )
   {
     previous = current;
     current = current.getNext( );
   }

   if ( current == null ) // not found
        throw new DataStructureException( searchID
                    + " not found: cannot be deleted" );
   else
   {
     if ( current == head )
       head = head.getNext( ); // delete head
     else
       previous.setNext( current.getNext( ) );

     numberOfItems--;
     return current.getPlayer( );
   }
  }

  /** peek method
  *   @param     searchID   id of Player to search for
  *   @return    the Player found
  */
  public Player peek( int searchID )
               throws DataStructureException
  {
    PlayerNode current = head;
    while ( current != null
            && current.getPlayer( ).getID( ) != searchID )
    {
      current = current.getNext( );
    }

    if ( current == null ) // not found
      throw new DataStructureException( searchID
                   + " not found: cannot be deleted" );
    else
    {
      return current.getPlayer( );
    }
 }
}
```

Description

The default constructor (lines 8–14) calls the constructor of the superclass to initialize the *head* and *numberOfItems* instance variables. The *insert* method, coded from lines 16 to 26, is similar to our insert method for a linked list of *ints*, except that it inserts a *Player* object instead of an *int*.

The *delete* method, coded from lines 28 to 57, returns the *Player* deleted if the deletion was successful and *throws* a *DataStructureException* if the deletion was not successful.

The *while* loop at lines 37–42 is very similar to the *delete* method for our linked list of *ints*. We first traverse the list searching for a node containing a *Player* object whose *id* has the same value as *searchID*, our *delete* method's parameter.

Once we find a *Player* whose *id* field matches *searchID*, we will connect *previous* to the *PlayerNode* after *current*. If we have reached the end of the list, that is, *current* is *null* (line 37), or if we have found a *Player* whose *id* value is *searchID* (line 38), we are ready to either *throw* an exception or delete the node by updating the links in our list. At that point, we exit the *while* loop and skip to line 44.

At line 44, we test whether *current* is *null*, because a *null* value indicates that we exited the *while* loop because the list is empty or we reached the end of the list (without finding a *Player* whose id is *searchID*). If the deletion is unsuccessful, we *throw* a *DataStructureException* with an appropriate message at lines 45–46.

If *current* is not *null*, that means that we have found a *Player* whose *id* is *searchID*. We update the list and return the deleted *Player* at lines 49–55.

The *peek* method is coded at lines 59–80. We traverse the list in the same way as the *delete* method, except that because we will not delete a node, we do not need to mark the node before *current*.

If we do not find a node containing a *Player* whose id is *searchID*, we *throw* an exception at lines 74–75. If we find one, we return that *Player* object. In this way, the client can directly update the objects in the list.

13.2.4 Testing a Linked-List Class

Again, we want to test the class before using it in a program, and we want to test all possible scenarios, similarly to what we did with our linked list of *ints*.

After each insertion and deletion, we use the *toString* method to verify that the items were inserted and deleted correctly.

Example 13.9 shows a client program that tests the *PlayerLinkedList* class.

Example 13.9 The *PlayerLinkedListTest* Class

```java
/* The PlayerLinkedListTest class
   Anderson, Franceschi
 */

public class PlayerLinkedListTest
{
  public static void main( String [ ] args )
  {
    Player p1 = new Player( 7,"Sarah","Mario" );
    Player p2 = new Player( 2,"Jin","Golf" );
    Player p3 = new Player( 5,"Ajay","Sonic" );

    // construct empty PlayerLinkedList
    PlayerLinkedList players = new PlayerLinkedList( );
    System.out.println( "Number of items in the list: "
     + players.getNumberOfItems( ) + "\n" + players.toString( ) );

    players.insert( p1 );  // insert in empty list
    System.out.println( "Number of items in the list: "
     + players.getNumberOfItems( ) + "\n" + players.toString( ) );

    players.insert( p2 );  // insert in list of one item
    System.out.println( "Number of items in the list: "
     + players.getNumberOfItems( ) + "\n" + players.toString ( ) );

    players.insert( p3 );  // insert in list of two items
    System.out.println( "Number of items in the list: "
     + players.getNumberOfItems( ) + "\n" + players.toString( ) );

    Player temp;    // will be assigned the deleted item

    try
    {
     temp = players.delete( 8 );           // unsuccessful
     System.out.println( "Player deleted: " + temp );
    }
    catch ( DataStructureException dse1 )
    {
     System.out.println( dse1.getMessage( ) + "\n" );
    }

    try
    {
     temp = players.peek( 2 );             // test peek
     System.out.println( "Player retrieved: " + temp );
     System.out.println( "Number of items in the list: "
       + players.getNumberOfItems( ) + "\n" + players.toString( ) );

     temp = players.delete( 2 );           // delete in the middle
     System.out.println( "Player deleted: " + temp );
     System.out.println( "Number of items in the list: "
       + players.getNumberOfItems( ) + "\n" + players.toString( ) );

     temp = players.delete( 7 );           // delete the last item
     System.out.println( "Player deleted: " + temp );
     System.out.println( "Number of items in the list: "
      + players.getNumberOfItems( ) + "\n" + players.toString( ) );

     temp = players.delete( 5 );         // delete the first item
     System.out.println( "Player deleted: " + temp );
     System.out.println( "Number of items in the list: "
      + players.getNumberOfItems( ) + "\n" + players.toString( ) );

     temp = players.delete( 7 );         // delete from empty list
     System.out.println( "Player deleted: " + temp );
     System.out.println( "Number of items in the list: "
      + players.getNumberOfItems( ) + "\n" + players.toString( ) );
    }
    catch ( DataStructureException dse2 )
    {
      System.out.println( dse2.getMessage( ) );
    }
  }
}
```

Description

In this example, we instantiate three *Player* object references *p1*, *p2*, and *p3* at lines 9, 10, and 11. We instantiate the *PlayerLinkedList* players object reference at line 14, then traverse the empty list *players* at lines 15–16.

We successively insert *p1*, *p2*, and *p3* and traverse *players* after each insertion at lines 18–28.

After that, we test our *delete* method. Because our *delete* method *throws* a *DataStructureException*, we use *try* and *catch* blocks when calling that method.

At line 34, we attempt to delete an item in the list whose *id* is 8; we know this will fail, and as the output shows in **Figure 13.7**, we execute the *catch* block at lines 37–40.

Figure 13.7 Output of Example 13.9

Description

In the next *try* block, at line 44, we call the *peek* method to see if there is a *Player* whose *id* is 2. We traverse the list at lines 46–47 and can verify that the list has not been modified by the call to *peek*.

We then delete in the middle of the list at line 49, at the end of the list at line 54, and at the beginning of the list (actually the only item left at that point) at line 59. Another attempt to delete is made at line 64, but at that time the list is empty. This causes us to execute the second *catch* block at lines 69–72, as shown in **Figure 13.7**.

13.3 Implementing a Stack Using a Linked List

Imagine a group of college students on a spring break, sharing an apartment. After they eat, they typically pile up the dirty dishes in the kitchen sink. Another meal is consumed, and more dirty dishes are piled on top of the existing ones. At the top of the pile is the dirty dish that was placed there last. Soon the students run out of clean dishes, and somebody will have to start cleaning them. He or she will start by cleaning the dish at the top of the pile, that is, the last dish placed on the pile. That approach is called **last in, first out**, or **LIFO**.

A **stack** is a linear data structure that organizes items in a last in, first out manner. **Figure 13.8** shows a stack of trays. The tray at the top of the stack was put on the stack last, but will be taken off the stack first.

Figure 13.8 A Stack of Trays

Description

A stack can be represented by a linked list. In a linked list representing a stack:

- we insert, or **push**, at the beginning of the list
- we delete, or **pop**, the item at the beginning of the list

Since we insert and delete at the beginning of the list, the item deleted is the last one that was inserted, reflecting the LIFO pattern.

Table 13.4 shows the APIs of the *push*, *pop*, and *peek* methods.

PlayerStackLinkedList Methods

Methods of the *PlayerStackLinkedList* Class

Return value	**Method name and argument list**
`void`	`push( Player p )` inserts *Player p* at the top of the stack.
`Player`	`pop( )` returns and removes the first *Player* of the list. If the list is empty, the method throws a *DataStructureException*.
`Player`	`peek( )` returns the first *Player* on the list without deleting it. If the list is empty, the method throws a *DataStructureException*.

Description

The *push* method is identical to the *insert* method of the *PlayerLinkedList* class discussed earlier, and is illustrated in Figures 13.3a to 13.3d.

The *pop* method is different from the *delete* method we coded earlier in our *PlayerLinkedList* class. In a stack, we always delete the first item in the list. Therefore, in a linked list implementing a stack, we do not delete an item based on the value of one of its instance variables. The *pop* method for our stack returns a *Player* object, the one stored at the head of the linked list. If our stack is empty, our *pop* method will *throw* a *DataStructureException* in order to avoid returning a *null* object reference.

The steps required to pop the first item are identical to the steps for deleting the first node in the *PlayerLinkedList*. That is illustrated in Figures 13.5a and 13.5b.

Example 13.10 shows our *PlayerStackLinkedList* class. This class also *extends* and inherits the functionality of our *ShellLinkedList* class.

Example 13.10 The *PlayerStackLinkedList* Class

```java
/* The PlayerStackLinkedList class
   Anderson, Franceschi
*/

public class PlayerStackLinkedList extends ShellLinkedList
{
   // head and numberOfItems are inherited instance variabl

   public PlayerStackLinkedList( )
   {
      super( );
   }

   /** push method
   *   @param p Player object to insert
   */
   public void push( Player p )
   {
     PlayerNode pn = new PlayerNode( p );
     pn.setNext( head );
     head = pn;
     numberOfItems++;
   }

   /** pop method
   *   @return    the Player object deleted
   */
   public Player pop( ) throws DataStructureException
   {
     if ( isEmpty( ) )
       throw new DataStructureException
                  ( "empty stack: cannot be popped" );
     else
     {
       Player deleted = head.getPlayer( );
       head = head.getNext( );
       numberOfItems--;
       return deleted;
     }
   }

   /** peek method
   *   @return    the Player object retrieved
   */
   public Player peek( ) throws DataStructureException
   {
     if ( isEmpty( ) )
          throw new DataStructureException
                     ( "empty stack: cannot peek" );
     else
     {
          return head.getPlayer( );
     }
   }
}
```

Description

The *push* method, coded from lines 14 to 23, is identical to the *insert* method in the *PlayerLinkedList* class (Example 13.8).

In the *pop* method (lines 25–40), we first test if the stack is empty at line 30. If it is empty, we *throw* a *DataStructureException* with the appropriate argument at lines 31–32. If the stack is not empty, we delete the first item in the stack and return it. We call the *getPlayer* method from the *PlayerNode* class to get the *Player* stored at the head of the stack, and assign it to the *Player* reference *deleted* (line 35). The *deleted* reference is then returned at line 38. At lines 36 and 37, we perform the bookkeeping on the stack to reflect the deletion. We update *head* at line 36 and decrement *numberOfItems* at line 37.

COMMON ERROR TRAP

Before popping an item from a linked list representing a stack, always check if the linked list is empty. Not doing so results in a *NullPointerException* at run time.

The *peek* method is coded at lines 42–54. If the list is empty, we *throw* an exception at lines 48–49. If the list is not empty, we return the *Player* at the head of the list at line 52.

Like our previous linked-list implementation, it is very important to test if the stack is empty before trying to delete a node; failure to do so will generate a *NullPointerException* at run time.

A similar program to Example 13.9 can be coded to test all possible scenarios when using the methods of the *PlayerStackLinkedList* class. This is proposed in the short program section of the exercises.

13.4 Implementing a Queue Using a Linked List

Imagine a line of people at an automated teller machine, or ATM, waiting to withdraw cash. The person at the front of the line is using the ATM. When a new customer arrives, the customer goes to the back of the line. As customers use the ATM, they exit the line, and the next customer moves to the front of the line. Thus, customers use the ATM in the order of their arrival times. We call this pattern “**first in, first out,**” or **FIFO**.

A **queue** is a linear data structure that organizes items in a first in, first out manner.

Figure 13.9 shows a queue of people at an ATM. The person at the front of the queue arrived first and will use the ATM first. The person at the back arrived last and will use the ATM last. The next person to arrive will stand after the person currently at the back of the queue. That newly arrived person will become the new back of the line.

Figure 13.9 A Queue of People Waiting at the ATM

Description

A queue can be represented by a linked list by providing the following operations:

- we insert, or **enqueue**, an item at the end of the list
- we delete, or **dequeue**, the item at the beginning of the list
- we *peek* at the item at the beginning of the list

Table 13.5 shows the APIs of the *enqueue*, *dequeue*, and *peek* methods.

PlayerQueueLinkedList Methods

Methods of the *PlayerQueueLinkedList* Class	
Return value	**Method name and argument list**
`void`	`enqueue( Player p )` inserts *Player p* at the end of the list.
`Player`	`dequeue( )` returns and removes the first *Player* from the list. If the list is empty, the method throws a *DataStructureException*.

`Player`	`peek( )` returns the first *Player* on the list, but does not delete the *Player*. If the list is empty, the method throws a *DataStructureException*.

Description

We can implement a queue using a linked list; however, we will make an important change. Because a queue inserts items at the end of the list, we will add an instance variable that represents the last node of the linked list. We call this the **tail reference**.

This way we will have direct access to the last node, without having to traverse the list. We will call that instance variable representing the last node in the list *tail*.

When inserting a new *Player*, our *enqueue* method will perform the following operations:

1. Instantiate a new node containing the *Player* to be inserted.
2. Attach that new node at the end of the list, i.e., make the last node in the list, *tail*, point to that new node.
3. Mark the new node so that it is the last node of the list, i.e., assign that node to *tail*.
4. Increase the number of items by 1.

Figure 13.10a to **Figure 13.10d** illustrate the *enqueue* operation.

Figure 13.10a Enqueueing: Our Original Queue

Description

Figure 13.10b Enqueueing: Our Queue and the New Node

Description

Figure 13.10c Enqueueing: The New Node Has Been Attached at the End of the Queue

Description

Figure 13.10d Enqueueing: *tail* Has Been Updated

Description

Example 13.11 shows our *PlayerQueueLinkedList* class. This class also extends and inherits the functionality of our *ShellLinkedList* class.

Example 13.11 The *PlayerQueueLinkedList* Class

```java
/* The PlayerQueueLinkedList class
   Anderson, Franceschi
*/

public class PlayerQueueLinkedList extends ShellLinkedList
{
  // head and numberOfItems are inherited instance variables
  private PlayerNode tail; // last node

  public PlayerQueueLinkedList( )
  {
    super( );
    tail = null;
  }

   /** enqueue method
   * @param p Player object to insert
   */
   public void enqueue( Player p )
   {
      // insert as tail
      PlayerNode pn = new PlayerNode( p );
      if ( isEmpty( ) )
      {
        tail = pn;
        head = pn;
      }
      else
      {
        tail.setNext( pn );
        tail = pn;
      }
      numberOfItems++;
   }

   /** dequeue method
   *   @return    a reference to the Player object deleted
   */
   public Player dequeue( ) throws DataStructureException
   {
     if ( isEmpty( ) )
        throw new DataStructureException
          ( "empty queue: cannot dequeue" );
     else
     {
       Player deleted = head.getPlayer( );
       head = head.getNext( );
       if ( --numberOfItems == 0 )
           tail = null;
       return deleted;
     }
    }

    /** peek method
    *   @return    a reference to the Player object retrieved
    */
    public Player peek( ) throws DataStructureException
    {
      if ( isEmpty( ) )
        throw new DataStructureException
          ( "empty queue: cannot peek" );
      else
      {
        return head.getPlayer( );
      }
   }
}
```

Description

The constructor, from lines 10 to 14, calls the constructor of the superclass, and because it constructs an empty list, sets *tail* to *null*. The *peek* method is identical to the *peek* method of our *PlayerStackLinkedList* class, except for the message passed to the *DataStructureException* constructor.

The *enqueue* method, which we coded at lines 16–34, inserts an item at the end of the list. We first instantiate a *PlayerNode* object reference named *pn* at line 22, using the parameter *Player p* of the *enqueue* method.

Because we insert at the end of the list, we must properly handle the case when the queue is empty, in which case *tail* is *null*. We test if the queue is empty at line 23. If it is, we assign *pn* to *head* and *tail* at lines 25 and 26. After we execute these two lines, the queue contains one element, and that element is both the first and last item in the queue.

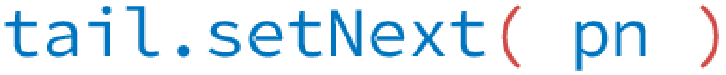
If the list is not empty, control skips to line 30, where we attach *pn* at the end of the list by setting the *next* instance variable of *tail* to *pn*. We then assign *pn* to *tail* in order to reflect that *pn* is now the last node of the list. Finally, and in all cases (empty list or not), we increment *numberOfItems* by 1 at line 33.

Figures 13.10a to 13.10d show the impact on the list of executing lines 22, 30, and 31 step by step.

COMMON ERROR TRAP

Before inserting or deleting an item in a linked list representing a queue, always check if the linked list is empty. Not doing so results in a *NullPointerException* at run time.

It is important to test if a queue is empty when coding the *enqueue* method. Indeed, if the queue is empty, then both *head* and *tail* are *null*. The code



```
tail.setNext( pn )
```

Description

at line 30 would, in this case, generate a *NullPointerException*.

The *dequeue* method, lines 36–52, is identical to the *pop* method of a linked list implementing a stack, except for lines 48 and 49. After decrementing *numberOfItems*, we check whether the list is empty. If so, we set *tail* to *null*.

A similar program to Example 13.9 can be coded to test all possible scenarios when using the methods of the *PlayerQueueLinkedList* class. This is proposed in the short program section of the exercises.

13.5 Array Representation of Stacks

Earlier in this chapter, we discussed how a stack can be represented by a linked list. Since a stack is a last in, first out data structure, we coded the *push* (insert) and *pop* (delete) methods of the linked list to insert or delete at the beginning of the list. Linked lists offer the advantage of being expandable one object at a time, so we do not have to worry about running out of capacity.

However, if we know in advance that the number of objects on a stack will always be less than some maximum number, we can represent the stack using an array, which is easier to implement.

Table 13.6 shows the APIs of the *push*, *pop*, and *peek* methods for a stack implemented using an array.

ArrayStack Methods

Methods of the *ArrayStack* Class	
Return value	**Method name and argument list**

`boolean`	`push( Player p )` inserts *Player p* at the top of the stack, if the stack is not full. Returns *true* if the insertion was successful; *false* otherwise.
`Player`	`pop( )` removes and returns the *Player* at the top of the stack, if the stack is not empty. If the stack is empty, the method throws a *DataStructureException*.
`Player`	`peek( )` returns the *Player* at the top of the stack if the stack is not empty. If the stack is empty, the method throws a *DataStructureException*.

Description

To match the LIFO functionality of a stack, we instantiate the array with the maximum number of elements. We add items to the stack starting at index 0, storing the items in adjacent locations in the array. To keep track of the array index of the last element inserted, we maintain an index **top**, short for “top of the stack.” We always remove (*pop*) the item at the top of the stack.

To push an item onto the stack, we increment the value of *top* by 1 and store the element at the new *top* index. To pop an item from the stack, we return the item at index *top* and decrement the value of *top* by 1.

Figure 13.11a shows how we can visualize a stack of *Players*. **Figure 13.11b** and **13.11c** show the stack after pushing a *Player* (*6*, *Steve*, *NFL*) and then popping one element. Figure 13.11c shows that the array element at index 3 is still *Player* (*6*, *Steve*, *NFL*), but that is irrelevant. Since *top* has the value 2, the element at index 3 is not on the stack. When the next item is pushed onto the stack, we will reuse that element.

Figure 13.11a Our Original Stack

Description

Figure 13.11b Our Stack After Pushing Player (6, Steve, NFL)

Description

Figure 13.11c Our Stack After Popping Once

Description

One disadvantage of implementing a stack with an array is that the array has a fixed size, and it is possible that the array can be filled completely with elements of the stack. Thus, our *push* method needs to test if the array is full before pushing an element onto the stack. Similarly, our *pop* method needs to test if the array is empty before popping an element from the stack.

Example 13.12 shows our *ArrayStack* class.

Example 13.12 The *ArrayStack* Class

```
/* The ArrayStack class
   Anderson, Franceschi
*/

public class ArrayStack
{
  private static final int STACK_SIZE = 100; // maximum array size
  private Player [ ] stack;            // array of Player objects
  private int top;             // last used index; top of the stack

  public ArrayStack( )
  {
    stack = new Player[STACK_SIZE];
    top = -1; // stack is empty
  }

   /** push method
   * @param p Player object to insert
   * @return    true if insertion was successful false otherwise
   */
   public boolean push( Player p )
   {
     if ( !isFull( ) ) // is there room to insert?
     {
       stack[++top] = p;
       return true;
     }
     else
       return false;
   }

   /** pop method
   *   @return    the Player deleted
   */
   public Player pop( ) throws DataStructureException
   {
     if ( !isEmpty( ) ) // is there an item to delete?
       return stack[top--];
     else
       throw new DataStructureException
                   ( "Stack empty: cannot pop" );
   }

   /** peek method
   *   @return    the Player at the top of the stack
   */
   public Player peek( ) throws DataStructureException
   {
     if ( !isEmpty( ) ) // stack is not empty
       return stack[top];
     else
       throw new DataStructureException
                   ( "Stack empty: cannot peek");
   }

   /** isEmpty method
   *   @return    true if stack is empty, false otherwise
   */
   public boolean isEmpty( )
   {
     return ( top == -1 );
   }

   /** isFull method
   *   @return    true if stack is full, false otherwise
   */
   public boolean isFull( )
   {
      return ( top == ( STACK_SIZE - 1 ) );
   }

  /** toString method
  *   @return the stack elements starting at top
  */
  @Override
  public String toString( )
  {
    String stackString = "";
    for ( int i = top; i >= 0; i-- )
      stackString += ( i + ": " + stack[i] + "\n" );
    return stackString;
  }
}
```

Description

We declare *STACK_SIZE*, *stack*, and *top*, our three fields at lines 7–9.

Stack is an array of *Players*. *STACK_SIZE* is the size of the array *stack*. *Top* represents the index of the element of the array *stack* that is at the top of the stack. The value of *top* will vary from *–1* (when the stack is empty) to *STACK_SIZE – 1* (when the stack is full).

In the default constructor, coded at lines 11–15, we instantiate *stack* and then set *top* to –1, which indicates that the stack is empty. When a client program pushes the first *Player* onto the stack, *top* will be incremented, so that the top of the stack will be the array element at index 0.

We coded the *push* method at lines 17–30. The *push* method returns *true* (line 26) if the stack is not full before we insert, and *false* (line 29) if it is, in which case we cannot insert. We test if the stack is not full at line 23. If it is not full, we use the prefix - auto-increment operator to combine two operations at line 25: first increment *top* by 1, then assign *p*, the *Player* parameter of the *push* method, to the element at index *top*.

We coded the *pop* method at lines 32–42. The *pop* method attempts to delete and return a *Player* object from the top of the stack. The method *throws* a *DataStructureException* at lines 40–41 if the stack is empty, in which case we cannot pop. If it is not empty, we use the postfix auto-decrement operator to combine two operations at line 38: first return the *Player* stored at index *top* in the array *stack*, then decrement *top* by 1.

COMMON ERROR TRAP

Do not confuse the top of the stack with the last index in the array. Array elements with an index higher than *top* are not on the stack.

We have also coded a few other methods in this class. The *peek* method (lines 44–54) is similar to *pop*, except that it does not delete from the stack and it returns the element at the top of the stack. Again, this enables the client to directly update that object in the stack. The *isEmpty* and *isFull* methods are coded at lines 56–62 and 64–70, respectively. And the *toString* method, coded at lines 72–82, returns a *String* representation of the contents of the stack. Note that in that method, we loop from *top* to 0, not from *STACK_SIZE – 1* to 0.

As before, a program similar to Example 13.9 can be coded to test all possible scenarios on the methods of the *ArrayStack* class. This is proposed in the short program section of the exercises.

13.6 Programming Activity 1: Writing Methods for a Stack Class

In this activity, you will work with a stack represented by an array, performing this activity:

> Code the *push* and *pop* methods to insert onto and delete from a stack represented by an array of *ints*.

The framework will animate your code to give you feedback on the correctness of your code. It will display the state of the stack at all times. The result of your operation will be displayed, reflecting the value returned by your *push* or *pop* method. The items in the stack will be displayed in black while the array elements that are not part of the stack will be displayed in red.

Instructions

Copy the contents of the Programming Activity 1 folder for this chapter from the companion website for this text onto a folder on your computer. Open the *StackArray.java* source file. Searching for five asterisks (*****) in the source code will position you to the code section where you will add your code.

In this task, you will fill in the code inside the methods *push* and *pop* to insert onto and delete from a stack. **Example 13.13** shows the section of the *StackArray* source code where you will add your code. This example is different from the one in the chapter. The stack is an array of *ints*, not *Players*. The *isFull* and *isEmpty* methods have not been provided; you can code them or not, depending on how you want to implement the *push* and *pop* methods.

Example 13.13 Location of Student Code in *StackArray* Class

```
/** push method
*   @param    value   value to be pushed onto the stack
*   @return   true if successful, false if unsuccessful
*/
public boolean push( int value )
{
 // ***** 1. Student code starts here *****
 // stack is an int array instance variable representing
 // the array that stores our stack

 // top is an instance variable representing
 // the index of the top of the stack

 // CAPACITY is a static constant representing
 // the size of the array stack

 // The push method adds the argument value
 // to the top of the stack, if it is possible
 // code the push method here
 // end of student code, part 1
}

/** pop method
*   @return   the value of the top element of the stack, if
*             successful
*/
public int pop( ) throws DataStructureException
{
 // ***** 2. Student code restarts here *****
 // stack is an int array instance variable representing
 // the array that stores our stack

 // top is an instance variable representing
 // the index of the top of the stack

 // CAPACITY is a static constant representing
 // the size of the array stack

 // The pop method deletes the element
 // at the top of the stack, if it is possible

// code the pop method here

  // end of student code, part 2
}
```

Description

To test your code, compile *StackArray.java* and run the *StackPracticeApplication* class, which contains the *main* method. When the program begins, a window will display the state of the stack, along with two buttons labeled “push” and “pop,” as shown in **Figure 13.12**.

Figure 13.12 Opening Window

Description

Enter a value into the text box, then click on the “push” button to insert onto the stack. Click on the “pop” button to delete from the stack. Close the window to exit the program.

If you successively push 34, 56, 12, and 98 onto the stack, then pop once, the window will look like the one shown in **Figure 13.13**.

Figure 13.13 Sample Window After Performing Some Stack Operations

Description

Troubleshooting

If your method implementation does not animate or animates incorrectly, check these items:

- Check the feedback in the window to see if your code gives the correct result.
- Verify that you updated the value of *top* correctly.
- Verify that you correctly coded the cases where the stack is full (*push* method) and the stack is empty (*pop* method).

DISCUSSION QUESTIONS

1. Explain how the array elements above the index *top* can have assigned values, but are still irrelevant.
2. Explain what happens if you do not test whether the stack is empty in the *pop* method or full in the *push* method.

13.7 Array Representation of Queues

Earlier in this chapter, we also saw how a queue can be represented by a linked list. Again, if we know in advance that the number of objects in a queue will always be less than some maximum number, we can also use an array to represent the queue.

To match the FIFO functionality of a queue, we will need to keep track of two things:

1. the location of the back of the queue. This is the index of the last element enqueued or added to the queue. We will call the index of that element *back*.
2. the location of the front of the queue. That is the index of the element that will be dequeued or retrieved next. We will call the index of that element *front*.

The queue will be comprised of the elements whose indexes are between *back* and *front*, inclusive.

To dequeue, or delete from the queue, we will return the item at index *front* and increase the value of *front* by one. To enqueue, or insert an element in the queue, we will increment the value of *back* by one, and insert the element at the array index *back*.

There is one important problem in representing a queue with a standard array: the number of available elements for the queue in the array will shrink over time as we enqueue and dequeue, since enqueueing and dequeueing both advance their indexes toward the end of the array.

To illustrate this point, let's consider a queue represented by an array of eight elements. We start by enqueueing five players in this order: (*5*, *Ajay*, *Sonic*), (*2*, *Jin*, *Golf*), (*7*, *Sarah*, *Mario*), (*8*, *Gino*, *Diablo*), and (*6*, *Steve*, *NFL*). Since (*5*, *Ajay*, *Sonic*) was the first to be inserted in the queue, that *Player* is now at the front of the queue. (*6*, *Steve*, *NFL*), inserted last, is at the back of the queue. Thus, (*5*, *Ajay*, *Sonic*) will be stored at index 0 and (*6*, *Steve*, *NFL*) will be stored at index 4, as shown in **Figure 13.14a**. Suppose now that we dequeue once. *Front* now has the value 1, as shown in **Figure 13.14b**. The array element at index 0 is no longer in the queue and its value is irrelevant. Since we insert at the back, the array element at index 0 can no longer be used for the queue. If we dequeue again, *front* will have the value 2, and we will no longer be able to use the array element at index 1. As we keep enqueueing and dequeueing, the values of *back* and *front* keep increasing and we have less and less usable space in the array. Indeed, when *back* reaches 7, we will no longer be able to enqueue at all.

Figure 13.14a Our Queue After Enqueueing the First Five Elements

Description

Figure 13.14b Our Queue After Dequeueing Once

Description

SOFTWARE ENGINEERING TIP

When implementing a queue as an array, think of it as a circular array.

There is a solution to this problem: deal with the array as if it were circular. After *back* reaches the last index of the array, we start enqueueing again at index 0. Thus, in a circular array, the next index after the last array index is 0. Let's say that at one point the *back* marker reaches 7 and the *front* marker is at 5. When we enqueue a new object, we will store that object at index 0, which is the "next" index after 7 if we imagine that the array is circular. In this way, our useful array capacity never shrinks and is always 8.

How do we know that we have reached the last array index and that the next index should be 0? We simply add 1 to the value of *back*, and then take that number modulo the size of the array, which we call QUEUE_SIZE.

Table 13.7 shows the APIs of the *enqueue* and *dequeue* methods.

ArrayQueue Methods

Methods of the *ArrayQueue* Class

Return value	**Method name and argument list**
`boolean`	`enqueue( Player p )` inserts *Player p* at the back of the queue if the queue is not full. Returns *true* if the insertion was successful, *false* otherwise.
`Player`	`dequeue( )` returns and removes the *Player* at the front of the queue. If the queue is empty, the method throws a *DataStructureException*.
`Player`	`peek( )` returns the *Player* at the front of the queue. If the queue is empty, the method throws a *DataStructureException*.

Description

Figure 13.15 illustrates a sequence of insertions and deletions in a queue of *Players* implemented as a circular array. When we begin, the queue is empty. The value of *front* is 0 and the value of *back* is *QUEUE_SIZE – 1*. When we enqueue the first item, that element is placed at index

```
( back + 1 ) % QUEUE_SIZE
```

Description

which is now 0, and *back* will be given the value 0. If we enqueue again, the new element will be placed at index 1 and *back* will be given the value 1. If we enqueue two more items, they will be placed at indexes 2 and 3, respectively, and back will be given the value 3. If we then dequeue, we will return the item at index 0, and *front* will become 1. If we dequeue again, we will return the item at index 1, and *front* will become 2.

Figure 13.15 Starting with an Empty Queue, Four Successive Enqueues Followed by Two Dequeues

Description

When we enqueue, we first need to check if the queue is full. When the queue is full, the relationship between *back* and *front* is:

```
( back + 1 - front ) % QUEUE_SIZE == 0
```

Description

For example, in a full queue with 8 elements, the values of *front* and *back* could be 0 and 7, respectively, or they could be 5 and 4 or any other pair of values for which the expression above is *true*.

When we dequeue, we first need to check if the queue is empty. When the queue is empty, the relationship between *front* and *back* is the same as when the queue is full:

```
( back + 1 - front ) % QUEUE_SIZE == 0
```

Description

Indeed, when there is only one item in the queue, *back* and *front* have the same index value. When we dequeue that last item from the queue, *front* will increase by 1 modulo *QUEUE_SIZE*, resulting in the preceding relationship between *front* and *back*. **Figure 13.16** shows an example of an empty queue and a full queue.

Figure 13.16 An Empty Queue and a Full Queue

Description

So, how do we know if the queue is full or empty? In order to distinguish a full queue from an empty queue, we must add another instance variable to our class. We will keep track of the number of elements in the queue: if the number of elements is 0, then the queue is empty; if the number of elements is equal to the size of the array, then the queue is full.

COMMON ERROR TRAP

Do not confuse array indexes 0 and *QUEUE_SIZE – 1* with *front* and *back*. In a queue represented by a circular array, the indexes 0 and *QUEUE_SIZE – 1* are irrelevant.

Example 13.14 shows our *ArrayQueue* class.

Example 13.14 The *ArrayQueue* Class

```java
/* The ArrayQueue class
   Anderson, Franceschi
*/

public class ArrayQueue
{
   private static final int QUEUE_SIZE = 8;
   private Player [ ] queue;
   private int front;
   private int back;
   private int numberOfItems;

   public ArrayQueue( )
   {
     queue = new Player[ QUEUE_SIZE ];
     front = 0;
     back = QUEUE_SIZE - 1;
     numberOfItems = 0;
   }

   public boolean isFull( )
   {
     return ( numberOfItems == QUEUE_SIZE );
   }

   public boolean isEmpty( )
   {
     return ( numberOfItems == 0 );
   }

   /** enqueue method
   *   @param    p    the Player to insert
   *   @return   true if list is not full, false otherwise
   */
   public boolean enqueue( Player p )
   {
     if ( !isFull( ) )
     {
       queue[( back + 1 ) % QUEUE_SIZE] = p;
       back = ( back + 1 ) % QUEUE_SIZE;
       numberOfItems++;
       return true;
     }
     else
       return false;
   }

   /** dequeue method
   *   @return    the Player deleted
   */
   public Player dequeue( ) throws DataStructureException
   {
     if ( !isEmpty( ) )
     {
        front = ( front + 1 ) % QUEUE_SIZE;
        numberOfItems--;
        return queue[( QUEUE_SIZE + front - 1 ) % QUEUE_SIZE];
     }
     else
       throw new DataStructureException
                   ( "Queue empty: cannot dequeue" );
   }

   /** toString method
   * @return a front-to-back String representation of the queue
   */
   @Override
   public String toString( )
   {
      String queueString = "";
      for ( int i = front; i < front + numberOfItems; i++ )
       queueString += queue[i % QUEUE_SIZE].toString( ) + "\n";
      return queueString;
   }
}
```

Description

In the constructor, coded at lines 13–19, we instantiate the array *queue*, set *front* to 0, *back* to *QUEUE_SIZE − 1*, and *numberOfItems* to 0. When the first element is inserted in the queue, *back* will be increased by 1 modulo *QUEUE_SIZE* and its value will become 0.

The *isFull* and *isEmpty* methods, coded at lines 21–24 and 26–29, enable a client program to check if the queue is full or empty before enqueueing or dequeueing a *Player*. Our *enqueue*, *dequeue*, and *toString* methods also call these methods.

In the *enqueue* method, coded at lines 31–46, we attempt to insert a *Player* into the queue. The *enqueue* method returns *false* if the queue is full (line 45) to indicate that we cannot insert. If the queue is not full, we place the *Player* at the back of the queue, update *back* accordingly, increment the number of items, and return *true* (lines 39–42).

In the *dequeue* method, coded at lines 48–62, we attempt to delete and return a *Player* from the front of the queue. The method *throws* a *Data StructureException* at lines 60–61 if the queue is empty, in which case there are no *Players* to delete. If the queue is not empty, we update *front*, decrement the number of items, and return the *Player* that was at the front of the queue (lines 55–57). Note that we add *QUEUE_SIZE* to the expression *front + 1* to guarantee that it will be nonnegative.

We could also code a *peek* method. It would be similar to the *peek* method we coded for the *StackArray* class, except that *top* would be replaced by *front*. Coding the *peek* method is included as an exercise at the end of the chapter.

The *toString* method, coded at lines 64–74, is slightly different from the *toString* methods we have written so far. Since we know that there are *numberOfItems* items in the queue and that the first item is at index *front*, we can simply start at *front* and loop *numberOfItems* times to build our *String* representation of the queue. Depending on how many items are in the queue and the value of *front*, the looping variable could get larger than *QUEUE_SIZE − 1*, so we use the modulus operator (line 72) to make sure we have a valid index.

As before, a very similar program to Example 13.9 can be coded to test all possible scenarios on the methods of the *ArrayQueue* class. This is proposed in the short program section of the exercises.

As we have demonstrated, a stack or queue can be implemented using either an array or a linked list. Each implementation has advantages and disadvantages. Arrays are easier to code and every item in the stack or queue can be accessed directly through its index. Linked lists are easily expanded one item at a time. To expand an array, we would need to instantiate a new, larger array and copy the elements of the existing stack or queue to the new array, which is quite tedious.

Table 13.8 summarizes these trade-offs.

Array Versus Linked-List Implementation of a Stack or a Queue

	Array	**Linked List**
Easily expanded	No	Yes
Direct access to every item	Yes	No
Easy to code	Yes	No

13.8 Sorted Linked Lists

Let’s go back to our linked list of video game players. If we want to display that list on a website so that all the players can see it, we might want to display the list in ascending (or descending) order by *id* number, or in alphabetical order by name or game. If we store the items in the list in sorted order, we can display the list by simply calling the *toString* method.

Often, a class includes a method that enables us to compare two objects of that class. That method is often named *compareTo*. It returns a positive number if *this* object is greater than the parameter object, *0* if they are equal, and a negative number if *this* object is less than the parameter object. The *Comparable* interface defines such a method. It is standard practice for a class to implement *Comparable* and override its *compareTo* method. Because the *Comparable* interface uses generics, the *Player* class header becomes:

```
public class Player implements Comparable<Player>
```

Description

The *compareTo* method is added to our *Player* class as shown in **Example 13.15**.

Example 13.15 The *compareTo* Method Is Added to the *Player* Class

```
...
105
106  /** compareTo method
107  *  @param p a Player to compare to this Player
108  *  @return  an int, -1, 0, or 1 as this Player is less than,
109  *                   equal to, or greater than player
110  */
111  public int compareTo( Player p )
112  {
113     if ( id == p.id && name.equals( p.name )
114                     && game.equals( p.game ) )
115        return 0;
116     else if ( id > p.id ||
117               ( id == p.id && name.compareTo( p.name ) > 0  ) ||
118               ( id == p.id && name.equals( p.name )
119                      && game.compareTo( p.game ) > 0  )  )
120        return 1;
121     else
122        return -1;
123  }
124 }
```

Description

A *Player* is greater than another *Player* if (lines 116–119)

- its *id* is greater, or
- its *id* is the same but its name is greater (in alphabetical order), or
- its *id* and name are the same and its game is greater than the one of the other *Player*.

A linked list that stores its items in ascending order (or descending order) according to a criterion is called a **sorted linked list**. Without loss of generality, we will consider a linked list sorted in ascending order.

Table 13.9 shows the APIs of the *insert* and *delete* methods for a sorted linked list. The only difference in this API from that of our unsorted list is that the location for inserting an element is dependent on the key value, rather than always inserting at the beginning of the list.

PlayerSortedLinkedList Methods

Methods of the *PlayerSortedLinkedList* Class

Return value	**Method name and argument list**
`void`	`insert( Player p )` inserts *Player p* in a location that keeps the list sorted in ascending order.
`Player`	`delete( int searchID )` returns and removes the first *Player* of the list with an *id* equal to *searchID*. If there is no such *Player* on the list, the method throws a *DataStructureException*.

Description

By default, an empty list is sorted, so a newly instantiated list is sorted. As we add elements, we need to maintain the sorted order of the list. Thus, the *insert* method must locate the proper position for inserting each element so that the inserted element's *id* is greater than the *id* of the previous element (if any) and less than or equal to the *id* of the next element (if any). We will find that proper place by traversing the list, comparing the value of the *id* of the new *Player* with the values of the *ids* of the *Players* stored at the various nodes in the list.

If the value of the item to insert will place it at the beginning of the list, then we will insert it in the same manner as we did in our earlier examples.

When inserting a new *Player* in the middle or at the end of the list, our *insert* method will do the following:

1. Instantiate a new node containing the *Player* to be inserted.
2. Traverse the list to identify the location to insert the new node. We will call the node before the insertion point *previous*, and the node after the insertion point *current*.
3. Attach the new node to *current*; that is, make the new node point to *current*.
4. Attach *previous* to the new node; that is, make *previous* point to the new node.
5. Increase the number of items in the list by 1.

Figures 13.17a to **13.17d** illustrate inserting a node somewhere in the middle of the sorted list.

Figure 13.17a Our Original Sorted List Before Inserting *Player (6, Steve, NFL*)

Description

Figure 13.17b Step 1: Instantiate the New Node

Description

Figure 13.17c Steps 2 and 3: Insert Occurs Between *previous* and *current*. Attach the New Node to *current*

Description

Figure 13.17d Step 4: Attach *previous* to the New Node

Description

The insertion code corresponding to Figures 13.17c and 13.17d is shown in **Example 13.16** at lines 38–39.

Keeping the list in sorted order also impacts our *delete* method. If the item we are looking for is not in the list, we may be able to determine that fact without traversing the entire list. As soon as we visit an item with a value greater than the key value, we know that the item we are looking for is not in the list. Because the list is sorted in ascending order, all the *Players* stored after that node must have an *id* value greater than the key. Thus, we will be able to exit our *delete* method at this point, saving processing time.

Example 13.16 shows our *PlayerSortedLinkedList* class. This class also extends and inherits the functionality of our *ShellLinkedList* class. The list is sorted in ascending order according to the value of each *Player's id*.

Example 13.16 The *PlayerSortedLinkedList* Class

```
 /* The PlayerSortedLinkedList class
    Anderson, Franceschi
*/

public class PlayerSortedLinkedList extends ShellLinkedList
{
  // head and numberOfItems are inherited instance variables

  public PlayerSortedLinkedList( )
  {
    super( );
  }

  /** insert method
  *   @param    p    Player object to insert
  */
  public void insert( Player p )
  {
    PlayerNode pn = new PlayerNode( p );

    // we will insert after previous and before current
    PlayerNode current = head;
    PlayerNode previous = null;
    while ( current != null
          && current.getPlayer( ).compareTo( p ) < 0 )
    {
      previous = current;
      current = current.getNext( );
    }

    if ( previous == null ) // insert as head
    {
      pn.setNext ( head );
      head = pn;
    }
    else
    {
      pn.setNext ( current );
      previous.setNext ( pn );
    }
    numberOfItems++;
  }

  /** delete method
  *   @param    searchID    id of Player to delete
  *   @return the Player deleted
  */
  public Player delete( int searchID )
                       throws DataStructureException
  {
    PlayerNode current = head;
    PlayerNode previous = null;
    while ( current != null
            && current.getPlayer( ).getID( ) != searchID )
    {
      if ( current.getPlayer( ).getID( ) > searchID )
           throw new DataStructureException
               ( searchID + " not found: cannot be deleted" );
      previous = current;
      current = current.getNext( );
    }

    if ( current == null ) // not found
           throw new DataStructureException
              ( searchID + " not found: cannot be deleted" );
    else       // searchID found at Player at node current
    {
      if ( current == head )
           head = head.getNext( ); // delete head
      else
           previous.setNext ( current.getNext ( ) );

      numberOfItems--;
      return current.getPlayer( );
     }
   }
 }
```

Description

The *insert* method, which we coded at lines 14 to 42, inserts a node containing its *Player* parameter *p*. Line 19 declares and instantiates a *PlayerNode* object, called *pn*, which we will insert in the linked list. To get ready to search for the insertion point for the new *Player*, we declare two *PlayerNode* object references, *current* and *previous*, at lines 22–23, and assign them *head* and *null*. We use *current* to traverse the list, going just past the point of insertion, and we use *previous* to track the node just before *current*. We will insert *pn* between *previous* and *current*. From lines 24 to 29, we use a *while* loop to traverse the list. We construct our *while* loop condition so that we will exit the loop if the list is empty or if we have reached the end of the list (we test if current is *null* at line 24), or if we are visiting a node containing a *Player* that is larger than or equal to *p*, the *Player* parameter of the *insert* method (line 25).

As mentioned earlier, there are two different cases for insertion: either we insert at the beginning of the list, or we insert in the middle or at the end of the list. At line 31 we test if *previous* is *null*, in which case we never entered the *while* loop because the list is empty or because the head node contains a *Player* whose *id* value is greater than *p's id*. Either way, we insert at the beginning of the list at lines 33 and 34.

If *previous* is not *null*, we will insert in the middle of the list or at the end of the list. To insert the node *pn* between *previous* and *current*, we connect *pn* to *current* at line 38, and *previous* to *pn* at line 39. Figures 13.17a to 13.17d show the step-by-step impact of lines 19, 38, and 39 on the sorted linked list.

The *delete* method (lines 44–76) is very similar to the *delete* method of the *PlayerLinkedList* class. The only difference is at lines 56–58. We first test at line 56 if the *id* of the *Player* at *current* is greater than *searchID*. If that is *true*, we have no chance of finding a *Player* object with an *id* of *searchID* since the list is sorted in ascending order. Therefore, we *throw* a *DataStructureException* with an appropriate message, and we exit the method.

Let's test our *PlayerSortedLinkedList* class. In order to keep things simple, we will test the *insert* method only, because the *delete* method is, as discussed, almost identical to the *delete* method of the *PlayerLinkedList* class.

We want to test the following cases:

- insert in an empty list
- insert at the beginning of the list
- insert in the middle of the list
- insert at the end of the list

We traverse the list after each insertion to check that the *Player* was inserted at the correct location in the sorted linked list.

Example 13.17 shows how to use the *PlayerSortedLinkedListTest* class and how to test its methods.

Example 13.17 The *PlayerSortedLinkedListTest* Class

```
/* The PlayerSortedLinkedListTest class
   Anderson, Franceschi
*/

public class PlayerSortedLinkedListTest
{
  public static void main( String [ ] args )
  {
    Player p1 = new Player( 7, "Sarah","Mario" );
    Player p2 = new Player( 2, "Jin","Golf" );
    Player p3 = new Player( 5, "Ajay","Sonic" );
    Player p4 = new Player( 8, "Gino","Diablo" );

    // construct empty PlayerSortedLinkedList
    PlayerSortedLinkedList players =
                  new PlayerSortedLinkedList( );

    System.out.println( "Number of items in the list: "
       + players.getNumberOfItems( ) + "\n" + players.toString( ) );

    System.out.println( "inserting " + p1 );
    players.insert( p1 ); // insert in empty list
    System.out.println( "Number of items in the list: "
       + players.getNumberOfItems( ) + "\n" + players.toString( ) );

    System.out.println( "inserting " + p2 );
    players.insert( p2 );    // insert at the beginning of the list
    System.out.println( "Number of items in the list: "
       + players.getNumberOfItems( ) + "\n" + players.toString( ) );

    System.out.println( "inserting " + p3 );
    players.insert( p3 ); // insert in the middle of the list
    System.out.println( "Number of items in the list: "
       + players.getNumberOfItems( ) + "\n" + players.toString( ) );

    System.out.println( "inserting " + p4 );
    players.insert( p4 ); // insert at the end of the list
    System.out.println( "Number of items in the list: "
       + players.getNumberOfItems( ) + "\n" + players.toString( ) );
  }
}
```

Description

In Example 13.17, we instantiate our usual four *Player* objects *p1*, *p2*, *p3*, and *p4* at lines 9–12. We choose the *id* values so that our four test cases will be covered when we successively insert the *Player* objects. We instantiate the *PlayerSortedLinkedList players* object at lines 14–16.

We first traverse the empty list at lines 18–19. Then, we successively insert *p1*, *p2*, *p3*, and *p4*, traversing the list after each insertion (lines 21–39). **Figure 13.18** shows the output of Example 13.17. As we can see, *players* remains sorted in ascending order after each insertion.

Figure 13.18 Output of Example 13.17

13.9 Programming Activity 2: Writing *Insert* and *Delete* Methods for a Sorted Linked List

In this activity, you will work with a sorted linked list of integers, performing the following activity:

> Code the *insert* and *delete* methods to insert and delete nodes in a sorted linked list of *ints*.

The framework will animate your code to give you feedback on the correctness of your code. It will display the state of the sorted linked list at all times.

Instructions

Copy the contents of the Programming Activity 2 folder for this chapter from the companion website for this text onto a folder on your computer. Open the *LinkedList.java* source file. Searching for five asterisks (*****) in the source code will position you to the code section where you will add your code.

In this task, you will fill in the code inside the *insert* and *delete* methods for a sorted linked list of integers. **Example 13.18** shows the section of the *LinkedList* source code where you will add your code. This example is different from the one presented earlier in the chapter. The nodes of the linked list contain *ints*, not *Players*. The *delete* method returns a *boolean* value to indicate whether the deletion was successful. Because the client has already provided the *int* value to delete, there is no reason to return the value to the client.

Example 13.18 Location of Student Code in *LinkedList*

```
public void insert( int value )
{
  // ***** Student writes the body of this method *****
  // code the insert method of a linked list of ints
  // the int to insert in the linked list is value

  //
  // Student code starts here
  //

  //
  // End of student code, part 1
  //
}
public boolean delete( int value )
{
  // ***** Student writes the body of this method *****

  // code the delete method of a linked list of ints
  // the int to delete in the linked list is value
  // if deletion is successful, return true
  // otherwise, return false

  //
  // Student code starts here
  //

  return true; // replace this return statement
  //
  // End of student code, part 2
  //
}
```

Description

You can first code the *insert* method and run the application. Once the *insert* method works properly, you can code the *delete* method and run the application again. We have provided a dummy *return* statement in the *delete* method so that the *LinkedList.java* file will compile if only the *insert* method is coded. When you write the *delete* method, modify the dummy *return* statement to return the appropriate value.

When coding the *insert* and *delete* methods, you will need to use constructors and methods of the *Node* class. The API of the

Node class is shown in **Table 13.10**.

API of the *Node* Class

Constructors and Methods of the *Node* Class

Constructors

Class	**Constructor and argument list**
`Node`	`Node( int data )` constructs a new *Node* object whose *data* instance variable is *data*. The pointer to the next node is set to the value *null*.
`Node`	`Node( int data, Node nextNode )` constructs a new *Node* object whose *data* instance variable is *data*. The *Node* points to *nextNode*.

Methods

Return value	**Method name and argument list**
`Node`	`setNext( Node nextNode )` sets the *Node* object reference pointed to by this *Node* to *nextNode*.
`Node`	`setData( int data )` sets the *data* instance variable to data
`Node`	`getNext( )` returns an object reference to the *Node* pointed to by this *Node*.
`int`	`getData( )` returns the *data* stored in this *Node*.

Description

To test your code, compile and run the *LinkedListPractice.java* file, which contains the *main* method. When the program begins, a window will display the state of the linked list (the list is empty when we start), along with various buttons labeled “insert,” “delete,” “toString,” “count,” and “clear,” as shown in **Figure 13.19**.

Figure 13.19 Opening Window

Description

To insert or delete a value, type the integer into the text field labeled “Node Data,” then click on the “insert” or “delete” button. The application only accepts integers greater than or equal to 0 and less than or equal to 9999; it will not let you enter characters that are not digits. The main panel will visually represent the sorted linked list. The text area at the bottom will give you feedback on your operations. Close the window to exit the program.

Figure 13.20 shows the application after successively inserting 45, 67, and 78, traversing the list, then deleting 67.

Figure 13.20 Sample Window After Performing Some Operations

Description

Troubleshooting

If your method implementation does not animate or animates incorrectly, check these items:

- Check the feedback in the window to see if your code gives the correct result.
- Verify that you correctly coded both cases of the *insert* method: insert at the beginning and insert in the middle of the list.
- Verify that you correctly coded all the cases of the *delete* method: fail to delete, delete at the beginning, and delete in the middle or at the end of the list.

DISCUSSION QUESTIONS

1. Explain why it is important to update *head* when inserting at the beginning of a list.
2. Explain the difference between deleting in a nonsorted list and deleting in a sorted list.

current

13.10 Doubly Linked Lists

So far, when traversing a linked list and looking for a node containing a particular value, we have used two nodes, which we called *previous* and *current*. We kept track of the *previous* node because we had no way to go backward in the list from the *current* node.

This problem can be solved by using a **doubly linked list**, which provides two links between nodes, one forward and one backward. Using the backward link, we can now backtrack from *current* if needed. The backward link is also represented by a node object reference.

Figure 13.21 shows how we can visualize such a node. The data in the node is *5, Ajay*, and *Sonic*. The right arrow points to the next node and the left arrow points to the previous node.

Figure 13.21 A Node with Two Links

Description

In order to implement a doubly linked list, we need to modify our *Player Node* class by adding a *previous* instance variable along with its accessor and mutator methods. **Example 13.19** shows a summary of our revised *PlayerNode* class.

Example 13.19 Summary of the *PlayerNode* Class for a Doubly Linked List

```java
/* The PlayerNode class
   Anderson, Franceschi
*/

public class PlayerNode
{
  private Player player;              // the player at that node
  private PlayerNode next;            // the next PlayerNode
  private PlayerNode previous;        // the previous PlayerNode

  // constructors
  // accessors are getPlayer, getNext, getPrevious
  // mutators are setPlayer, setNext, setPrevious
}
```

Description

When inserting a node, we need to reset both forward and backward links, i.e., the *next* and *previous* instance variables. Suppose, for example, that we insert a node containing *Player p* before a node named *current*. We will illustrate only the general case, when *current* is in the middle or at the end of the doubly linked list; that is, *current* is neither *head* nor *null*.

The steps we need to perform are the following:

1. Instantiate the new node.
2. Attach the new node to *current* by setting its *next* field to *current*.
3. Attach the node before *current* to the new node by setting its *next* field to the new node.
4. Set *previous* in the new node to point to the node before *current*.
5. Set *previous* in *current* to point to the new node.
6. Add 1 to the number of items in the list.

Steps 2 and 3 set the forward links, and Steps 4 and 5 set the backward links.

Figures 13.22a to **13.22f** provide a step-by-step illustration for inserting a node in the middle of a doubly linked list. Note that we no longer need to keep a *previous* object reference, because we can get the location of the previous node from the *current* node.

Figure 13.22a Our Original Doubly Linked List

Description

Figure 13.22b Step 1: Instantiate a New Node

Description

Figure 13.22c Step 2: Set *next* in the New Node to *current*

Description

Figure 13.22d Step 3: Set *next* in the Node Before *current* to the New Node

Description

Figure 13.22e Step 4: Set *previous* in the New Node to the Node Before *current*

Description

Figure 13.22f Step 5: Set *previous* in *current* to the New Node

Description

Our code updating the links inside the *insert* method of the doubly linked list class will be the following:

```
PlayerNode pn = new PlayerNode( p );        // Step 1
pn.setNext( current );                      // Step 2
current.getPrevious( ).setNext( pn );       // Step 3
pn.setPrevious( current.getPrevious( ) );   // Step 4
current.setPrevious( pn );                  // Step 5
numberOfItems++;                            // Step 6
```

Description

The order in which these statements are executed is important. Indeed, if Step 5 were executed immediately after Step 1, we would overwrite the reference to the previous node. Then we could not access the node before *current*, and we would be unable to properly reset the links between the nodes.

Note that if *current* is either *head* (insert at the beginning) or *null* (insert at the end), the preceding code needs to be modified; that is proposed in the group project.

When deleting a node, we also need to reset all the appropriate forward and backward links. Suppose, for example, that we delete a node named *current*. We will illustrate only the general case, when *current* is in the middle of the doubly linked list. In this case, *current* is neither the *head* nor the last node in the list (since we are deleting *current*, we are assuming that *current* is not *null*); that is, there is a node after *current* in the list.

To delete a node, *current*, from the middle of a doubly linked list, we need to perform the following steps.

1. Set *next* in the node before *current* to the node after *current*.
2. Set *previous* in the node after *current* to the node before *current*.
3. Decrease the number of items by 1.

Figures 13.23a to **13.23c** give a step-by-step illustration of deleting a node.

Figure 13.23a Our Original Linked List

Description

Figure 13.23b Step 1: Set *next* in the Node Before *current* to the Node After *current*

Description

Figure 13.23c Step 2: Set *previous* in the Node After *current* to the Node Before *current*

Description

Our code updating the links inside the *delete* method of the doubly linked list class is:

```
current.getPrevious( ).setNext( current.getNext( ) );          // Step 1
current.getNext( ).setPrevious( current.getPrevious( ) );      // Step 2
numberOfItems--;                                               // Step 3
```

Description

Again, note that if *current* is either *head* or the last node in the list, the previous code would need to be modified; that is also proposed in the group project at the end of the chapter, which builds a sorted, doubly linked list.

```
Number of items in the list: 0

Number of items in the list: 1
id: 7   name: Sarah    game: Mario

Number of items in the list: 2
id: 2   name: Jin      game: Golf
id: 7   name: Sarah    game: Mario

Number of items in the list: 3
id: 5   name: Ajay     game: Sonic
id: 2   name: Jin      game: Golf
id: 7   name: Sarah    game: Mario

Player successfully deleted:
Number of items in the list: 2
id: 5   name: Ajay     game: Sonic
id: 7   name: Sarah    game: Mario

Player successfully deleted:
Number of items in the list: 1
id: 7   name: Sarah    game: Mario
```

13.11 Linked Lists Using Generic Types

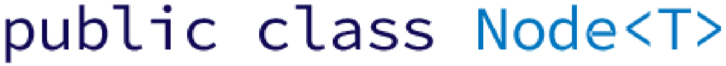
Many classes in the Java Class Library, such as the *ArrayList* class, implement generics, meaning that the data type for the data of the class can be specified by the client. User-defined classes can also implement generic types. In this section, we will build a linked list class that implements generic types, so that the client can specify the class type of the data stored in our linked list. In a linked list, the data of the item is stored in the node; thus, the data in our *Node class* will be a generic object.

The basic syntax for the header of a class that implements generics is:

```
accessModifier class ClassName<IdentifierForGenericClass>
```

Description

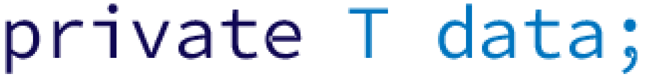
For the identifier for our generic class, we will use the uppercase letter *T*. Thus, for our *Node* class, the header will be:



```
public class Node<T>
```

Description

Inside the class, we can then use that identifier, here *T*, as we would use an existing or user-defined class. For example, to declare an instance variable named *data* of class *T*, we write:



```
private T data;
```

Description

In order to use an object reference of a class implementing generics, we use the following syntax:

```
ClassName<IdentifierForGenericClass>
```

Description

Thus, in order to declare an object reference of the *Node* class as a return type or a parameter for a method, we use the notation *Node<T>*.

Example 13.20 shows our *Node<T>* class.

Example 13.20 The *Node* Class Using Generics

```java
/** The Node class
*   Anderson, Franceschi
*/

public class Node<T>
{
  private T data;
  private Node<T> next;

  /**  default constructor
  *   sets data and next to null
  */
  public Node( )
  {
    data = null;
    next = null;
  }

  /** constructor
  *   @param data reference to data
  *   sets next to null
  */
  public Node( T data )
  {
    setData( data );
    next = null;
  }

  /**  accessor for data
  *   @return reference to data item
  */
  public T getData( )
  {
    return data;
  }

  /** accessor for next
  *  @return next
  */
  public Node<T> getNext( )
  {
    return next;
  }

  /**  mutator for data
  *   @param data reference to new data item
  *   @return reference to this object
  */
  public Node setData( T data )
  {
    this.data = data;
    return next;
  }

  /**  mutator for next
  *   @param reference to next Node
  *   @return reference to this object
  */
  public Node setNext( Node<T> next )
  {
    this.next = next;
    return this;
  }
}
```

Description

Example 13.21 shows our *ShellLinkedList<T>* class.

Example 13.21 The *ShellLinkedList* Class Using Generics

```java
/* The ShellLinkedList class
   Anderson, Franceschi
*/

public abstract class ShellLinkedList<T>
{
  protected Node<T> head;
  protected int numberOfItems;

  /**  constructor
  *    sets head to null and numberOfItems to 0
  */
  public ShellLinkedList( )
  {
    head = null;
    numberOfItems = 0;
  }

  /**  accessor for numberOfItems
  *   @return numberOfItems
  */
  public int getNumberOfItems( )
  {
    return numberOfItems;
  }

  /** isEmpty method
  *  @return true if no items in list; false otherwise
  */
  public boolean isEmpty( )
  {
    return ( numberOfItems == 0 );
  }

  /**  toString method
  *   @return all items in the list
  */
  @Override
  public String toString( )
  {
    String listString = "";
    Node<T> current = head;
    for ( int i = 0; i < numberOfItems; i++ )
    {
      listString += current.getData( ).toString ( ) + "\n";
      current = current.getNext( );
    }
    return listString;
  }
}
```

Description

Our *GenericLinkedList* class, shown in **Example 13.22**, implements the same methods as our *PlayerLinkedList* from earlier in the chapter. The only differences in the code are the class header and the declaration and instantiation of *Node* variables.

Example 13.22 The *GenericLinkedList* Class with Generics

```java
/* The GenericLinkedList class
   Anderson, Franceschi
*/

public class GenericLinkedList<T> extends ShellLinkedList<T>
{
  // head and numberOfItems are inherited instance variables

  /**  constructor
  *   calls constructor of ShellLinkedList
  */
  public GenericLinkedList( )
  {
    super( );
  }

  /** insert method
  *  @param     item   T object to insert
  */
  public void insert( T item )
  {
    // insert as head
    Node<T> nd = new Node<T>( item );
    nd.setNext( head );
    head = nd;
    numberOfItems++;
  }

  /** delete method
  *   @param    item   T object to delete
  *   @return   true if the deletion was successful, false otherwise
  */
  public boolean delete( T item )
  {
    Node<T> current = head;
    Node<T> previous = null;
    while ( current != null
            &&  ! ( item.equals ( current.getData( ) ) ) )
    {
      previous = current;
      current = current.getNext( );
    }

    if ( current == null ) // not found
         return false;
    else
    {
      if ( current == head )
        head = head.getNext( ); // delete head
      else
        previous.setNext ( current.getNext( ) );

      numberOfItems--;
      return true;
    }
  }
}
```

Description

The *insert* method, coded at lines 17–27, is very similar to the *insert* method of the *PlayerLinkedList* class. Instead of a *Player* reference, its parameter *item* is a *T* reference, where *T* is a generic class. It also inserts *item* at the beginning of the list. At line 23, we declare and instantiate a *Node<T>* object reference, which is then connected to the list. The rest of the *insert* method is identical to the code in our *insert* method of a nongeneric linked-list class.

Because we do not know in advance what type of object our class will be instantiated with, we implemented our *delete* method differently. We cannot delete an item based on the value of one of its fields because we do not know what the fields of that item are, since that item is a generic object. Thus, the parameter of our *delete* method is a generic object of the same type as the items in the list. There is no need to return an item if we find it and can delete it because we already have that item as the parameter of the method. For that reason, our *delete* method returns a *boolean* value: *true* if we were able to delete the parameter item, *false* otherwise. In order to compare *item* with the items in the list, we call the *equals* method at line 38, inherited by any class from the *Object* class, and which will need to be overwritten in the class the client specifies as the type for the linked list.

Now that we have defined and implemented our linked list class storing generic objects, how do we use it in a client class? We use the same syntax as we would using an existing Java class implementing generics. In fact, in the *GenericLinkedList* class, we used the *Node* class, which implements generics.

Example 13.23 shows a client class using the *GenericLinkedList* class.

Example 13.23 The *LinkedListTest* Class

```
 1 /* The LinkedListTest class
 2    Anderson, Franceschi
 3 */
 4
 5 public class LinkedListTest
 6 {
 7   public static void main( String [ ] args )
 8   {
 9     Player p1 = new Player( 7,"Sarah","Mario" );
10     Player p2 = new Player( 2,"Jin","Golf" );
11     Player p3 = new Player( 5,"Ajay","Sonic" );
12
13     // construct empty LinkedList of Player objects
14     GenericLinkedList<Player>players = new GenericLinkedList<Player>( );
15     System.out.println( "Number of items in the list: "
16      + players.getNumberOfItems( ) + "\n" + players.toString( ) );
17
18     players.insert( p1 ); // insert in empty list
19     System.out.println( "Number of items in the list: "
20      + players.getNumberOfItems( ) + "\n" + players.toString( ) );
21
22     players.insert( p2 ); // insert in list of one item
23     System.out.println( "Number of items in the list: "
24      + players.getNumberOfItems( ) + "\n" + players.toString( ) );
25
26     players.insert( p3 ); // insert in list of two items
27     System.out.println( "Number of items in the list: "
28      + players.getNumberOfItems( ) + "\n" + players.toString( ) );
29
30     if ( players.delete( p2 ) ) // delete in the middle
31         System.out.println( "Player successfully deleted: " );
32     System.out.println( "Number of items in the list: "
33      + players.getNumberOfItems( ) + "\n" + players.toString( ) );
34
35     if ( players.delete( p3 ) ) // delete at the beginning
36        System.out.println( "player successfully deleted: " );
37     System.out.println( "Number of items in the list: "
38      + players.getNumberOfItems( ) + "\n" + players.toString( ) );
39   }
40 }
```

Description

The only statement that is specific to the generic character of the *GenericLinkedList* is at line 14 when we declare and instantiate an object reference of *GenericLinkedList*. If we wanted to declare and instantiate a list containing *Integer* objects, we would have written:

```
GenericLinkedList<Integer> numbers = new GenericLinkedList<Integer>( );
```

13.12 Recursively Defined Linked Lists

A linked list can be defined recursively. A recursively defined linked list is made up of two items:

- *first*, an item, which is the first item in the linked list
- *rest*, a linked list, which consists of the rest of the linked list

Figure 13.25 shows a representation of a recursively defined linked list.

Figure 13.25 A Recursively Defined Linked List

Description

In our recursively defined linked list, we have two instance variables: the item *first* and the linked list *rest*. Because we can access the rest of the list through the *rest* instance variable, we do not need a node class.

In designing our class encapsulating a recursive linked list of generic objects, we will limit ourselves to an unsorted linked list. We will insert at the beginning of the list. When we delete, we will attempt to delete and return an object that matches a parameter object. When we cannot delete, we will return *false*.

Table 13.11 shows the APIs of the *insert* and *delete* methods.

***RecursiveLinkedList* Methods**

Methods of the *RecursiveLinkedList* Class

Return value	Method name and argument list
`void`	`insert( T item )` inserts *item* at the beginning of the list.
`boolean`	`delete( T item )` removes the first object of the list that matches *item* and returns *true*. If there is no such object in the list, the method returns *false*.

Description

After we insert, *first* will hold the item inserted, and *rest* will hold the original list. **Figures 13.26a** and **13.26b** show a recursively defined linked list before and after inserting a *Player* named *p*. In the figures, *p1* represents the current first item, and *r1* represents the rest of the list before the insertion. The *insert* method is not recursive.

Figure 13.26a The List Before Inserting *Player p*

Description

Figure 13.26b The List After Inserting *Player p*

Description

The *delete* method is recursive. We have three base cases:

- The list is empty.
- The element to delete is the first item of the list.
- The element to delete is not the first item of the list and the rest of the list is empty.

In the general case, we try to delete the element from the rest of the list.

If the list is empty (the first base case), we will return *false*. If the list is not empty, we will look at *first* and check to see if it matches the parameter *item*. If it does (the second base case), we will delete *first*, and *rest* will become our list. If it does not, then we will attempt to delete inside *rest*. If rest is *null*, we cannot delete (the third base case) and we will return *false*. If rest is not *null*, we will make a recursive call to the *delete* method with *rest* (the general case).

More generally, we want to do the following:

- If the list is empty (base case #1), the method returns.
- Process *first*, that is, the first element in the list (base case #2); the method may or may not return at that point.
- If *rest* is *null*—that is, the list has only 1 item (base case #3)—the method returns.
- If *rest* is not *null*, make a recursive call on *rest*.

Example 13.24 shows our *RecursiveLinkedList* class. Because of its recursive design, the *RecursiveLinkedList* class does not extend the *ShellLinkedList* class.

Example 13.24 The *RecursiveLinkedList* Class

```java
/* The RecursiveLinkedList class
   Anderson, Franceschi
*/

public class RecursiveLinkedList<T>
{
  private T first;
  private RecursiveLinkedList<T> rest;

  public RecursiveLinkedList( )
  {
    first = null;
    rest = null;
  }

  /** insert method
  *   @param    item object to insert at beginning of list
  */
  public void insert( T item )
  {
    if ( isEmpty ( ) ) // is list empty?
      first = item;
    else
    {
      RecursiveLinkedList<T> tempList =
                 new RecursiveLinkedList<T>( );
      tempList.first = first;
      tempList.rest = rest;
      first = item;
      rest = tempList;
    }
  }

  /** delete method
  *   @param    item    the T object to delete
  *   @return   true if item is deleted, false otherwise
  */
  public boolean delete( T item )
  {
    if ( isEmpty( ) )                   // is list empty?
      return false;
    else if ( first.equals( item ) )  // found it
    {
      T temp = first;
      if ( rest == null )
          first = null;
      else       // rest not null
      {
          first = rest.first;
          rest = rest.rest;
      }
      return true;
    }
    else if ( rest == null )
        return false;
    else                        // try to delete in rest
        return rest.delete( item );
   }

   /** isEmpty  method
  *   @return   true if the list has no elements;
  *             false, otherwise
  */
  public boolean isEmpty( )
  {
    return ( first == null );
  }

  /** toString method
  *  @return a String listing the elements in the list
  */
  @Override
  public String toString( )
  {
    String listString = "";
    if ( first != null )
    {
      listString = first.toString( ) + "\n";
      if ( rest != null )
        listString += rest.toString( );
    }
    return listString;
  }
}
```

Description

We declare the two instance variables at lines 7–8: *first* represents the first *T* object in the list, and *rest* represents the rest of the list, which is a *RecursiveLinkedList* object reference itself. We coded the default constructor, which constructs an empty list, at lines 10–14.

We coded the *insert* method at lines 16–32. After insertion, *first* will be the method's *T* parameter *item*, and *rest* will be the list before we inserted *item*. We begin by testing if the list is empty by calling the *isEmpty* method (defined at lines 60 to 67), which returns *true* if *first* is *null*. If the list is empty, we assign *item* to *first* at line 22. If *first* is not *null*, we copy the current list into a new list at lines 25–28. We instantiate a temporary list, *tempList*. We then assign *first* to the *first* instance variable of *tempList* and *rest* to the *rest* instance variable of *tempList*. At that point, we have copied the current list into *tempList*. Now we can insert the new item into the first position (line 29) and make *tempList* the rest of the list (line 30).

The recursive *delete* method (lines 34–58) takes the *T* parameter *item*. If the list is empty (line 40), we return *false*. If the list is not empty, then *first* is not *null*, and we can call the *equals* method on *first*. More generally, when processing a recursively designed list, not testing for all the base case conditions could result in a *NullPointerException*.

If the list is not empty and *first* is equal to *item* (line 42), we do the necessary bookkeeping on the list to delete the first element at lines 44–51 before returning *true* at line 52. In order to delete the first element of the list, we need to update *first* and *rest*. *First* will be assigned the first element of *rest*. However, *rest* could be *null*, in which case *rest* does not have a first element. Thus, we test if *rest* is *null* at line 45. If it is, the list is now empty, so we assign *null* to *first* at line 46. If *rest* is not *null*, we assign the first element of *rest* to *first* at line 49, and we assign the *rest* of *rest* to *rest* at line 50.

Figures 13.27a to **13.27c** show the list before deleting *Player p*, after line 49 is executed, and after line 50 is executed, when *Player p* has been deleted from the list.

Figure 13.27a The List Before Deleting *Player p*

Description

Figure 13.27b The List After *first* Is Assigned *first* of *rest*

Description

Figure 13.27c The List After *rest* of *rest* Is Assigned to *rest; Player p* Has Been Deleted

Description

Finally, if the list is not *null* and the *first* is not equal to *item*, we skip to line 54, where we test if *rest* is *null*. If it is, we cannot delete and return *false*. If *rest* is not *null*, we make the recursive call to try to delete from *rest* at line 57.

We coded our *toString* method at lines 69–83. This method is also recursive. If the list is empty, it returns the empty *String*. If the list is not empty, we assign the contents of *first* to the temporary variable *listString* at line 78. Note that the class the client specifies as the type of the *RecursiveLinkedList* will need to provide an overriding *toString* method. We then need to traverse *rest* in order to add its contents to *listString*. But *rest* could be *null*, in which case we are finished traversing the list. So if *rest* is not *null* (line 79), we traverse *rest* at line 80 by making the recursive call:

```
rest.toString( )
```

Description

That recursive call returns a *String* representing the contents of *rest*; we concatenate that *String* to *listString* at line 80 before returning *listString* at line 82.

Example 13.25 shows how to use our *RecursiveLinkedList* class in a client program.

Example 13.25 The *RecursiveLinkedListTest* Class

```java
/* The RecursiveLinkedListTest class
   Anderson, Franceschi
*/

public class RecursiveLinkedListTest
{
  public static void main( String [ ] args )
  {
    Player p1 = new Player( 7,"Sarah","Mario" );
    Player p2 = new Player( 2,"Jin","Golf" );
    Player p3 = new Player( 5,"Ajay","Sonic" );

    RecursiveLinkedList<Player> players =
        new RecursiveLinkedList<Player>( );
    System.out.println( "The list is\n"
        + ( players.isEmpty( ) ? "empty\n" : players.toString( ) ) );

    players.insert( p1 );
    System.out.println( "Inserting " + p1 );
    System.out.println( "The list is\n"
        + ( players.isEmpty( ) ? "empty\n" : players.toString( ) ) );

    players.insert( p2 );
    System.out.println( "Inserting " + p2 );
    System.out.println( "The list is\n"
        + ( players.isEmpty( ) ? "empty\n" : players.toString( ) ) );

     players.insert( p3 );
     System.out.println( "Inserting " + p3 );
     System.out.println( "The list is\n"
        + ( players.isEmpty( ) ? "empty\n" : players.toString( ) ) );

     if ( players.delete( p2 ) )  // delete in middle of list
       System.out.println( "Player deleted: " + p2 );
     System.out.println( "The list is\n"
         + ( players.isEmpty( ) ? "empty\n" : players.toString( ) ) );

     if ( players.delete( p1 ) )  // delete at end of the list
       System.out.println( "Player deleted: " + p1 );
     System.out.println( "The list is\n"
         + ( players.isEmpty( ) ? "empty\n" : players.toString( ) ) );

     if ( players.delete( p1 ) )  // attempt to delete will fail
       System.out.println( "The list deleted: " + p1 );
     System.out.println( "The list is\n"
         + ( players.isEmpty( ) ? "empty\n" : players.toString( ) ) );

     if ( players.delete( p3 ) )  // delete only Player in list
       System.out.println( "Player deleted: " + p3 );
     System.out.println( "The list is\n"
         + ( players.isEmpty( ) ? "empty\n" : players.toString( ) ) );

     if ( players.delete( p3 ) )  // try to delete from empty list
       System.out.println( "Player deleted: " + p3 );
     System.out.println( "The list is\n"
         + ( players.isEmpty( ) ? "empty\n" : players.toString( ) ) );
  }
}
```

Description

COMMON ERROR TRAP

When processing a recursively defined list, not testing for all the base case conditions can eventually result in a *NullPointerException* at run time.

In Example 13.25, we again instantiate our usual three *Player* object references *p1*, *p2*, and *p3* at lines 9–11. We instantiate the *RecursiveLinkedList players* at lines 13–14. This example tests the following operations:

- inserting in an empty list (line 18)
- inserting in a list of one element (line 23)
- inserting in a list of two elements (line 28)
- deleting an element in the middle of the list (line 33)
- deleting an element at the end of the list (line 38)
- failing to delete from a non-empty list (line 43)
- deleting the only element in the list (line 48)
- failing to delete from an empty list (line 53)

SOFTWARE ENGINEERING TIP

When a class is defined recursively, think in terms of implementing recursive methods.

Figure 13.28 shows the output of Example 13.25.

CHAPTER REVIEW

13.13 Chapter Summary

- A data structure is a mechanism for organizing the data a program stores in memory.
- A linked list is a data structure consisting of nodes linked together like a chain.
- Typical instance variables for a node are an object reference to the data stored at the node, and a node reference, which points to the next node in the list.
- Because each node has a reference to the next node as an instance variable, a linked list needs only one instance variable, its first node, which is usually called *head*. Often, for convenience, we also include an instance variable representing the number of items in the list.
- A linked list can be expanded one node at a time, therefore optimizing memory use.
- A stack is a data structure organized as last in, first out.
- A queue is a data structure organized as first in, first out.
- A linked list can be used to represent a stack. In that case, we push onto the stack by inserting an item at the beginning of the list. We pop by deleting the first item of the list.
- A linked list can also be used to represent a queue. In that case, we enqueue by inserting at the end of the list. We

dequeue by deleting the first item of the list. Because we insert at the end of the list, it is useful to have an instance variable representing the last node in the list, often called *tail*.

- A stack can also be represented by an array, if we know in advance the maximum number of items that will be stored on the stack at one time. An instance variable called *top* represents the index of the last array element pushed onto the stack. We pop, or delete, that element, unless the stack is empty. We push, or insert, onto the stack a new element at index (*top* + *1*), unless the stack is full.
- A queue can also be represented by an array, if we know in advance the maximum number of items that will be stored in the queue at one time. A circular array is usually implemented for the queue. Two instance variables called *front* and *back* represent the indexes of the first and last element inserted in the queue. We dequeue, or delete, the element at index *front* unless the queue is empty. We enqueue, or insert, a new element at index (*back* + *1*% *QUEUE_SIZE*), unless the queue is full.
- In a class encapsulating a data structure, a method returning an object can *throw* an exception if we cannot return or cannot find the object. Indeed, when the object we are looking for is not found, it is preferable to *throw* an exception rather than to return *null*.
- A linked list can be sorted in ascending or descending order. One of the instance variables of the list objects is used as the key to sort the list elements. The *insert* method finds the appropriate location to insert an item so that the list remains sorted.
- A variation of the linked list includes a doubly linked list. In this case, each node contains three instance variables: an object representing the data, a node reference representing the next node, and another node reference representing the previous node. The latter enables us to backtrack in the list, if we need to, whereas in a singly linked list, we can traverse the list in a forward direction only. However, implementing such a list is more difficult; each method, in particular *insert* and *delete*, involves more operations to

maintain these double links between nodes.

- Linked lists can implement generic types; when such a linked list is instantiated, the client specifies the class of the items for the list.
- Linked lists can also be recursively defined. A recursively defined linked list is made up of two elements: *first*, which is the first item in the linked list, and *rest*, a linked list that consists of the rest of the linked list.

13.14 Exercises, Problems, and Projects

13.14.1 Multiple Choice Exercises

1. What is an advantage of linked lists over arrays?

    - Linked lists are easily expanded.
    - Linked lists are limited in size.
    - Linked lists can store objects, whereas arrays are limited to primitive data types.

5. How is a stack organized?

    - FIFO
    - LIFO
    - Items are sorted in ascending order.
    - Items are sorted in descending order.

10. How is a queue organized?

    - FIFO
    - LIFO
    - Items are sorted in ascending order.
    - Items are sorted in descending order.

15. The following linked list represents a stack. If we pop once from the stack, what item is popped?

    (*7, Ajay, NFL*) → (*3, Sarah, Mario*) → (*9, Jin, Golf*)
    head
    → (*5, Joe, Sonic*) → *null*

    - (*7, Ajay, NFL*)
    - (*3, Sarah, Mario*)
    - (*9, Jin, Golf*)
    - (*5, Joe, Sonic*)

20. The linked list that follows represents a stack. After we push the player (*5, Joe, Sonic*) onto the stack, what are the first and last items on the stack?

(*7, Ajay, NFL*) → (*3, Sarah, Mario*) → (*9, Jin, Golf*) → *null*
head

- (*7, Ajay, NFL*) and (*9, Jin, Golf*)
- (*5, Joe, Sonic*) and (*9, Jin, Golf*)
- (*3, Sarah, Mario*) and (*5, Joe, Sonic*)
- (*7, Ajay, NFL*) and (*5, Joe, Sonic*)

25. The linked list that follows represents a queue. If we dequeue once, what item is dequeued?

(*7, Ajay, NFL*) → (*3, Sarah, Mario*) → (*9, Jin, Golf*) →
head
(*5, Joe, Sonic*) → *null*
tail

- (*7, Ajay, NFL*)
- (*3, Sarah, Mario*)
- (*9, Jin, Golf*)
- (*5, Joe, Sonic*)

30. The linked list that follows represents a queue. After we enqueue the player (*5, Joe, Sonic*), what are now the first and last items on the queue?

(*7, Ajay, NFL*) → (*3, Sarah, Mario*) → (*9, Jin, Golf*) → *null*
head *tail*

- (*7, Ajay, NFL*) and (*9, Jin, Golf*)
- (*5, Joe, Sonic*) and (*9, Jin, Golf*)
- (*3, Sarah, Mario*) and (*5, Joe, Sonic*)
- (*7, Ajay, NFL*) and (*5, Joe, Sonic*)

35. The diagram that follows shows the current state of a stack

represented by an array of 50 integers. After pushing 36 and 62 onto the stack and then popping once, what will be the value of *top*, and what element will be stored at index *top*?

Index	**Item stored**
47 (top)	28
46	98
…	…
3	17
2	12
1	20
0	45

- *top* is 47 and the element at index *top* is 28
- *top* is 49 and the element at index *top* is 62
- *top* is 48 and the element at index *top* is 36
- *top* is 49 and the element at index *top* is 20

40. The diagram that follows shows the current state of a stack represented by an array of 50 integers. After pushing 36, 88, and 62 onto the stack and popping three times from the stack, what will be the value of *top* and what element will be stored at index *top*?

Index	**Item stored**
47 (top)	28
46	98
…	…
3	17
2	12
1	20
0	**45**

- *top* is 49 and the element at index *top* is 62
- *top* is 47 and the element at index *top* is 28
- *top* is 46 and the element at index *top* is 98
- *top* is 50 and the element at index *top* is 17

45. The diagram that follows shows the current state of a queue represented by a circular array of 8 integers. After enqueuing 36 and 62, and dequeuing once, what are the values of *front* and *back*, and what elements are stored at indexes *front* and *back*?

Index	**Item stored**
7	
6 (back)	28
5	97
4	25
3	54
2 (front)	12
1	
0	

- *front* = 0, stores 62; *back* = 5, stores 97
- *front* = 3, stores 54; *back* = 0, stores 62
- *front* = 3, stores 54; *back* = 8, stores 62
- *front* = 1, stores 36; *back* = 6, stores 28

50. The diagram that follows shows the current state of a queue represented by a circular array of 8 integers. After enqueuing 36, 100, 83, 77, and 62, what are the values of *front* and *back*, and what elements are stored at indexes *front* and *back*?

Index	**Item stored**
7	
6 (back)	28
5	97
4	25
3	54
2 (front)	12
1	
0	

- *front* = 2, stores 12; *back* = 11, stores 62
- *front* = 2, stores 12; *back* = 3, stores 62
- *front* = 3, stores 62; *back* = 6, stores 28

- *front* = 2, stores 12; *back* = 1, stores 83

55. The diagram that follows shows the current state of a queue represented by a circular array of 8 integers. After dequeuing 5 times, what are the values of *front* and *back*, and what elements are stored at indexes *front* and *back*?

Index	**Item stored**
6 (back)	28
5	97
4	25
3	54
2 (front)	12
1	
0	

- *front* = 7; *back* = 6; the queue is empty
- *front* = 2; *back* = 1; the queue is empty
- *front* = 2; *back* = 6; the queue is empty

59. The diagram that follows shows the current state of a queue represented by a circular array of 8 integers. After dequeuing 8 times, what are the values of *front* and *back*, and what elements are stored at indexes *front* and *back*?

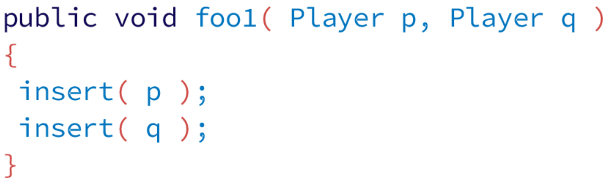
Index	**Item stored**
7	
6 (back)	28
5	97
4	25
3	54
2 (front)	12
1	
0	

- *front* = 7; *back* = 6; the queue is empty
- *front* = 2; *back* = 1; the queue is empty
- *front* = 2; *back* = 6; the queue is empty
- *front* = 6; *back* = 2; the queue is empty

13.14.2 Reading and Understanding Code

For Questions 14 to 21, consider the following classes from this chapter: *Player*, *PlayerNode*, and *PlayerLinkedList*.

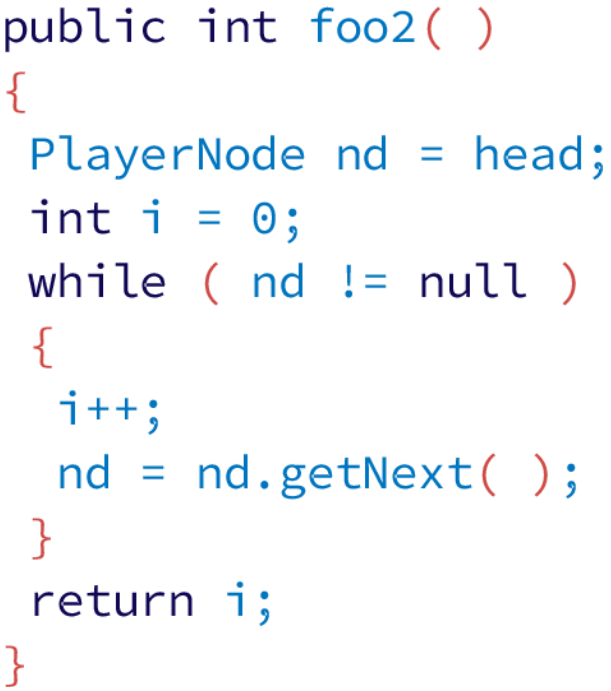
1. What does this method of the *PlayerLinkedList* class do?



```
public void foo1( Player p, Player q )
{
 insert( p );
 insert( q );
}
```

Description

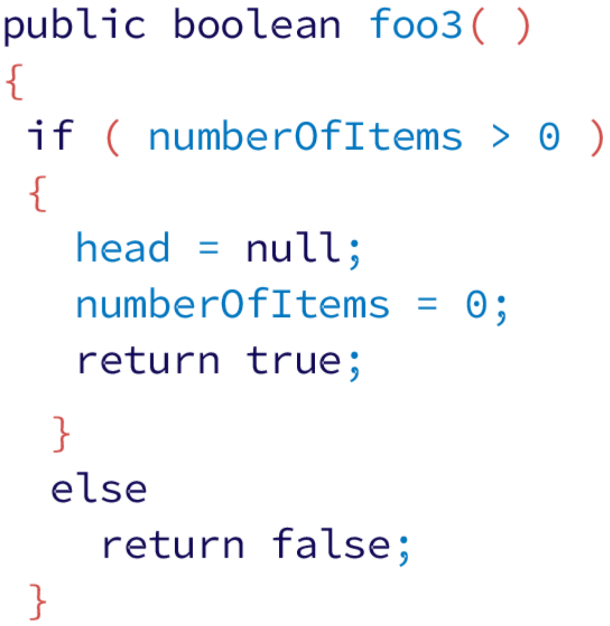
2. What does this method of the *PlayerLinkedList* class do?



```
public int foo2( )
{
 PlayerNode nd = head;
 int i = 0;
 while ( nd != null )
 {
  i++;
  nd = nd.getNext( );
 }
 return i;
}
```

Description

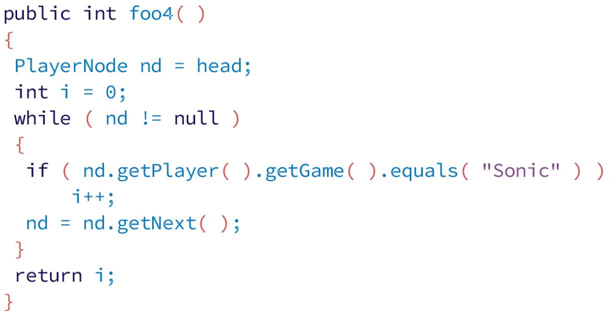
3. What does this method of the *PlayerLinkedList* class do?



```
public boolean foo3( )
{
 if ( numberOfItems > 0 )
 {
    head = null;
    numberOfItems = 0;
    return true;
  }
  else
     return false;
 }
```

Description

4. What does this method of the *PlayerLinkedList* class do?



```
public int foo4( )
{
 PlayerNode nd = head;
 int i = 0;
 while ( nd != null )
 {
  if ( nd.getPlayer( ).getGame( ).equals( "Sonic" ) )
      i++;
  nd = nd.getNext( );
 }
 return i;
}
```

Description

5. What does this method of the *PlayerLinkedList* class do?

```
public boolean foo5( int i )
{
 PlayerNode nd = head;
 while ( nd != null )
 {
  if ( nd.getPlayer( ).getID( ) == i )
     return true;
  nd = nd.getNext( );
 }
 return false;
}
```

Description

6. What does this method of the *PlayerLinkedList* class do?

```
public void foo6( )
{
 PlayerNode nd = head;
 while ( nd != null )
 {
   if ( nd.getPlayer( ).getGame( ).equals( "Diablo" ) )
     System.out.println( nd.getPlayer( ).toString( ) );
   nd = nd.getNext( );
 }
}
```

Description

7. What does this method of the *PlayerLinkedList* class do?

```
public void foo7( Player p )
{
    if ( numberOfItems == 0 )
      System.out.println( "Do nothing" );
    else
    {
      PlayerNode pn = new PlayerNode( p );
      pn.setNext( head.getNext( ) );
      head.setNext( pn );
      numberOfItems++;
   }
    }
```

Description

8. What does this method of the *PlayerLinkedList* class do?

```
public boolean foo8( )
{
 if ( numberOfItems <= 2 )
   return false;
 else
 {
   head.setNext( ( head.getNext( ) ).getNext( ) );
   numberOfItems--;
   return true;
 }
}
```

Description

13.14.3 Fill In the Code

1. Consider the following state of a linked list of *Player* items.

   → (*7*, *Ajay*, *NFL*) → (*3*, *Sarah*, *Mario*) → (*9*, *Jin*, *Golf*) → (*5*, *Joe*, *Sonic*)

   previous

   As indicated, *previous* is the *PlayerNode* whose player is (*7*, *Ajay*, *NFL*).

   Write the code to modify the list so that (*9*, *Jin*, *Golf*) has been deleted.

   → (*7*, *Ajay*, *NFL*) → (*3*, *Sarah*, *Mario*) → (*5*, *Joe*, *Sonic*) →

   ```
   // your code goes here
   ```

2. Consider the following state of a linked list of *Player* items.

   → (*7*, *Ajay*, *NFL*) → (*3*, *Sarah*, *Mario*) → (*9*, *Jin*, *Golf*) → (*5*, *Joe*, *Sonic*)

   previous

   As indicated, *previous* is the *PlayerNode* whose player is (*7*, *Ajay*, *NFL*).

   Write the code to modify the list so that the two items in the middle have been deleted.

   → (*7*, *Ajay*, *NFL*) → (*5*, *Joe*, *Sonic*) →

   ```
   // your code goes here
   ```

3. Consider the following state of a linked list of Player items.

→ (*7*, *Ajay*, *NFL*) → (*3*, *Sarah*, *Mario*) → (*9*, *Jin*, *Golf*) → (*5*, *Joe*, *Sonic*)

previous *current*

As indicated, *previous* is the *PlayerNode* whose player is (*7*, *Ajay*, *NFL*) and *current* is the *PlayerNode* whose player is (*3*, *Sarah*, *Mario*). Write the code to modify the list so that the two nodes in the middle have been swapped as shown here. (You need to swap the actual nodes, rather than modify their respective data.)

→ (*7*, *Ajay*, *NFL*) → (*9*, *Jin*, *Golf*) → (*3*, *Sarah*, *Mario*) → (*5*, *Joe*, *Sonic*)

```
// your code goes here
```

For Questions 25 to 28, consider the *LLNode* class that follows, representing a node with a *char* instance variable, representing a grade (A, B, C, D, or F):

```
public class LLNode
{
 private char grade;
 private LLNode next;
     // constructors and methods here
}
```

Description

4. Code the overloaded constructor with one parameter, a *char*.

```
// your code goes here
```

Description

5. Code the overloaded constructor with two parameters.

```
// your code goes here
```

Description

6. Code the accessors for the class.

```
// your code goes here
```

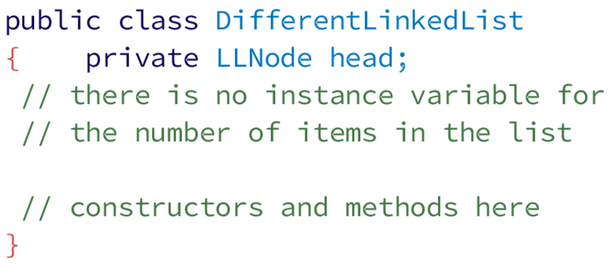
Description

7. Code the mutators for the class.

```
// your code goes here
```

Description

For Questions 29 to 31, consider the following *DifferentLinkedList* class, using the *LLNode* class from Questions 25 to 28 (assume that the *LLNode* class has all appropriate accessors, mutators, and other methods).



```
public class DifferentLinkedList
{    private LLNode head;
 // there is no instance variable for
 // the number of items in the list

 // constructors and methods here
}
```

Description

8. Code a method that returns *true* if the list is empty; *false* otherwise.

```
// your code goes here
```

Description

9. Code a method that returns *true* if the list contains at least one item; *false* otherwise.

```
// your code goes here
```

Description

10. Code a method that returns the number of items in the list.

```
// your code goes here
```

Description

11. Consider a method of class *PlayerLinkedList* with the following header:

```
public Player retrieveMe( int index )
```

Description

Write a few statements showing how you would call that method from a client program.

```
// your code goes here
```

Description

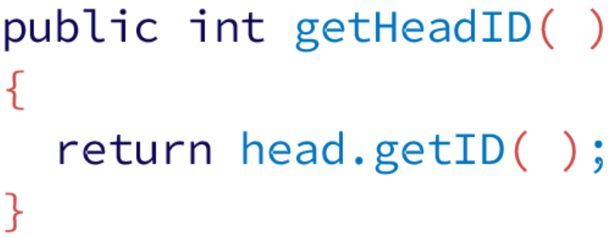
13.14.4 Identifying Errors in Code

1. What would happen if you execute the following code just before traversing a linked list?

```
head.setNext( head );
```

Description

2. Suppose we have coded the following method in the *PlayerLinkedList* class. Where is the error?



```
public int getHeadID( )
{
  return head.getID( );
}
```

Description

3. Suppose we modify the code of the *push* method in the

StackArray class as follows (that is, without incrementing *top*). What type of problem could that method create?

```
public boolean push( Player p )
{
  if ( !isFull( ) ) // is there room to insert?
  {
     stack[ top ] = p;
     return true;
  }
  else
     return false;
}
```

Description

4. Suppose we modify the code of the *pop* method in the *StackArray* class as follows (that is, without decrementing *top*). What type of problem could that method create?

```
public Player pop( ) throws DataStructureException
{
 if ( !isEmpty( ) ) // is there an item to delete?
  return ( stack[top] );
 else
  throw new DataStructureException
          ( "Stack empty: cannot pop" );
}
```

Description

5. Suppose we modify the code of the *enqueue* method in the *QueueArray* class as follows (that is, without incrementing the number of items). What type of problem could that method create?

```
public boolean enqueue( Player p )
{
  if ( !isFull( ) )
  {
   queue[( back + 1 ) % QUEUE_SIZE] = p;
   back = ( back + 1 ) % QUEUE_SIZE;
   return true;
  }
  else
   return false;
}
```

Description

6. Suppose we modify the code of the *dequeue* method in the *QueueArray* class as follows (that is, with a change in the expression computing the index in the *return* statement). Where is the error?

```
public Player dequeue( ) throws DataStructureException
{
 if ( !isEmpty( ) )
 {
   front = ( front + 1 ) % QUEUE_SIZE;
   numberOfItems--;
   return queue[( front - 1 ) % QUEUE_SIZE];
 }
 else
   throw new DataStructureException
                ( "Queue empty: cannot dequeue" );
}
```

Description

13.14.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

1. You coded the following inside the *main* method of the *Test* class, using the *Player* and *PlayerNode* classes.

```
PlayerNode pn = new PlayerNode( );
Player p = pn.getPlayer( );
p.setID( 10 );            // line 10
```

Description

The code compiles, but at run time you get a *NullPointerException* at line 10.

```
Exception in thread "main" java.lang.NullPointerException:
Cannot invoke "Player.setID(int)" because "<local2>" is null
       at Test.main(Test.java:10)
```

Description

Explain what the problem is and how to fix it.

2. You coded the following in the *main* method of the *Test* class, using the *Player* and *PlayerLinkedList* classes.

```
Player p = new Player( 5,"Ajay","Mario" );
PlayerLinkedList pll = new PlayerLinkedList( );
pll.insert( p );
PlayerNode temp = pll.getHead( );           // line 10
System.out.println( "head is " + temp.toString( ) );
```

Description

At compile time, you get the following error:

```
Test.java:10: error: cannot find symbol
   PlayerNode temp = pll.getHead( ); // line 10
                        ^
   symbol  : method getHead ()
   location: variable pll of type PlayerLinkedList
1 error
```

Description

Explain what the problem is and how to fix it.

3. You coded the following in the *main* method of the *Test class*, using the *Player* and *PlayerLinkedList* classes.

```
Player p = new Player( 5,"Ajay","Mario" );
PlayerLinkedList pll = new PlayerLinkedList( );
pll.insert( p );
if ( pll.delete( 5 ) )      // line 10
      System.out.println( "Successful deletion" );
```

Description

At compile time, you get the following error:

```
Test.java:10: error: incompatible types: Player cannot be
converted to boolean
  if ( pll.delete( 5 ) )   // line 10
                 ^
1 error
```

Description

Explain what the problem is and how to fix it.

4. You coded the following inside the *foo* method of the *PlayerLinkedList* class.

```
PlayerNode current = head;    // line 9
while ( current.getPlayer( ).getID( ) != 99 )
      current = current.getNext( );
// more code here but no problem
```

Description

The code compiles, but when you call *foo* inside *main*, you get a *NullPointerException* at run time at line 10.

```
Exception in thread "main" java.lang.NullPointerException:
Cannot invoke "PlayerNode.getPlayer()" because "<local1>" is null
            at PlayerLinkedList.foo(PlayerLinkedList.java:10)
            at Test.main(Test.java:24)
```

Description

What would be a possible scenario that may have caused this error? Explain how to fix this problem.

13.14.6 Write a Short Program

1. Modify the *PlayerLinkedList* class to include one more method: that method inserts a new player in the third position of the list, *head* being the first position. If the list is empty, the method will insert the new player as the head of the list. Be sure to test your method with the appropriate client code.
2. Modify the *PlayerLinkedList* class to include one more method: that method inserts a new player in the next-to-last position of the list. If the list is empty, the method will insert the new player as the head of the list. Be sure to test your

method with the appropriate client code.

3. Modify the *PlayerLinkedList* class to include one more method: that method inserts a new player in the last position of the list. For this, you cannot use the *tail* instance variable. Be sure to test your method with the appropriate client code.
4. Modify the *PlayerLinkedList* class to include one more method: that method deletes the second node of the list, if there is one. Be sure to test your method with the appropriate client code.
5. Modify the *GenericLinkedList* class to include one more method: that method inserts a new item at a given position (a parameter of the method). If the list is empty, the method will insert the new item as the head of the list. If the value of the parameter is greater than the number of items in the list, then the method inserts at the end of the list. You should consider that *head* is at position 1 in the list. Be sure to test your method with the appropriate client code.
6. Modify the *GenericLinkedList* class to include one more method: that method deletes an item at a given position (a parameter of the method). If the value of the parameter is greater than the number of elements in the list, then no item is deleted and an exception is thrown. Your method should return the item deleted, if any. You should consider that the first node is at position 1 in the list. Be sure to test your method with the appropriate client code.
7. Modify the *PlayerLinkedList* class to include one more method: that method takes a parameter that represents a game. The method inserts a new player at a position just after the first *Player* of the list with a *game* instance variable equal to that game. If there is no such node, then

your method should insert at the end of the list. Be sure to test your method with the appropriate client code.

8. Modify the *PlayerLinkedList* class to include one more method: a traversal that outputs the players in the list until we reach a player with a given *id*; that player's data should not be output. Be sure to test your method with the appropriate client code.
9. Modify the *GenericLinkedList* class to include one more method: a method that returns the *n*th item on the list (*n* is a parameter of the method). If there is no *n*th item on the list, the method should *throw* an exception. Test your method with a client that traverses the list by requesting each item in position order.
10. Modify the *PlayerStackLinkedList* class to include one more method: a method that returns the ID of the last player on the stack. Be sure to test your method with the appropriate client code.
11. Modify the *PlayerQueueLinkedList* class to include one more method: a method that outputs every other player in the queue; that is, it outputs the first player, skips the second, outputs the third player, skips the fourth, and so on. Be sure to test your method with the appropriate client code.
12. Modify the *RecursiveLinkedList* class to include one more method: one that inserts at the end of the list. Be sure to test your method with the appropriate client code.
13. Modify the *RecursiveLinkedList* class to include one more method: one that deletes at the end of the list. Be sure to test your method with the appropriate client code.
14. Modify the *RecursiveLinkedList* class to include one more method: one that deletes at the beginning of the list. Be

sure to test your method with the appropriate client code.

15. Code a class encapsulating a stack of *doubles* using an array of 10 elements. Be sure to test your methods with the appropriate client code.
16. Code a class encapsulating a queue of *chars* using a circular array of 10 elements. Be sure to test your methods with the appropriate client code.

13.14.7 Programming Projects

1. Modify the *PlayerLinkedList* to include two more methods: one that returns the *Player* with the minimum *id*, and one that returns all the games played by players with a given *id*. You also need to include the appropriate client code to test your classes.
2. Modify the *PlayerLinkedList* to include two more methods: one that returns the *Player* with the first name in alphabetical order, and one that returns all of the *ids* of the players playing a given game. You also need to include the appropriate client code to test your classes.
3. Code a class encapsulating a singly linked list of website objects. A website has two attributes: a URL address (a *String*, you do not need to use the existing URL Java class) and 10 or fewer keywords describing the topic of the website. In addition to *insert*, *delete*, *peek*, and *toString*, add one more method: a method that, based on a keyword, returns all URL addresses in the list containing that keyword. Your *delete* method should delete an item based on the value of its URL. You also need to include the appropriate client code to test your classes.
4. Code a class encapsulating a singly linked list of football teams. A football team has three attributes: its nickname,

its number of wins, and its number of losses (assume there are no tied games). In addition to *insert*, *delete*, *peek*, and *toString*, add two more methods: a method that returns the nicknames of the teams with the most wins, and another method that returns the five best teams based on winning percentages (if multiple teams have the same winning percentage, you can return the first five such teams in the list). You also need to include the appropriate client code to test your classes.

5. Code a class encapsulating a singly linked list of HTML tags. We will define a valid HTML tag as a string of characters starting with < and ending with >. In addition to *insert*, *delete*, *peek*, and *toString*, add two more methods: a method that returns *true* or *false*, checking if the list contains valid HTML tags only (as previously defined), and another that counts how many items in the list contain the slash (/) character in them. You also need to include the appropriate client code to test your classes.
6. Code a class encapsulating a singly linked list of stocks. A stock is defined by the following attributes: its ticker symbol (a short word, for instance AMD), its price (for example 54.35), and the company's earnings per share (for example 3.25). In addition to *insert*, *delete*, *peek*, and *toString*, add two more methods: a method that returns the list of all the tickers for the penny stocks (a penny stock is a stock whose price is $1.00 or less), and another method that, given a number representing a price earnings ratio (the price earnings ratio of a stock, also known as P/E ratio, is the price of the stock divided by the earnings per share), returns all the tickers with a price earnings ratio less than or equal to that number. You also need to include the appropriate client code to test your classes.

7. Code a class encapsulating a singly linked list of books. A book is defined by the following attributes: its title, its author, its price, and how many are in stock. In addition to *insert*, *delete*, *peek*, and *toString*, add two more methods: a method that, based on a word, returns all the book titles in the list containing that word, and another returning the list of book titles that are out of stock (i.e., there are quantity 0 in stock). You also need to include the appropriate client code to test your classes.
8. Code a class encapsulating a stack of clothes using an array. A clothing item has the following attributes: its name, its color, and whether it can be washed at high temperature. We will limit our stack to 100 clothing items. In addition to *push*, *pop*, *peek*, and *toString*, add two more methods: a method that returns all the clothing items of a given color, and another method that returns how many clothing items in the stack can be washed at high temperature. You also need to include the appropriate client code to test your classes.
9. Code a class encapsulating a queue of foods using a circular array. A food has the following attributes: its name, the number of calories per serving, and the number of servings per container. We will limit our queue to 100 foods. In addition to *enqueue*, *dequeue*, *peek*, and *toString*, add two more methods: a method that returns the average calories per serving of all the foods in the queue, and another method that returns the food item with the highest “total calories” (i.e., calories per serving times number of servings). You also need to include the appropriate client code to test your classes.
10. Code a class encapsulating a sorted linked list of foods; a

Food class is defined in question 67. Your list should be sorted in ascending order using the name of the food as the key. In addition to *insert*, *delete*, *peek*, and *toString*, add two more methods: a method that returns all the *Food* objects in the list that have a number of calories per serving lower than a given value, and another method that returns all the *Food* objects in the list that are located after a given food name. You also need to include the appropriate client code to test your classes.

11. Look at the documentation of the *LinkedList* class in the *java.util* package. Create a class of your choice and code a client class to test the *LinkedList* class; in particular use the *addFirst*, *add*, and *addLast* methods to build a linked list. Also test the *set* and *get* methods. Do you have access to a *toString* method that returns a *String* representation of the linked list? In this implementation, what is the index of the first element in the list? Do the *get* and *element* methods return a copy of an element of the list or a reference to it?

12. Code a stack class using a generic type; the stack should be represented by an array. You should include *push*, *pop*, and *toString* methods. You also need to include the appropriate client code to test your class. In the client class, you should declare and instantiate stacks using at least two different class types.
13. Code a queue class using generics; the queue should be represented by a circular array. You should include *enqueue*, *dequeue*, and *toString* methods. You also need to include the appropriate client code to test your class. In the client class, you should declare and instantiate queues using at least two different class types.

13.14.8 Technical Writing

1. In this chapter, we coded a linked-list class with just two instance variables: the head node and the number of items in the list. We also said that we did not really need the

number of items in the list. Explain how we can traverse the whole list if the class has only one instance variable, *head*.

2. Consider the *PlayerQueueLinkedList* class presented in this chapter, which includes an instance variable called *tail*, in addition to *head*. We want to make the list circular; that is, *tail* "points to" *head*. If you made the method call *tail.getNext( )*, it would return *head*. Describe why and how you would need to modify the *toString* method of the class (assume you do not know the number of items in the list).

13.14.9 Group Project (for a group of 1, 2, or 3 students)

1. Code a doubly linked, sorted list (in ascending order). Each item of the list will just store an *int*.

   You need to code three classes: *Node*, *SortedList*, and *GroupProject*.

   The Node class has three instance variables, all *private*:

   - an *int*, representing the value stored inside the *Node*
   - a *Node* (*next*)
   - another *Node* (*previous*)

   The methods to code are: constructor (at least one), accessors, mutators.

   The *SortedList* class is a doubly linked list, sorted in ascending order.

   It has two instance variables, both private:

   - an *int*, representing the number of items in the list
   - a *Node*, representing the head node in the list

   The methods to code are:

   - *insert*: this method takes one parameter, an *int*; it has a *void* return value.
   - *delete*: this method takes one parameter, an *int*; it

returns a *boolean* value. If we were successful in deleting the item (i.e., the value of the parameter was found in the list), then we return *true*; if we were not successful, then we want to output a message that the value was not found, and therefore, not deleted, and return *false*.

- *toString*: this method takes no parameters and returns a *String* representation of the list.
- constructor (at least one), and accessors and mutators as appropriate.

All methods should keep the list sorted in ascending order.
The *GroupProject* class contains the *main* method; it should do the following:

- create a *SortedList* object reference
- insert successively the values 25, 17, 12, 21, 78, and 47 in the sorted list
- output the contents of the sorted list using the *toString* method
- delete from the sorted list the value 30, using the *delete* method (obviously, 30 will not be found)
- output the contents of the sorted list using the *toString* method
- delete from the sorted list the value 21, using the *delete* method
- output the contents of the sorted list using the *toString* method

Your *insert* and *delete* methods should work properly in all possible scenarios: inserting in an empty list, inserting at the beginning of a list, inserting in the middle of a list, inserting at the end of a list, deleting from an empty list (cannot delete), deleting an item not in the list (cannot delete), deleting the first item in a list, deleting in the middle of a list, deleting the last item in a list.

    14.8.2 Compute the Running Time of a Method
    14.8.3 Programming Projects
    14.8.4 Technical Writing
    14.8.5 Group Project

Introduction

Today's Internet websites have millions of users. The databases storing data on the web servers have grown in size dramatically to accommodate both the growing number of users and the growing volume of data that is posted by these users.

Scientific applications have also experienced a data explosion. Sensors used in these scientific applications, such as meteorology or fluid mechanics, are becoming more precise while at the same time they are getting cheaper. More and more sensors are being used, and application programs have to manage more and more data.

Programs that handle and manipulate this ever-increasing amount of Big Data need to use algorithms that are well-designed and efficient so that they minimize waiting time for users. Two programs that solve the same problem using different algorithms can result in completely different levels of performance—everything else, in particular the hardware platform, being equal. For example, two search engines performing the same search could run at different speeds: one could return its results in tenths of a second while the other could take several seconds to return results.

Many programmers tend to disregard speed and space (memory utilization) issues when writing code. They rely on increasing hardware performance to solve speed problems and the decreasing cost of memory to solve space problems. However, with the Big Data explosion and the resulting data processing issues that we are experiencing today across many industries, designing efficient algorithms has become more and more important. In this chapter, we will focus on algorithms' speed performance.

When we measure the performance of an algorithm, we use the expression **running time**. We cannot predict a single, precise running time for many algorithms, because the amount of processing depends in large part on the number of inputs and the values of those inputs. So we express the running time of an algorithm as a mathematical function of its inputs. This allows us to compare the relative performance of multiple algorithms. For example, the running time for computing the factorial of an integer varies according to the integer value. Factorials of larger numbers require more processing to compute than factorials of smaller numbers. If we can express the running time of multiple algorithms that compute a factorial as a function of their input, then we can compare the relative efficiency of each algorithm. In other cases, such as sorting an array of integers, the running time depends on the number of array elements. Similarly, if we express the running time as a function of the number of elements in the array, we can compare the relative efficiency of multiple sorting algorithms.

The input value or number of inputs for an algorithm represents the size of the problem for which we are trying to compute the running time. We will call that number n. We are interested in relative time, independent of the hardware platform, not absolute time. Furthermore, we are typically interested in the order of magnitude of the algorithm, rather than a precise mathematical expression as a function of n. Indeed, if n is very large (for example, 1 million or more), performance does not vary noticeably if the algorithm takes n steps or $n + 17$ steps to complete.

However, if an algorithm has a running time expressed as n^2, then the number of inputs has a big impact on performance. For example, we can predict that 10 inputs will require the execution of 100 statements and 1,000 inputs will require the execution of 1 million statements.

The objectives of this chapter are:

- To be able to evaluate the running time of a given algorithm through various methodologies
- To understand that how we code an algorithm directly impacts its running time

of another function

14.1 Orders of Magnitude and Big-Oh Notation

Table 14.1 shows examples of various orders of magnitude for an algorithm as a function of the number of inputs *n*, along with the corresponding number of statement executions for different values of *n*.

Comparisons of Various Functions Representing Running Times

Order of Magnitude	Number of Statements Executed			
	$n = 10$	$n = 20$	$n = 1{,}000$	n = 1 million
$\log n$	2.23	3.23	Approx. 10	Approx. 20
n	10	20	1,000	10^6
$n \log n$	22.3	64.6	Approx. 10,000	Approx. $20*10^6$
n^2	100	400	10^6	10^{12}
n^3	1,000	8,000	10^9	10^{18}
2^n	1,024	Approx. 10^6	Approx. 10^{300}	Approx. 10^{300000}

Description

Let’s look at an example to see how we can use these values. As we will demonstrate later in the chapter, Sequential Search has a running time of *n*, and Binary Search has a running time of *n*. Thus, if we are searching an array of 1 million users for a particular user name, a Sequential Search will take, on average, the execution of an order of 1 million statements, while a Binary Search will require the execution of only 20 statements. Remember, however, that for a Binary Search to work, the array must already be sorted**.** Later in this chapter, we will discuss how to compute these running times.

As we can see from the table, algorithms that have a running time where *n* is the exponent of the function, such as 2, take a very large number of statement executions and are very slow; they should be used only if no better algorithm can be found.

Running times of algorithms are often represented using the **Big-Oh** or the **Big-Theta** notation, as in $O(n)$ or $\Theta(n^2)$, for example. The mathematical definition of Big-Theta is as follows:

A function $f(n)$ is Big-Theta of another function $g(n)$, or $\Theta(g(n))$, if and only if:

1. $f(n)$ is **Big-Omega** of $g(n)$, or $\Omega(g(n))$, i.e., there exist two positive constants, $n1$ and $c1$, such that for any $n >= n1$, $f(n) >= c1 * g(n)$.
   In other words, for n sufficiently big, $g(n)$ is a lower bound of $f(n)$; that is, $g(n)$ is smaller than $f(n)$, if we ignore the constants.
   and
2. $f(n)$ is Big-Oh of $g(n)$, or $O(g(n))$, i.e., there exist two positive constants, $n2$ and $c2$, such that for any $n >= n2$, $f(n) <= c2 * g(n)$.
   In other words, for n sufficiently big, $g(n)$ is an upper bound of $f(n)$; that is, $g(n)$ is bigger than $f(n)$, if we ignore the constants.

It has become common in the industry to say Big-Oh instead of Big-Theta. Indeed, we are really interested in an upper bound running time (Big-Oh), and as tight an upper bound as possible (Big-Theta).

Although the preceding definition may sound a bit complex, when trying to estimate the Big-Oh of a particular function representing a running time, the following rules can be used:

- Keep only the dominant term, i.e., the term that grows the fastest as n grows.
- Ignore the coefficient of the dominant term.

Table 14.2 shows a few examples illustrating these rules.

Examples of Functions Representing Running

Times and Their Respective Big-Oh

f(n)	**Dominant Term**	**Big-Oh**
$2*n+19$	$2*n$	$O(n)$
$3*n^2+6*n+12$	$3*n^2$	$O(n^2)$
$n^3+9*n^2+5*n+2$	n^3	$O(n^3)$
$3*2^n+5*n^3+3*n+7$	$3*2^n$	$O(2^n)$
$n+7*\log n$	n	$O(n)$
$2*n*\log n+8*n+\log n+8$	$2*n*\log n$	$O(n*\log n)$
$3*\log n+35$	$3*\log n$	$O(\log n)$

Description

As an example, we will show that the function f(n) = 3*n2 + 6*n +12 is $\Theta(n^2)$.

First we show that f(n) is $\Omega(n^2)$:

$$\text{For } n >= 0,$$

$$f(n) = 3*n^2 + 6*n + 12 >= 3*n^2$$

Description

So if we choose n1 = 0 and c1 = 3, we just proved by definition that *f(n)* is $\Omega(n^2)$.

Now we show that the same function *f(n)* is $O(n^2)$.

For $n >= 1$, we can rewrite *f(n)* as

$$f(n) = n^2 * (3 + 6/n + 12/n^2)$$

Description

For n >= 6, we have

$$6/n <= 1 \text{ and } 12/n^2 < 1$$

Description

therefore,

$$f(n) <= n^2 * (3+1+1) = 5 * n^2$$

Description

So if we choose n2 = 6 and c2 = 5, we just proved by definition that *f(n)* is $O(n^2)$.

Since *f(n)* is both Big-Omega(n^2) and Big-Oh(n^2), then *f(n)* is Big-Theta(n^2).

To show that a polynomial function is Big-Oh of its most dominant term, we simply factor by the most dominant term as follows:

For $n > 0$,

$$f(n) = a_p\, n^p + a_{p-1}\, n^{p-1} + \ldots + a_2\, n^2 + a_1\, n + a_0, \text{where } a_p \text{ is strictly positive}$$

$$f(n) = a_p\, n^p\, (1 + (a_{p-1} / a_p) 1 / n + \ldots + (a_2 / a_p) 1 / n^{p-2} + (a_1 / a_p) 1 / n^{p-1} + (a_p / a_0) 1 / n^p)$$

$$f(n) <= a_p\, n^p\, (1 + |(a_{p-1} / a_p)| 1 / n + \ldots + |(a_2 / a_p)| 1 / n^{p-2} + |(a_1 / a_p)| 1 / n^{p-1} + |(a_p / a_0)| 1 / n^p)$$

Description

All a_i's are constants; let M be the maximum of all $|(a_i/a_p)|$. Thus,

$$f(n) <= a_p\, n^p\, (1 + M 1 / n + \ldots + M 1 / n^{p-2} + M 1 / n^{p-1} + M 1 / n^p)$$

$$f(n) <= a_p\, n^p\, (1 + M(1 / n + \ldots + 1 / n^{p-2} + 1 / n^{p-1} + 1 / n^p))$$

$$f(n) <= a_p\, n^p\, (1 + M(-1 + 1 + 1 / n + \ldots + 1 / n^{p-2} + 1 / n^{p-1} + 1 / n^p))$$

Description

since we know mathematically that

$1 + a + a^2 + \ldots + a^p = \Sigma a^i$ *from i = 0 to p is equal to* $(1 - a^{p+1}) / (1 - a)$ *for a different from1.*

Using a = 1/*n* and *n* >= 2, we get

$$f(n) <= a_p\, n^p\, (1 + M(-1 + (1 - 1 / n^{p+1}) / (1 - 1 / n)))$$

$$f(n) <= a_p\, n^p\, (1 + M(-1 + (1 - 1 / n^{p+1}) * (n / (n - 1))))$$

Description

Thus

$$f(n) <= a_p\, n^p\, (1 + M\, (-1 + (n\, /\, (n - 1))))$$

$$f(n) <= a_p\, n^p\, (1 + M\, ((-n + 1 + n)\, /\, (n - 1)))$$

$$f(n) <= a_p\, n^p\, (1 + M\, (1\, /\, (n - 1)))$$

Description

Thus

$$f(n) <= a_p\, n^p\, (1 + \mathrm{M}) \text{ for } n >= 2$$

Description

choosing $n_0 = 2$ and $c_0 = a_p\ (1 + M)$.
For n >= n_0, we have

$$f(n) <= c_0\, n^p$$

Description

and therefore,
f(n) is $O(n^p)$, i.e., *f(n)* is Big-Oh of its most dominant term.

14.2 Running Time Analysis of Algorithms: Counting Statements

One simple method to analyze the running time of a code sequence or a method is simply to count the number of times each statement is executed and to calculate a total count of statement executions.

Example 14.1 is a method that calculates the total value of all the elements of an array of size *n* and returns the sum.

Example 14.1 A Single Loop

```
public static int addElements( int [ ] arr )
{
  int sum = 0;                   // ( 1 )
  int i = 0;                     // ( 2 )
    while ( i < arr.length )     // ( 3 )
    {
     sum += arr[i];              // ( 4 )
     i++;                        // ( 5 )
  }
  return sum;                    // ( 6 )
}
```

Description

Let's count how many times each statement is executed.

Assuming the array has *n* elements, we can develop the following analysis:

Statement	**# Times Executed**
(1)	1
(2)	1
(3)	$n + 1$
(4)	n
(5)	n
(6)	1

Description

Note that the loop condition, *i < arr.length*, is executed one more time than each statement of the loop body: when *i* is equal to *arr.length*, we evaluate the loop condition, but we exit the loop and thus do not execute the two statements in the loop body. Thus, the total number of statements executed, *T(n)*, is equal to:

$$
\begin{aligned}
T(n) &= 1 + 1 + (n+1) + n + n + 1 \\
&= 3n + 4 \\
&= O(n)
\end{aligned}
$$

Description

So we can say that the running time of the *addElements* method is *O(n)*. Note that in the end, we do not need an exact count of the statements executed, since we are really interested in the Big-Oh running time of the function.

Example 14.2 is a method that determines the maximum value in a two-dimensional array of *ints*.

Example 14.2 A Double Loop

```
public static int calculateMaximum( int [ ][ ] arr )
{
  int maximum  = arr[0][0];                        // ( 1 )
  for ( int i = 0; i < arr.length; i++ )           // ( 2 )
  {
  for ( int j = 0; j < arr[i].length; j++ )       // ( 3 )
  {
   if ( maximum < arr[i][j] )                     // ( 4 )
        maximum = arr[i][j];                      // ( 5 )
  }
 }
 return maximum;                                  // ( 6 )
```

Description

Let’s count how many times each statement is executed. In order to keep things simple, we assume that the array has n rows and each row has n columns. We can then develop the following analysis:

Statement	**# Times Executed**
(1)	1
(2)	$1 + (n+1) + n = 2* n + 2$
(3)	$n *(1 + (n+1) + n) = 2* n^2 + 2* n$
(4)	$n * n = n^2$
(5)	between 0 and $n * n$
(6)	1

Description

Statement (2) actually contains three statements: *int i = 0* is executed 1 time, *i < arr.length* is executed (n + 1) times as *i* goes from 0 to n, and *i++* is executed n times as *i* is incremented n times.

In evaluating the number of times statements (3), (4), and (5) will be executed, we first note that we will enter the outer loop n times. Statement (3) also contains three statements: *int j = 0* is executed each time we enter the outer loop, or n times; *j < arr.length*[i] is executed n times each time we enter the outer loop, or $n * n$ times, as *j* goes from 0 to n; and *j++* is executed n times each time we enter the outer loop, or $n * n$ times.

Since we enter the outer loop n times and for each outer loop iteration, we enter the inner loop n times, statement (4) will be executed $n * n$ times. As for statement (5), it will be executed once each time the Boolean expression *maximum < arr*[i][j] evaluates to *true*. We cannot tell how many times that will happen, but we can tell that it will happen no more than $n * n$ times. We will call this unknown value x.

Thus, the total number of statements executed, $T(n)$, is equal to:

$$\begin{aligned} T(n) &= 1+(2*n+2)+(2*n^2+2*n)+(n^2)+x+1 \\ &= 3*n^2+4*n+4+x \end{aligned}$$

Description

with $x < n * n$

Furthermore, since the value of x is between 0 and n^2,

$$3 * n^2 + 4 * n + 4 <= T(n) <= 3 * n^2 + 4 * n + 4 + n^2$$

$$3 * n^2 + 4 * n + 4 <= T(n) <= 4 * n^2 + 4 * n + 4$$

Description

since $T(n)$ has both lower and upper bounds that are $O(n^2)$, $T(n)$ is $O(n^2)$.

For our third example, let's compute the running time of a Sequential Search, implemented by the code shown in **Example 14.3**.

Example 14.3 Sequential Search Algorithm

```
public static int sequentialSearch( int [ ] array, int key )
{
  for ( int i = 0; i < array.length; i++ )    // ( 1 )
    if ( array[ i ] == key )                   // ( 2 )
      return i;                                // ( 3 )
  return -1;                                   // ( 4 )
}
```

Description

Let's count how many times each statement is executed. Assuming the array has n elements, we can develop the following analysis:

Statement	**# Times Executed**
(1)	1 + (between 1 and (n + 1)) + (between 0 and n)
(2)	between 1 and n
(3)	0 or 1
(4)	1 or 0

Description

Thus, if $T(n)$ represents the total number of statements executed, we can say that

$$1 + (1) + (0) + 1 + 1 <= T(n) <= 1 + (n + 1) + n + n + 1$$

$$4 <= T(n) <= 3n + 3$$

Description

$T(n) <= 3n + 3$ shows that $T(n)$ is $O(n)$.

However, we cannot really tell, from the coding of the function, how many statements will be executed as a function of *n.* In these situations, it is interesting to consider three running times:

- the worst-case running time
- the best-case running time
- the average-case running time

In the worst case, where the search key is not found in the array or it is found in the last element, $T(n) = 3n+ 3$, and therefore $T(n)$ is $O(n)$, as mentioned earlier.

In the best case, the element we are looking for is at index 0 of the array, and only four statements will be executed, independently of the value of *n*. Thus, the best-case running time is $O(1)$ since we do not take the multiplying constant into consideration when we compute a Big-Oh.

In the average case, we find the element we are looking for in the middle of the array, and the value of $T(n)$ will be

$$\begin{aligned} T(n) &= 1+(n+1)/2+n/2+n/2+1 \\ &= 3n/2+2\tfrac{1}{2} \\ &= O(n) \end{aligned}$$

Description

14.3 Running Time Analysis of Algorithms and Impact of Coding: Evaluating Recursive Methods

In this section, we will learn how to compute the running time of a recursive method. We will also look at how coding a method has a direct impact on its running time.

Consider coding a recursive method that takes one parameter, *n,* and returns 2^n. There are several ways to code that method, and we will consider two of them here so that we can assess which algorithm is more efficient.

Our first method, *powerOf2A*, is designed using this approach:

- when $n = 0$, $2^0 = 1$. This is our base case.
- For our general case, we use this calculation: $2^n = 2 * 2^{n-1}$

This first problem formulation results in the method shown in **Example 14.4**.

Example 14.4 First Recursive Formulation of 2^n

```
public static int powerOf2A( int n ) // n >= 0
{
   if ( n == 0 )
        return 1;
   else
        return 2 * powerOf2A( n - 1 );
}
```

Description

Our second method, *powerOf2B*, is designed using this approach:

- when $n = 0$, $2^n = 1$. This is our base case.
- For our general case, we use this calculation: $2^n = 2^{n-1} +$

2^{n-1}

This second problem formulation results in the method shown in **Example 14.5**.

Example 14.5 Second Recursive Formulation of 2^n

```
public static int powerOf2B( int n ) // n >= 0
{
   if ( n == 0 )
      return 1;
   else
      return powerOf2B( n - 1 ) + powerOf2B( n - 1 );
}
```

Description

Let's compute the running time of *powerOf2A* as a function of the input *n*; we will call it $T1(n)$.

In the base case (*n* is equal to 0), *powerOf2A* makes only one comparison and returns 1. Thus,

$$T1(0) = 1$$

Generally, since it takes $T1(n)$ to compute and return *powerOf2A*(*n*), then it takes $T1\ (n - 1)$ to compute and return *powerOf2A*($n - 1$).

Thus, in the general case, the comparison in the *if* statement will cost us 1 instruction; computing and returning *powerOf2A*(n – 1) will cost us $T1 n - 1$); and multiplying that result by 2 will cost us 1 instruction. Thus, the total time $T1(n)$ can be expressed as follows:

$$\begin{aligned} T1(n) &= 1 + T1(n-1) + 1 \\ &= T1(n-1) + 2 \ // \quad \text{Equation 14.1} \end{aligned}$$

Description

The preceding equation, which we will call Equation 14.1, is called a recurrence relation between $T1(n)$ and $T1 n - 1$)

because $T1(n)$ is expressed as a function of $T1n - 1)$.

From there, we can use a number of techniques to compute the value of $T1(n)$ as a function of n.

Handwaving Method

This method is called handwaving because it is more an estimation method, rather than a method based on strict mathematics.

From the preceding recurrence relation, we can say that it costs us two instructions to go down one step (from n to $n - 1$). Therefore, to go down n steps will cost us $2 * n$ instructions. We then add one instruction for $T(0)$, and get

$$T1(n) = 2 * n + 1$$

Iterative Method

This method involves iterating several times, starting with the recurrence relation until we can identify a pattern. In general, we can say that

$$T1(x) = T1(x-1) + 2, \text{where } x \text{ is some integer} \quad // \text{ Equation 14.2}$$

Description

We call this Equation 14.2, which is the same as Equation 14.1, except that x has been substituted for n.

We now want to express $T(n)$ as a function of $T(n - 2)$; thus, we want to replace $T(n - 1)$ in Equation 14.1 by an expression using $T(n - 2)$.

Substituting $n - 1$ for x in Equation 14.2, we get

$$T1(n-1) = T1(n-2) + 2$$

Description

Plugging the value of $T1(n - 1)$ into Equation 14.1, we get

$$\begin{aligned} T1(n) &= T1(n-2)+2+2 \\ &= T1(n-2)+2*2 \quad // \text{ Equation 14.3} \end{aligned}$$

Description

Note that in Equation 14.3, we do not simplify 2 ∗ 2. In this way, we are trying to let a pattern develop so we can easily identify it.

SOFTWARE ENGINEERING TIP

When trying to develop and identify a pattern using iteration, do not precisely compute all the terms. Instead, leave them as patterns.

Using $x = n - 2$ in Equation 14.2, we get

$$T1(n-2) = T1(n-3)+2$$

Description

Plugging the value of $T1(n-2)$ into Equation 14.3, we get

$$\begin{aligned} T1(n) &= T1(n-3)+2+2*2 \\ &= T1(n-3)+2*3 \quad // \text{ Equation 14.4} \end{aligned}$$

Description

Using $x = n - 3$ in Equation 14.2, we get

$$T1(n-3) = T1(n-4)+2$$

Description

Plugging the value of $T1(n-3)$ into Equation 14.4, we get

$$\begin{aligned} T1(n) &= T1(n-4)+2+2*3 \\ &= T1(n-4)+2*4 \end{aligned}$$

Description

Now we can see the pattern as follows:

$$T1(n) = T1(n-k) + 2 * k, \text{where } k \text{ is an integer between 1 and } n \quad // \text{ Equation 14.5}$$

Description

Plugging $k = n$ in Equation 14.5 in order to reach the base case of *T*10), we get

$$T1(n) = T1(0) + 2 * n = 1 + 2 * n = 2 * n + 1$$

Description

Proof by Induction Method

If we can guess the value of *T*1(*n*) as a function of *n,* then we can use a proof by induction in order to prove that our guess is correct. We can use the preceding iteration method to come up with a guess for *T*1(*n*).

Generally, a proof by induction works as follows:

- Verify that our statement (equation in this case) is true for a base case.
- Assume that out statement is true up to *n.*
- Prove that it is true for *n* + 1.

Let's go through the induction steps with our guess that *T*1(*n*) = 2 ∗ *n* + 1, which we may have generated from our iterative or handwaving method.

Step 1: Verify that the value that our guess gives to *T*1(0) is correct.

$$\begin{aligned} T1(0) &= 2 * 0 + 1 \\ &= 1 \end{aligned}$$

Description

Thus, our guess is correct for $T1(0)$.
Step 2: Assume that $T1(n) = 2 * n + 1$.
Step 3: Prove that $T1(n + 1) = 2 *(n + 1) + 1$.
Plugging $x = n + 1$ in Equation 14.2, we get

$$T1(n+1) = T1(n) + 2$$

Description

Then, using our assumption and replacing $T1(n)$ by $2 * n + 1$, we get

$$\begin{aligned} T1(n+1) &= 2 * n + 1 + 2 \\ &= 2 * n + 2 + 1 \\ &= 2 * (n+1) + 1 \end{aligned}$$

Description

Thus, we just proved, by induction, that our guess $T1(n) = 2 * n + 1$ is correct.

Other Methods

When applicable, another method is to use the Master Theorem, but that is beyond the scope of this text.

So the running time of *powerOf2A*(n) is $2 * n + 1$, or $O(n)$.

Let's now compute the running time of *powerOf2B* as a function of the input n. We will call it $T2(n)$.

In the base case (n is equal to 0), *powerOf2B* takes only one comparison to return 1. Thus,

$$T2(0) = 1$$

Generally, since it takes *T*2(*n*) to compute and return *powerOf2B*(*n*), then it takes *T*2(*n* – 1) to compute and return *powerOf2B*(*n* – 1). Thus, in the general case, the comparison in the *if* statement will cost us one instruction; computing and returning *powerOf2B*(*n* – 1) will cost us *T*2 (*n* – 1); doing it a second time will cost us another *T*2(*n* – 1); and adding the two and returning the sum as the result will cost us one instruction. Thus, the total time *T*2(*n*) can be expressed as follows:

$$\begin{aligned} T2(n) &= 1+T2(n-1)+T2(n-1)+1 \\ &= 2*T2(n-1)+2 \text{ // Equation 14.6} \end{aligned}$$

Description

From there, we will use the iteration method in order to compute the value of *T*2(*n*) as a function of *n*.

Substituting *x* for *n*, we can rewrite Equation 14.6 as follows:

$$T2(x)=2*T2(x-1)+2 \text{ // Equation 14.7}$$

Description

Using $x = n - 1$ in Equation 14.7, we get

$$T2(n-1)=2*T2(n-2)+2$$

Description

Plugging the value of *T*2(*n* – 1) into Equation 14.6, we get

$$\begin{aligned} T2(n) &= 2*(2*T2(n-2)+2)+2 \\ &= 2^2*T2(n-2)+2^2+2 \text{ // Equation 14.8} \end{aligned}$$

Description

Again, we leave $2^2 + 2$ as an expression to try to let a pattern develop.

Using $x = n - 2$ in Equation 14.7, we get

$$T2(n-2) = 2 * T2(n-3) + 2$$

Description

Plugging the value of *T*2(*n* – 2) into Equation 14.8, we get

$$\begin{aligned} T2(n) &= 2^2 * (2 * T2(n-3) + 2) + 2^2 + 2 \\ &= 2^3 * T2(n-3) + 2^3 + 2^2 + 2 \quad \text{// Equation 14.9} \end{aligned}$$

Description

Using *x* = *n* – 3 in Equation 14.7, we get

$$T2(n-3) = 2 * T2(n-4) + 2$$

Description

Plugging the value of *T*2(*n* – 3) into Equation 14.9, we get

$$\begin{aligned} T2(n) &= 2^3 * (2 * T2(n-4) + 2) + 2^3 + 2^2 + 2 \\ &= 2^4 * T2(n-4) + 2^4 + 2^3 + 2^2 + 2 \quad \text{// Equation 14.10} \end{aligned}$$

Description

Now we can see the pattern as follows:

$$T2(n) = 2^k * T2(n-k) + 2^k + 2^{k-1} + \ldots + 2^2 + 2,$$
$$\text{where } k \text{ is an integer between 1 and } n \quad \text{// Equation 14.11}$$

Description

Noting that

$$\begin{aligned} 2^k + 2^{k-1} + \ldots + 2^2 + 2 &= -1 + 2^k + 2^{k-1} + \ldots + 2^2 + 2 + 1 \\ &= -1 + (2^{k+1} - 1) / (2 - 1) \\ &= 2^{k+1} - 2 \end{aligned}$$

Description

Equation 14.11 becomes

$$T2(n) = 2^k * T2(n-k) + 2^{k+1} - 2,$$

where k is an integer between 1 and n // Equation 14.12

Description

Plugging $k = n$ in Equation 14.12 in order to reach the base case of $T2(0)$, we get

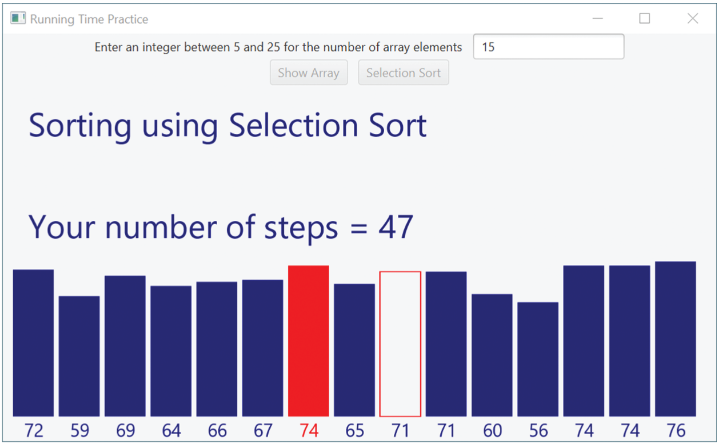
$$\begin{aligned} T2(n) &= 2^n * T2(0) + 2^{n+1} - 2 \\ &= 2^n * 1 + 2^{n+1} - 2 \\ &= 2^n + 2^{n+1} - 2 \\ &= 2^n (1 + 2) - 2 \\ &= 3 * 2^n - 2 \\ &= O(2^n) \end{aligned}$$

Description

Thus, *powerOf2A* runs in $O(n)$ while *powerOf2B* runs in $O(2^n)$, although they perform the same function.

As a result, computing 2^{20} using *powerOf2A* will cost 20 statement executions, while computing 2^{20} using *powerOf2B* will cost 1 million statement executions.

This simple example shows that how we code a method can have a significant impact on its running time.



Running Time Practice
Enter an integer between 5 and 25 for the number of array elements
15
Show Array
Selection Sort

Sorting using Selection Sort

Your number of steps = 47

72 59 69 64 66 67 74 65 71 71 60 56 74 74 76

14.4 Programming Activity: Tracking How Many Statements Are Executed by a Method

In this activity, you will work with a variable-size integer array. Specifically, you will perform the following operations:

1. Write code to keep track of the number of statement executions during a selection sort.
2. Run a simulation to compute the number of statements executed as a function of the number of elements in the array.
3. Estimate the running time of Selection Sort as a function of *n*, the number of elements in the array being sorted.

The framework for this Programming Activity will animate your algorithm so that you can perform a simulation on the number of statement executions inside the *selectionSort* method compared to the number of elements in the array that is sorted. For example, **Figure 14.1** shows the current number of statement executions for an array of 15 elements.

Figure 14.1 Animation of the Programming Activity

Description

At this point, the application has executed 47 statements.

Instructions

In this chapter's Programming Activity folder, you will find the source files needed to complete this activity. Copy all the files to a folder on your computer. Note that all files should be in the same folder.

Open the *RunningTimePracticeController.java* source file. Searching for five asterisks (*****) in the source code will position you at the sample method where you will add your code. In this task, you will fill in the code for the *selectionSort* method in order to keep track of the number of statement executions needed to sort an array using the Selection Sort algorithm. You should not instantiate the array; we have done that for you. **Example 14.6** shows the section of the *RunningTimePracticeController* source code where you will add your code.

Example 14.6 Location of Student Code in *RunningTimePracticeController*

```
//  1. *****  student writes this method
/**  Sorts arr in ascending order using the selection sort algorithm
*    Adds a counter to count the number of statement executions
*/
public int selectionSort( )
{
 // Note:  To count the number of statement executions, use a counter
 // The variable counter has been declared and initialized for you
 // at the beginning of this method
 // Inside the body of the inner loop, increment the counter
 // Replace the return statement so that this method returns the value of
 // the counter. To slow down or accelerate the animation, modify the
 // argument of Pause.wait in the handle method of the ArrayAnimationTimer inner class
 int counter = 0;
 int temp, indexOfMax;
 for ( int i = 0; i < arr.length - 1; i++ )
 {
    // find index of largest value in the subarray
    indexOfMax = 0;
    animate( i,  0,  0,  counter );
    for ( int j = 1; j < arr.length - i; j++ )
    {
      if ( arr[j] > arr[indexOfMax] )
        indexOfMax = j;
      animate( i, j, indexOfMax, counter );
    }
     // swap arr[indexOfMax] and arr[arr.length - i - 1]
    temp = arr[indexOfMax];
    arr[indexOfMax] = arr[arr.length - i - 1];
    arr[arr.length - i - 1] = temp;
 }
 animate( arr.length  -  1,  0,  0,  counter );
 return 0;
} // end of selectionSort
```

Description

Note that we provide a dummy *return* statement (*return* 0;). We do this so that the source code will compile. Just replace the dummy *return* statement with the appropriate *return* statement for the method.

Our framework will animate your algorithm so that you can watch your code work. If you want to accelerate or slow down the animation, modify the argument of *Pause.wait* in the *handle* method of the *ArrayAnimationTimer* inner class.

To test your code, compile *RunningTimeController.java* and run the *RunningTimePracticeApplication*. When the program begins, you will see a text box. Enter the number of elements for the array, and press the “Show Array” button to populate the array. Then press the “Selection Sort” button to execute your selection sort code. Because the values of the array are randomly generated, the values will be different each time the program runs.

Troubleshooting

If the animation is incorrect, and you think your method does return a correct value for the counter, verify that you correctly incremented the counter inside the inner loop.

In order to derive a closed-end expression for the number of statement executions as a function of the size of the array, follow these tips:

- If n is the size of the array, compare n, n^2, n^3, n^4, …, 2^n, to the value of the counter.
- When doing the preceding, divide n, n^2, n^3, n^4, …, 2^n by the number of statements executed.

DISCUSSION QUESTIONS

1. What is the value of the counter with the following array sizes: 5, 10, 15, 20, 25?
2. In relation to n, the size of the array, what is the value of the counter?
3. What is the running time of Selection Sort in Big-Oh notation?
4. If the array is already sorted in either the correct or opposite order, does that make a difference in the number of statement executions? What can you say about the worst-case and best-case running times?

14.5 Running Time Analysis of Searching and Sorting Algorithms

In studying the running time of various searching and sorting algorithms, we will look at the following scenarios:

- best case
- worst case
- average case

Some methods have a very efficient running time. We mentioned earlier that the running time of Binary Search was log *n*. Thus, searching a sorted array of 1 billion items using Binary Search will take only 30 statement executions since log (1 billion) is approximately 30.

Example 14.7 shows the code for a recursive binary search.

Example 14.7 Recursive Binary Search

```
public static int recursiveBinarySearch
                 ( int [ ] arr, int key, int start, int end )
{
  if ( start <= end )
  {
   // look at the middle element of the subarray
   int middle = ( start + end ) / 2;
   if ( arr[middle] == key )      // found key, base case
     return middle;
   else if ( arr[middle] > key )  // look lower
     return recursiveBinarySearch( arr, key, start, middle - 1 );
   else                           // look higher
     return recursiveBinarySearch( arr, key, middle + 1, end );
  }
   else                           // key not found, base case
     return -1;
}
```

Description

In the best-case scenario, we will find the search value exactly in the middle of the array, at the array index we check first. Thus, the best-case running time of Binary Search is *O*(1). In the worst-case scenario, we will not find the search value in the array. **Table 14.3** shows the number of elements in the subarray we are searching versus the comparison count for an initial array of 1024 elements. To keep things simple, we halved the size of the subarray after each comparison (in reality, the element in the middle is eliminated). The total of *11* comparisons for an array of *1024* elements suggests a running time of *log n*. Let's compute the running time of the worst-case scenario.

Worst Case Number of Comparisons for Binary Search

Number of Elements in Subarray As We Are Searching	Comparison Count
1024	1
512	2
256	3
128	4
64	5
32	6

16	7
8	8
4	9
2	10
1	11

Description

In the general case, the comparison of the first *if* statement will cost us one instruction; the assignment statement will cost us two instructions; the comparison in the second *if* statement will cost us one instruction; the comparison in the *else/if* statement will also cost us one instruction; computing and returning *recursiveBinarySearch*(*arr, key, start, middle* – 1) or *recursiveBinarySearch*(*arr, key, middle* + 1, *end*) will cost us $T(n/2 - 1)$ or $T(n/2)$ instructions. Note that only one recursive call will be made. Thus, the total time $T(n)$ can be expressed as follows:

$$\begin{aligned} T(n) &= 1+2+1+1+T(n/2) \\ &= T(n/2)+5 \text{ // Equation 14.13} \end{aligned}$$

Description

In the base case (n is equal to 1), *recursiveBinarySearch* makes only the first comparison, one addition, one division, the second comparison, and then returns the index of the found element or –1. Thus,

$$T(1) = 5.$$

From there, we will use the iteration method in order to compute the value of $T2(n)$ as a function of n.

Substituting x for n, we can rewrite Equation 14.13 as follows:

$$T(x) = T(x/2)+5 \text{ // Equation 14.14}$$

Using $x = n/2$ in Equation 14.14, we get

$$\begin{aligned} T(n/2) &= T((n/2)/2)+5 \\ &= T(n/2^2)+5 \end{aligned}$$

Description

Plugging the value of $T(n/2)$ into Equation 14.13, we get

$$\begin{aligned} T(n) &= (T(n/2^2)+5)+5 \\ &= T(n/2^2)+5*2 \quad \text{// Equation 14.15} \end{aligned}$$

Description

Using $x = n/2^2$ in Equation 14.14, we get

$$\begin{aligned} T(n/2^2) &= T((n/2^2)/2)+5 \\ &= T(n/2^3)+5 \end{aligned}$$

Description

Plugging the value of $T(n/2^2)$ into Equation 14.15, we get

$$\begin{aligned} T(n) &= (T(n/2^3)+5)+5*2 \\ &= T(n/2^3)+5*3 \quad \text{// Equation 14.16} \end{aligned}$$

Description

Using $x = n/2^3$ in Equation 14.14, we get

$$\begin{aligned} T(n/2^3) &= T((n/2^3)/2)+5 \\ &= T(n/2^4)+5 \end{aligned}$$

Description

Plugging the value of $T(n / 2^3)$ into Equation 14.16, we get

$$\begin{aligned} T(n) &= (T(n / 2^4) + 5) + 5 * 3 \\ &= T(n / 2^4) + 5 * 4 \quad \text{// Equation 14.17} \end{aligned}$$

Description

Now we can see the pattern as follows:

$$T(n) = T(n / 2^k) + 5 * k,$$

Description

We now want to choose k such that $n / 2^k$ is equal to 1 in order to reach our base case. If $n / 2^k = 1$, then $n = 2^k$, and taking the log of each side:

$$\begin{aligned} \log n &= \log 2^k \\ &= k \log 2 \\ &= k * 1 \\ &= k \end{aligned}$$

Description

Plugging $k = \log n$ in Equation 14.18, we get

$$
\begin{aligned}
T(n) &= T(1) + 5 * \log n \\
&= 2 + 5 * \log n \\
&= O(\log n)
\end{aligned}
$$

Description

Thus, Binary Search is $O(\log n)$ in the worst case. Note that the value of the original constant, here 5, does not impact the order of magnitude of the running time.

In the average case, we will find the search value after performing half the number of comparisons as in the worst-case scenario. Thus, the average running time of binary search is also $O(\log n)$.

Now, let’s calculate the running time of Insertion Sort as a function of n, the number of elements in the array. The code for an Insertion Sort is shown in **Example 14.8**.

Example 14.8 Insertion Sort

```
/**  Performs an Insertion Sort on an integer array
*    @param array   array to sort
*/
public static void insertionSort( int [  ] array )
{
  int j, temp;
  for ( int i = 1; i < array.length; i++ )
  {
      j = i;
      temp = array[i];
      while ( j != 0 && array[j - 1] > temp )
      {
        array[j] = array[j - 1];
        j--;
      }
      array[j] = temp;
  }
}
```

Description

The *for* loop header will execute n times. We will execute the body of the *for* loop $n - 1$ times.

In the best case, the array is already sorted. In this case, the *while* loop condition will always evaluate to *false*, and we will never execute the *while* loop body. So inside the *for* loop, the three statements and the loop condition will each execute once for each iteration of the *for* loop, thus executing a total of $4 * (n - 1)$ times. Therefore, the best-case running time is $O(n)$.

In the worst case, the array is sorted in the opposite order. In this case, the *while* loop condition will always be *true* for its first evaluation, and we will enter the *while* loop every time we iterate the *for* loop. Thus, the two statements inside the *while* loop will each execute $(1 + 2 + 3 + 4 + \ldots + (n - 1))$ times. Since $(1 + 2 + 3 + 4 + \ldots + (n - 1)) = n * (n - 1) / 2$, the worst-case running time of insertion sort is $O(n^2)$.

In the average case, we will enter the *while* loop half the times we try. The average case is still $O(n^2)$.

Bubble Sort, like Insertion Sort, is implemented with a double loop and runs also $O(n^2)$.

Merge Sort and Quick Sort are two sorting algorithms implemented recursively.

The pseudocode for Merge Sort is as follows:

- If the array has only one element, it is already sorted, thus do nothing; otherwise:
    - Merge sort the left half of the array.
    - Merge sort the right half of the array.
    - Merge the two sorted half arrays into one so that the resulting array is sorted.

The last operation involves looping through all the elements of the two half-arrays; it takes $O(n)$; thus, we can derive the following recursive formulation for its running time of Merge Sort:

$$\begin{aligned} T(n) &= T(n/2) + T(n/2) + n \\ &= 2T(n/2) + n \end{aligned}$$

Description

Using derivation, we get

$$\begin{aligned} T(n) &= 2T(n/2) + n \\ &= 2(2T(n/2^2) + n/2) + n \\ &= 2^2 T(n/2^2) + 2n \end{aligned}$$

Description

Continuing to iterate,

$$\begin{aligned} T(n) &= 2^2\, T(n/2^2) + 2n \\ &= 2^2\,(2\,T(n/2^3) + n/2^2) + 2n \\ &= 2^3\, T(n/2^3) + 3n \end{aligned}$$

$$\begin{aligned} T(n) &= 2^3\, T(n/2^3) + 3n \\ &= 2^3\,(2\,T(n/2^3) + n/2^3) + 3n \\ &= 2^4\, T(n/2^4) + 4n \end{aligned}$$

Description

Thus, we identify the general pattern

$$T(n) = 2^k\, T(n/2^k) + kn$$

Description

Choosing k so that $n/2^k = 1$ in order to reach the base case, i.e., $n = 2^k$, $k = \log n$, we get

$$\begin{aligned} T(n) &= n\,T(1) + n\log n \\ &= O(n\log n) \end{aligned}$$

Description

So Merge Sort is $O(n \log n)$, which is better than Insertion Sort, Bubble Sort, and Selection Sort. It is the same for best-case, worst-case, and average-case scenarios.

The running time of Quick Sort is also $O(n \log n)$ in the average-case scenario but is $O(n^2)$ in the worst-case scenario. The worst-case scenario for Quick Sort happens when the array is already sorted.

CODE IN ACTION

Within the online resources, you will find a movie with a step-by-step illustration of how to compute running times for various methods. Click on the link to start the movie.

Sorted array: Quick sort count = 523776
```

14.6 Simulation of Various Sorting Algorithms

A way to validate a running time is to run some simulation and count the statements, in particular the comparison statements, that execute as the program runs. **Example 14.9** is a simulation program that counts the number of comparisons for insertion sort, merge sort, and quick sort. We declare and initialize count, a *static* variable, at line 10. Before we run each sorting algorithm, we reinitialize count to *0* (lines 23, 31, 38, 46, 53). Inside each sorting method, we increment *count* each time we make a comparison (lines 100, 157, 229). We call each sorting method twice, first on an unsorted array, and then on the sorted array. **Figure 14.2** shows the output. **Table 14.4** compares the simulation results to mathematical expressions as a function of *n*, the number of elements in the array. In this example, we use a value of *1024* for *n* (line 9), but it can easily be changed to make further simulation runs. Our simulation confirms our earlier math analysis: insertion sort runs in $O(n^2)$ and merge sort and quick sort run in $O(n \log n)$.

Example 14.9 Simulation of Various Sorting Algorithms

```java
/* Simulation of various sorting algorithms
   Anderson, Franceschi
*/

import java.util.*;

public class Simulation
{
  public static int SIZE = 1024;
  public static int count = 0;

  public static void main( String [] args )
  {
     int [] grades = generateArray( SIZE );

     // sort unsorted array using insertion sort
     insertionSort( grades );
     output( grades );
     System.out.println( "Unsorted array: " +
        "Insertion sort count = " + count );

     // sort sorted array using insertion sort
     count = 0;
     insertionSort( grades );
     output( grades );
     System.out.println( "Sorted array: " +
        "Insertion sort count = " + count );

     grades = generateArray( SIZE );
     // sort unsorted array using merge sort
     count = 0;
     mergeSort( grades, 0, grades.length - 1 );
     output( grades );
     System.out.println( "Unsorted array: " +
        "Merge sort count = " + count );

     // sort sorted array using merge sort
     count = 0;
     mergeSort( grades, 0, grades.length - 1 );
     output( grades );
     System.out.println( "Sorted array: " +
        "Merge sort count = " + count );

     grades = generateArray( SIZE );
     // sort unsorted array using quick sort
     count = 0;
     quickSort( grades, 0, grades.length - 1 );
     output( grades );
     System.out.println( "Unsorted array: " +
        "Quick sort count = " + count );

     // sort sorted array using quick sort
     count = 0;
     quickSort( grades, 0, grades.length - 1 );
     output( grades );
     System.out.println( "Sorted array: " +
        "Quick sort count = " + count );
  }

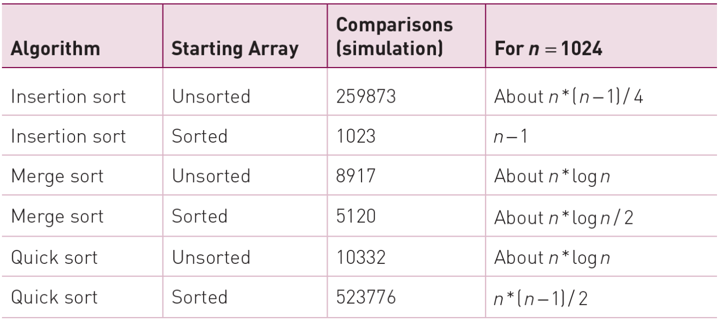
Description

Figure 14.2 Output of Example 14.9

Description

Sorting Simulation Counts for an Array of 1024 Elements



Algorithm	Starting Array	Comparisons (simulation)	For $n = 1024$
Insertion sort	Unsorted	259873	About $n*(n-1)/4$
Insertion sort	Sorted	1023	$n-1$
Merge sort	Unsorted	8917	About $n*\log n$
Merge sort	Sorted	5120	About $n*\log n/2$
Quick sort	Unsorted	10332	About $n*\log n$
Quick sort	Sorted	523776	$n*(n-1)/2$

Description

It also shows that insertion sort runs in $O(n)$ if the array is already sorted. This is due to the fact that each insertion takes $O(1)$ and there are $n - 1$ insertions when the array is already sorted. Quick sort runs in $O(n^2)$ when the array is already sorted, which is worse than its running time of $O(n \log \mathbf{n})$ when the array is unsorted. Indeed, when the array is already sorted, *partition* splits the array into a subarray of *1* element and a subarray of $n - 1$ elements at each call of *partition*, the worst possible scenario, dividing the array as unevenly as possible. Merge sort shows a very slight improvement, but not significant in terms of Big-Oh, in the number of comparisons when the array is already sorted: We make exactly $n / 2$ comparisons in the merge step because the elements in the left half of the array are all less than the elements in the right half of the array.

CHAPTER REVIEW

14.7 Chapter Summary

- The running time of an algorithm is expressed as a function of its inputs or its number of inputs.
- Orders of magnitude are, in increasing order of execution time: constant, log, polynomial, and exponential. Exponential running times are undesirable.
- Big-Oh notation is the industry standard notation for running times.
- Considering a mathematical function that represents a running time of an algorithm, that function is Big-Oh of its most dominant term, and we ignore the coefficient of that term.
- The coding of a method directly impacts its running time.

14.8 Exercises, Problems, and Projects

14.8.1 Multiple Choice Exercises

1. What is the Big-Oh of this function:
   $T(n)=n^2 - 2n + 99$

   - $O(n^2)$
   - $O(99)$
   - $O(n)$
   - $O(1)$

6. What is the Big-Oh of this function:
   $T(n) = n^3 + 10n^2 + 20n + 30$

   - $O(n^3)$
   - $O(n^2)$
   - $O(n)$
   - $O(1)$

11. What is the Big-Oh of this function:
    $T(n) = n^2 + n*\log n + 12n + 5$

    - $O(n * \log n)$
    - $O(n^2)$
    - O$O(n)$
    - $O(1)$

16. We have the following recurrence relation representing the running time of a function; what is the running time of that function?
    $T(n) = T(n - 1) + 1$

    - $O(2_n)$

- $O(n * \log n)$
- $O(n^2)$
- $O(n)$

21. Which of these running times is the worst?

- $O(n^5)$
- $O(2^n)$
- $O(n * \log n)$
- $O(n)$

26. Look at the following method:

```
public static int foo1( int n )
{
  if ( n > 1 )
   return ( 2 * foo1( n / 4 ) );
  else
   return 1;
}
```

Description

What recurrence formulation best illustrates the running time of the preceding method?

- $T(n) = T(n * 4) + 3$
- $T(n) = T(n / 4) + 3$
- $T(n) = T(n - 4) + 3$
- $T(n) = T(n + 4) + 3$

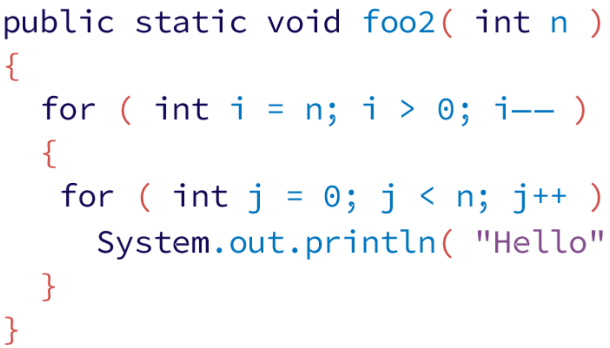
31. What is $\Sigma\, i$ for $i = 1$ to n equal to?

- n^2
- $n * (n + 1) / 2$
- $2n$
- n

36. What is Σ 1 for $i = 1$ to n equal to?

- n^2
- n
- $n * (n + 1) / 2$
- i

41. What is the running time of the *foo2* method?

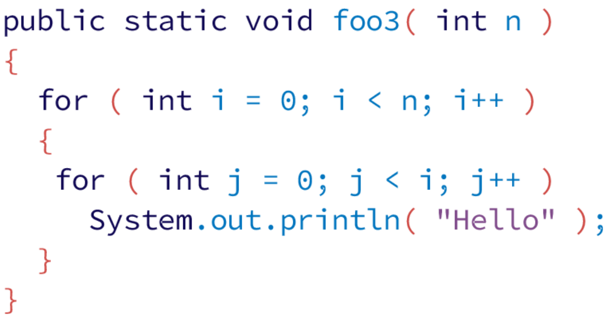


```
public static void foo2( int n )
{
  for ( int i = n; i > 0; i-- )
  {
   for ( int j = 0; j < n; j++ )
     System.out.println( "Hello"
  }
}
```

Description

- $O(n^4)$
- $O(n^3)$
- $O(n^2)$
- $O(n)$

46. What is the running time of the *foo3* method?



```
public static void foo3( int n )
{
  for ( int i = 0; i < n; i++ )
  {
   for ( int j = 0; j < i; j++ )
     System.out.println( "Hello" );
  }
}
```

Description

- $O(n^4)$
- $O(n^3)$
- $O(n^2)$
- $O(n)$

14.8.2 Compute the Running Time of a Method

1. What is the running time of the *foo4* method (assume that the parameter *arr* is a two-dimensional array of *n* rows and *n* columns)?

```
public static void foo4( int [ ][ ] arr )
{
  for ( int i = 0; i < arr.length; i++ )
  {
   for ( int j = arr[i].length - 1; j >= 0; j-- )
     System.out.println( "Hello world" );
  }
}
```

   Description

2. What is the running time of the *foo5* method (assume that the parameter *arr* is a three-dimensional array where each dimension has exactly *n* elements)?

```
public static void foo5( int [ ][ ][ ] arr )
{
  for ( int i = 0; i < arr.length; i++ )
  {
   for ( int j = 0; j < arr[i].length; j++ )
   {
    for ( int k = 0; k < arr[i][j].length; k++ )
     System.out.println( "Hello world" );
   }
  }
}
```

   Description

3. What is the running time of the *foo6* method?

```
public static void foo6( int n )
{
  if ( n <= 0 )
     System.out.println( "Hello world" );
  else
     foo6( n - 1 );
}
```

Description

4. What is the running time of the *foo7* method?

```
public static int foo7( int n )
{
  // n is guaranteed to be >= 0
  if ( n == 0 )
      return 0;
  else
      return ( n + foo7( n - 1 ) );
}
```

Description

5. What is the running time of the *foo8* method?

```
public static int foo8( int n )
{
  // n is guaranteed to be >= 1
  if ( n == 1 || n == 2 )
     return 1;
  else
     return ( foo8( n - 1 ) + foo8( n - 2 ) );
}
```

Description

Hint: Note that $T(n - 2) <= T(n - 1)$.

6. What is the running time of the *foo9* method?

```
public static void foo9( int n )
{
  // n is guaranteed to be >= 0
  if ( n == 0 )
     System.out.println( "done" );
  else
     foo9( n / 2 );
}
```

Description

7. What is the running time of the *foo10* method as a function of *n* and *p*?

```
public static void foo10( int n, int p )
{
  // n and p are guaranteed to be >= 1
  if ( p >= n )
    System.out.println( "done" );
  else
    foo10( n, 2 * p );
}
```

Description

8. What is the running time of the *foo11* method?

```
public static void foo11( int n )
{
  // n is guaranteed to be >= 0
  if ( n == 0 )
      return 0;
   else
      return ( 5 + 2 * foo11( n - 1 ) );
 }
```

Description

14.8.3 Programming Projects

1. Write a program that includes a method taking a single-dimensional array of *ints* as its only parameter, and returning the average of all the elements of the array. Add the necessary code to count how many statements are executed in the innermost loop. Run several simulations depending on the number of elements in the parameter integer array. What is the running time of that method as a function of the number of elements of the parameter array?
2. Write a program that includes a method converting a two-dimensional array of *ints* to a two-dimensional array of *boolean* values. If the integer value is greater than or equal to 0, then the corresponding *boolean* value is *true;* otherwise it is *false*. Add the necessary code to count how many statements are executed in the innermost loop. Run several simulations depending on the number of rows and columns in the argument integer array. What is the running time of that method as a function of the number of rows and columns of the parameter array? (You should assume that each row has the same number of columns.)
3. Write a program that includes a method computing the largest element of a given column (represented by a parameter of the method) of a two-dimensional array of *ints*. Add the necessary code to count how many statements are executed in the innermost loop. Run several simulations depending on the number of rows and columns in the parameter integer array, as well as the index of the column for which the method calculates the largest element. Does the running time of the method depend on the column index? the number of rows? the number of columns? What is the running time of that method as a function of the number of rows and columns of the parameter array and the column index? (You should

assume that each row has the same number of columns.)

4. Write a program that includes a method taking a two-dimensional array of *ints* as its only parameter, and returning a single dimensional array of *ints* such that each element of the returned array is the sum of the corresponding row in the parameter array. Add the necessary code to count how many statements are executed in the innermost loop. Run several simulations depending on the number of rows and columns in the parameter integer array. What is the running time of that method as a function of the number of rows and columns of the parameter array? (You should assume that each row has the same number of columns.)
5. Write a program that implements a recursive Binary Search, and add the necessary code to count how many times *binarySearchRecursive* is being called. Run several simulations on arrays of 32, 64, and 128 elements. How many times is the method called in the best-case scenario and worst-case scenario? Does that match our analysis in the chapter?
6. Write a program that implements a recursive method to compute the factorial of a number and add the necessary code to count how many times the method is being called. Run several simulations depending on the value of *n*. How many times is the method called? What is the running time of this method?
7. Write a program that includes a method converting a *String* of 0s and 1s to its equivalent decimal number and add the necessary code to count how many times the method is being called. Run several simulations depending on the length of the input *String*. How many times is the method

called? What is the running time of that method?

8. Write a program that implements Counting Sort to sort an array of integers. Research how Counting Sort works before you implement it. What is the main difference between Counting Sort and other sorting algorithms such as Selection Sort, Bubble Sort, and Insertion Sort? In what situations would Counting Sort be efficient or inefficient to sort an array of integers?

14.8.4 Technical Writing

1. Explain why it is important to consider running time when coding algorithms. Use an example to illustrate your point. Your example, web-based or not, should deal with a lot of data.

14.8.5 Group Project (for a group of 1, 2, or 3 students)

1. The Fibonacci sequence is defined as follows:

$$Fib(1) = Fib(2) = 1$$

$$Fib(n) = Fib(n-1) + Fib(n-2)$$

Description

Write a class with two *static* methods and a *main* method. The two *static* methods compute and return the *n*th Fibonacci number two different ways:

- Recursively using the general case formula and base cases above
- Using a loop (based on the formulas above)

Analyze mathematically the running time of each method as a function of *n*, the only parameter.

Inside the *main* method, call both methods with an argument such that they run for approximately 1 second. What value of *n* did you come up with for each method? What conclusion can you draw from this simulation? Does it validate your mathematical analysis?

Introduction

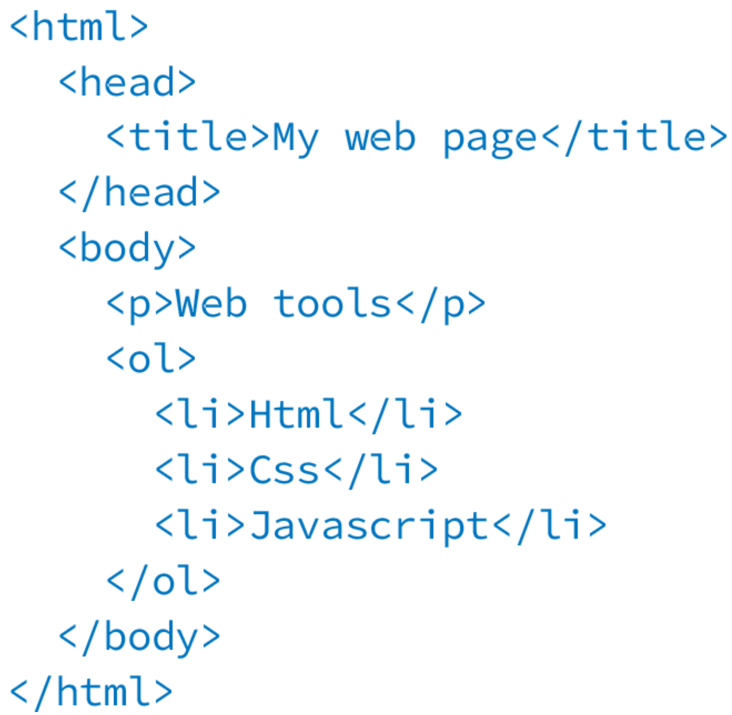
A **tree** is a data structure simulating the hierarchical nature of a tree, including a root and its descendants. As in linked lists, data is stored in nodes; nodes are connected via a parent-child relationship. Trees are used in many software applications, like database management software, and client-side web development.

Ideally, the objective is to provide an abstract data structure that is compact and efficient to search, insert into, modify, and delete from.

Relational database tables can be visualized as two-dimensional tables, but are stored in memory in B-trees, which guarantee efficient inserting, deleting and searching at all times.

In web programming, the **document object model (DOM)** specifies a tree structure that an HTML document is converted to when loaded in memory. Any change to the DOM tree is reflected on the web page by the browser. For example, the following HTML code will display a simple web page with a paragraph and an ordered list of three items (**Example 15.1**):

Example 15.1 HTML Code for a Simple Web Page



```
<html>
  <head>
    <title>My web page</title>
  </head>
  <body>
    <p>Web tools</p>
    <ol>
      <li>Html</li>
      <li>Css</li>
      <li>Javascript</li>
    </ol>
  </body>
</html>
```

Description

When a web browser receives that HTML page, it converts it to the following tree (**Figure 15.1**):

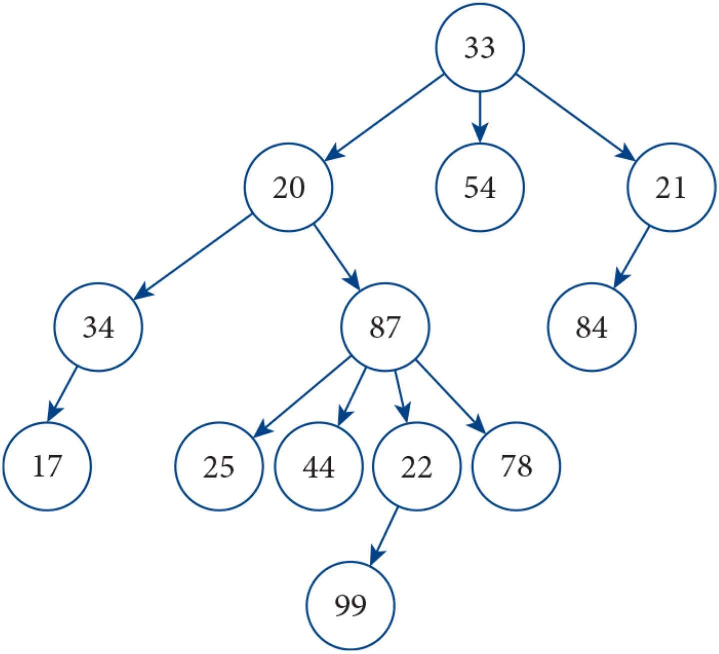
Figure 15.1 The Tree for the HTML Code of Example 15.1

Description

By navigating the tree, we can retrieve elements of the web page—for example, the paragraph or any of the list elements above—modify them, style them, delete them, or insert new elements. Any change to the DOM tree will trigger an update of the web page displayed by the browser.

REFERENCE POINT

You can get more information about HTML at https://www.w3.org/TR/html/. To get more information about the Document Object Model (DOM), visit https://www.w3.org/DOM/DOMTR



15.1 Trees

Figure 15.2 shows a tree storing integers. The top node in the tree is called the **root**. The root has children nodes, its children nodes have children nodes themselves, ...

Figure 15.2 A Tree Storing Integers

Description

Nodes are connected with **directed edges**. A directed edge defines a **parent-child** relationship between two nodes. A node can have 0 or more children but can only have one parent maximum. Every node in the tree except the root has exactly one parent. The node containing 87 has four children. The parent of the node containing 87 is the node containing 20. Nodes that have the same parent are called **siblings;** thus, the nodes containing 25, 44, 22, and 78 are siblings.

A node with no child is called a **leaf;** a node that is not a leaf is called an **interior** node. The node containing 33 is the root.

The other interior nodes are the nodes containing 20, 34, 87, 22, and 21. The nodes containing 17, 25, 44, 99, 78, 54, and 84 are leaves.

The **degree** of a node is its number of children. The degree of the node containing 20 is 2; the degree of the node containing 87 is 4.

The **depth,** or **level,** of a node is the number of links, or edges, from the root to that node. The nodes containing 20, 54, and 21 have a depth of 1; they are at level 1. The nodes containing 34, 87, and 84 have a depth of 2; they are at level 2.

The **height** of a node is the largest number of edges from that node to a leaf. The node containing 87 has height 2. The node containing 21 has height 1; the node containing 33 has height 4. The height of the tree is the height of its root, 4 in this example.

Table 15.1 summarizes all these definitions.

Tree Terminology

Term	Description
Leaf	A node with no child.
Interior node	A node with at least one child.
Siblings	Two (or more) nodes with the same parent.
Degree of a node	The number of children of a node.
Depth of a node	The number of edges on the path from the root to the node.
Level of a node	The number of edges on the path from the root to the node.
Height of a node	The largest number of edges on a path from a node to a leaf.
Height of the tree	The height of the root.

15.2 Binary Trees

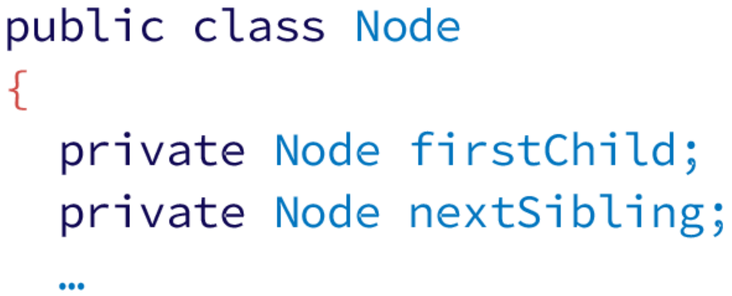
A *binary tree* is a tree whose nodes have degree 0, 1, or 2; i.e., they have either 0, 1, or 2 children. **Figure 15.3** shows a binary tree storing integers. All its nodes have degree 0, 1, or 2. The nodes containing 17, 25, 44, and 84 have degree 0; they are leaves. The nodes containing 34 and 21 have degree 1. The nodes containing 33, 20, and 87 have degree 2.

Figure 15.3 A Binary Tree Storing Integers

Description

Every general tree can be converted to a binary tree. In order to do that, we can define a *Node* as having two *Node* children (they may or may not be *null):* a first child and a next sibling. **Example 15.2** shows how such a *Node* class can be coded. **Figure 15.4** shows an example of such a node corresponding to the node containing 20 in Figure 15.2.

Example 15.2 A *Node* Class That Can Be Used to Convert a Regular Tree to a Binary Tree



```
public class Node
{
  private Node firstChild;
  private Node nextSibling;
  ...
```

Figure 15.4 An Example of a First Child – Next Sibling Node

Description

Using that type of node, any general tree can be represented and stored as a binary tree. **Figure 15.5** shows the general tree of Figure 15.2 represented and stored as a binary tree.

Figure 15.5 The Regular Tree from Figure 15.2 Represented as a Binary Tree Using First Child – Next Sibling Nodes

Description

Generally, it is desirable for a binary tree to have minimal height, so that it is as compact as possible. Later in the chapter, we explain why in great detail.

A tree that has all its levels completely full and its last level filled from left to right is called a **complete binary tree.** An example is shown in **Figure 15.6**. A tree that has all its levels completely full is called a **full binary tree.** An example is shown in **Figure 15.7**. A full binary tree is a special case of a complete binary tree; a complete binary tree is generally not a full binary tree.

Figure 15.6 A Complete Binary Tree

Description

Figure 15.7 A Full Binary Tree

Description

Binary trees that are either full, complete, or close to complete can be very compact data structures. A lot of nodes can be stored in a tree that has very low height. **Table 15.2** shows the number of nodes per level in a full binary tree (remember that in a full binary tree, every level is full). As we go down one level at a time in the binary tree, every level contains two times the number of nodes in its previous level. Thus, at level *L*, we have 2^L nodes.

Number of Nodes per Level in a Full Binary Tree

Level	Number of Nodes
0	$1 = 2^0$
1	$2 = 2^1$
2	$4 = 2^2$
3	$8 = 2^3$
4	$16 = 2^4$
5	$32 = 2^5$
6	$64 = 2^6$
L	2^L

Description

If we have *n* nodes in a binary tree whose deepest level is *L*, what is the value of *L* as a function of *n*?

$$n = \text{total \# of nodes} = \text{sum of nodes for all levels} = 1 + 2^1 + 2^2 + 2^3 + 2^4 + 2^5 + \ldots + 2^L$$

Description

This is a geometric series of ratio 2 and is equal to $(2^{L+1} - 1)/(2 - 1) = 2^{L+1} - 1$. This formula can easily be proven by induction. The following is another simple proof:

$$n = 1 + 2^1 + 2^2 + 2^3 + 2^4 + 2^5 + \ldots + 2^L$$

Description

Multiplying each side by 2, we get:

$$2n = 2^1 + 2^2 + 2^3 + 2^4 + 2^5 + \ldots + 2^L + 2^{L+1}$$

Description

Thus, subtracting *n* from *2n,* most terms cancel out and we have:

$$2n - n = 2^{L+1} - 1; \text{thus, } n = 2^{L+1} - 1, \text{or } n + 1 = 2^{L+1}$$

Description

Taking the log of both sides:

$$\log(n+1) = L + 1, \text{or } L = \log(n+1) - 1$$

Description

Thus, *L* is very small in comparison to *n.* If we store the emails of all the Facebook users, i.e., over 1 billion emails, in a full (or complete) binary tree, we only need 30 levels in the binary tree (1 billion is roughly equal to 2^{30}, and therefore the log of 1 billion is roughly equal to 30).

Any node in a tree can be considered the root of a tree, the tree comprised of itself and its descendants. The tree rooted at the left child of a node is considered its **left subtree.** The tree rooted at the right child of a node is considered its **right subtree.** For the tree in Figure 15.3, the “root” of the left subtree is the node containing 20; the “root” of the right subtree is the node containing 21.

For many types of binary trees, it is very desirable that the height of a tree is minimal or close to it. A node is **height-balanced** if the difference in height between its left and right subtrees (or vice-versa) is less than or equal to 1. A binary tree is height-balanced if all its nodes are height-balanced; an empty tree is height-balanced. The binary trees in Figure 15.3, 15.6, and 15.7 are all height-balanced. The binary tree in **Figure 15.8** is not height-balanced because the node containing 21 is not height-balanced.

15.3 Binary Tree Implementation

As with linked lists, we use a *Node* class as a tool when implementing a binary tree. A *Node* stores data and links or references to its two children. The data contained in a *Node* can be of a basic data type or a user-defined data type; we can also use generics for the most flexible implementation. To keep things simple and focus on the functionality of binary trees, we store integers in *IntegerNode* objects. In addition to the data, an *IntegerNode* has a left child, an *IntegerNode,* and a right child, another *IntegerNode.* **Example 15.3** shows the *IntegerNode* class, a class encapsulating a node storing an *int.* In addition to the instance variables, it includes a constructor, accessors, and mutators. The constructor (lines 11–18) constructs an *IntegerNode* storing a given value, its parameter; its left and right children are *null.* The *IntegerNode* class is simply a utility class to store an *int* and links to other nodes in the binary tree.

Example 15.3 The *IntegerNode* Class

```java
/** The IntegerNode class
  Anderson, Franceschi
*/

public class IntegerNode
{
  private int data;
  private IntegerNode left;
  private IntegerNode right;

  /** Constructor
  * @param data
  * initializes data instance variable with data
  */
  public IntegerNode( int data )
  {
     setData( data );
  }

  /** Accessor for data
  * @return data
  */
  public int getData( )
  {
     return data;
  }

  /** Accessor for left
  * @return left
  */
  public IntegerNode getLeft( )
  {
     return left;
  }

  /** Accessor for right
  * @return right
  */
  public IntegerNode getRight( )
  {
     return right;
  }

  /** Mutator for data
  * @param data    an int, the new value for data
  * @return        a reference to this object
  */
  public IntegerNode setData(int data )
  {
     this.data = data;
     return this;
  }

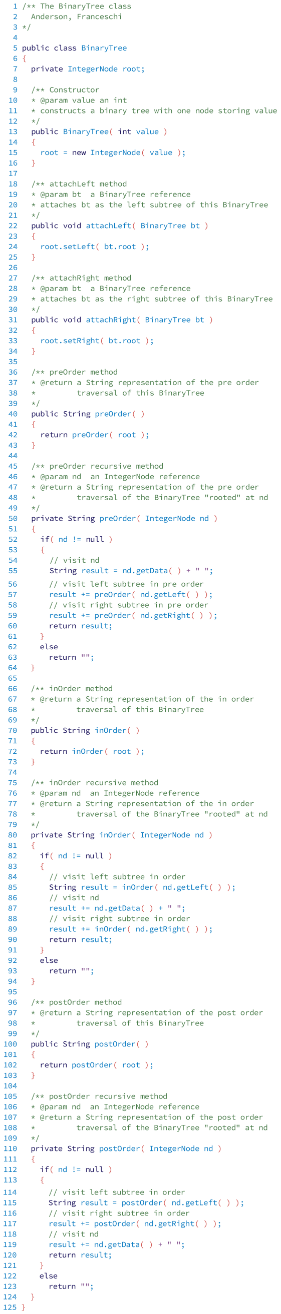
  /** Mutator for left
  * @param left a Node, the new Node reference for left
  * @return     a reference to this object
  */
  public IntegerNode setLeft(IntegerNode left )
  {
     this.left = left;
     return this;
  }

  /** Mutator for right
  * @param right a Node, the new Node reference for right
  * @return      a reference to this object
  */
  public IntegerNode setRight( IntegerNode right )
  {
     this.right = right;
     return this;
  }
}
```

Description

Example 15.4 shows the *BinaryTree* class. We only need one instance variable (line 7), *root,* an *IntegerNode,* the root of the binary tree. From *root,* we can access its left and right children, their left and right children, ...

Example 15.4 The *BinaryTree* Class



```java
/** The BinaryTree class
  Anderson, Franceschi
*/

public class BinaryTree
{
  private IntegerNode root;

  /** Constructor
  * @param value an int
  * constructs a binary tree with one node storing value
  */
  public BinaryTree( int value )
  {
    root = new IntegerNode( value );
  }

  /** attachLeft method
  * @param bt  a BinaryTree reference
  * attaches bt as the left subtree of this BinaryTree
  */
  public void attachLeft( BinaryTree bt )
  {
    root.setLeft( bt.root );
  }

  /** attachRight method
  * @param bt  a BinaryTree reference
  * attaches bt as the right subtree of this BinaryTree
  */
  public void attachRight( BinaryTree bt )
  {
    root.setRight( bt.root );
  }

  /** preOrder method
  * @return a String representation of the pre order
  *         traversal of this BinaryTree
  */
  public String preOrder( )
  {
    return preOrder( root );
  }

  /** preOrder recursive method
  * @param nd  an IntegerNode reference
  * @return a String representation of the pre order
  *         traversal of the BinaryTree "rooted" at nd
  */
  private String preOrder( IntegerNode nd )
  {
    if( nd != null )
    {
      // visit nd
      String result = nd.getData( ) + " ";
      // visit left subtree in pre order
      result += preOrder( nd.getLeft( ) );
      // visit right subtree in pre order
      result += preOrder( nd.getRight( ) );
      return result;
    }
    else
      return "";
  }

  /** inOrder method
  * @return a String representation of the in order
  *         traversal of this BinaryTree
  */
  public String inOrder( )
  {
    return inOrder( root );
  }

  /** inOrder recursive method
  * @param nd  an IntegerNode reference
  * @return a String representation of the in order
  *         traversal of the BinaryTree "rooted" at nd
  */
  private String inOrder( IntegerNode nd )
  {
    if( nd != null )
    {
      // visit left subtree in order
      String result = inOrder( nd.getLeft( ) );
      // visit nd
      result += nd.getData( ) + " ";
      // visit right subtree in order
      result += inOrder( nd.getRight( ) );
      return result;
    }
    else
      return "";
  }

  /** postOrder method
  * @return a String representation of the post order
  *         traversal of this BinaryTree
  */
  public String postOrder( )
  {
    return postOrder( root );
  }

  /** postOrder recursive method
  * @param nd  an IntegerNode reference
  * @return a String representation of the post order
  *         traversal of the BinaryTree "rooted" at nd
  */
  private String postOrder( IntegerNode nd )
  {
    if( nd != null )
    {
      // visit left subtree in order
      String result = postOrder( nd.getLeft( ) );
      // visit right subtree in order
      result += postOrder( nd.getRight( ) );
      // visit nd
      result += nd.getData( ) + " ";
      return result;
    }
    else
      return "";
  }
}
```

Description

The constructor (lines 9–16) constructs a binary tree storing one element, *value,* its parameter. Its root node contains *value* (line 15).

At this point, our binary tree has no particular ordering. Thus, in order to add elements to our binary tree, we provide methods that attach a binary tree to this binary tree (lines 18–25 and 27–34).

The *attachLeft* method (lines 18–25) takes a *BinaryTree* parameter (that contains 0 or more elements) and attaches its *root* as the left child of *root* (line 24). The *attachRight* method (lines 27–34) takes a *BinaryTree* parameter (that contains 0 or more elements) and attaches its *root* as the right child of *root* (line 33). **Figure 15.9** shows what the *attachLeft* and *attachRight* methods do.

Figure 15.9 The *attachLeft* and *attachRight* Methods

Description

In addition to the methods above, we provide methods that return a *String* listing all the elements stored in the binary tree. Going through all the elements in the binary tree is called **traversing** the tree. That gives us a human-readable representation of the tree, and that is what the *toString* method usually does. However, we can traverse the binary tree several ways, so we do not have one *toString* method, but several traversal methods.

We typically can traverse the binary tree in level order, pre order, in order, or post order.

Traversing the tree in level order, we start at the root (level 0), and visit all the nodes one level at a time from top to bottom, going left to right at each level. Thus, we first visit the root (level 0), then visit its left child and right child (level 1), then the nodes at level 2 from left to right, then the nodes at level 3 from left to right, and so on.

Traversing in pre order, in order, and post order involve walking around the tree counterclockwise, as shown in **Figure 15.10**, visiting one node at a time. **Figure 15.11** shows how we visit the node containing 34. Even if the left child of a node is *null,* it is considered a visit. We will “see” 34 a total of three times: two times before seeing 17 and one time after it. Traversing in pre order, we list the element the first time we see it. Traversing in order, we list the element the second time we see it. Traversing in post order, we list the element the last (third) time we see it.

Figure 15.10 Pre Order, In Order, and Post Order Traversals Are Performed Walking Counterclockwise Around the Tree

Description

Figure 15.11 We Can Visit a Node on Three Occasions: 1 → Pre Order, 2 → In Order, 3 → Post Order

Description

Thus, when traversing the tree either in pre order or in order, we will list 34 before we list 17. When traversing the tree in post order, we will list 17 before we list 34.

Table 15.3 lists how each traversal works and what the results are for the tree in Figure 15.10.

Tree Traversal Strategies and Results for the Binary Tree in Figure 15.10

Traversal	Strategy	Result
Level Order	Visit one level at a time, left to right	33 20 21 34 87 84 17 25 44
Pre Order	Visit node the first time we see it	33 20 34 17 87 25 44 21 84
In Order	Visit node the second time we see it	34 17 20 25 87 44 33 21 84
Post Order	Visit node the third/last time we see it	17 34 25 44 87 20 84 21 33

Description

COMMON ERROR TRAP

When traversing a binary tree in order, if a node has no left child, we will see that node two times before seeing its right child. Thus, its data will be listed before the data of its right child or its right child’s descendants when traversing the binary tree in order.

The level order traversal is more complicated to code than the three other traversals and one of the topics of Programming Activity 1. The pre order, in order, and post order traversals are well suited for a recursive implementation.

The recursive algorithm for the pre order traversal is as follows:

- List the content of the current node.
- Traverse in pre order the left subtree, i.e., the binary tree rooted at the left child of the current node.
- Traverse in pre order the right subtree, i.e., the binary tree rooted at the right child of the current node.

As described above, we make two recursive calls when traversing a binary tree, one on the left subtree and one on the right subtree. Thus, we need a way to programmatically define a subtree. Like a binary tree is fully defined by its root, a subtree is fully defined by one node, its “root.” For example, the root of the left subtree is the left child of *root.* Thus, our recursive pre order traversal method has this method header (line 50):

```
private String preOrder( IntegerNode nd )
```

Description

It traverses in pre order the subtree rooted at *nd* and returns a *String* representation of that traversal.

To traverse in pre order the whole binary tree, i.e., the “subtree” rooted at *root,* we simply call the method above and pass *root* as its argument. However, from a client class, we do not have access to the *root* instance variable of a binary tree and therefore cannot call that method. We define this method as *private* and provide a *public* “wrapper” method (lines 36–43) that takes no parameter and calls the *private* recursive method (line 42) in order to traverse the whole binary tree.

The base case of the recursive method happens when the subtree that we traverse is empty, i.e., *nd* is *null* (line 62); in this case, it returns an empty *String* (line 63). If the subtree is not empty (line 52), we place the data in *nd* in the *String result* (line 55), then concatenate to *result* the *String* returned by the pre order traversal of the left subtree (lines 56–57), and finally concatenate to *result* the *String* returned by the pre order traversal of the right subtree (lines 58–59). At line 60, we return *result.*

The in order and post order traversal methods (lines 66–94 and 96–124) are coded using the same pattern as the *preOrder* method.

The recursive algorithm for the in order traversal is as follows:

- Traverse in order the left subtree, i.e., the binary tree rooted at the left child of the current node.
- List the content of the current node.
- Traverse in order the right subtree, i.e., the binary tree rooted at the right child of the current node.

  The recursive algorithm for the post order traversal is as follows:
- Traverse in post order the left subtree, i.e., the binary tree rooted at the left child of the current node.
- Traverse in post order the right subtree, i.e., the binary tree rooted at the right child of the current node.
- List the content of the current node.

Example 15.5 shows how we can use the *attachLeft* and *attachRight* methods to build the binary tree in Figure 15.10. We traverse the binary tree at lines 29–31. The output, shown in **Figure 15.12**, matches the traversals listed in Table 15.3.

Example 15.5 A Client of the *BinaryTree* Class

```java
/** The BinaryTreeClient class
   Anderson, Franceschi
 */
 public class BinaryTreeClient
 {
   public static void main( String [] args )
   {
     BinaryTree bt33 = new BinaryTree( 33 );
     BinaryTree bt20 = new BinaryTree( 20 );
     BinaryTree bt21 = new BinaryTree( 21 );
     BinaryTree bt34 = new BinaryTree( 34 );
     BinaryTree bt87 = new BinaryTree( 87 );
     BinaryTree bt84 = new BinaryTree( 84 );
     BinaryTree bt17 = new BinaryTree( 17 );
     BinaryTree bt25 = new BinaryTree( 25 );
     BinaryTree bt44 = new BinaryTree( 44 );

     bt33.attachLeft( bt20 );
     bt33.attachRight( bt21 );

     bt20.attachLeft( bt34 );
     bt20.attachRight( bt87 );
     bt21.attachRight( bt84 );

     bt34.attachRight( bt17 );
     bt87.attachLeft( bt25 );
     bt87.attachRight( bt44 );

     System.out.println( "Pre order: " + bt33.preOrder( ) );
     System.out.println( "In order: " + bt33.inOrder( ) );
     System.out.println( "Post order: " + bt33.postOrder( ) );
  }
}
```

Description

Figure 15.12 The Output of Example 15.5

Description

15.4 Programming Activity 1: Working with Binary Trees

In this activity, you will add methods to the *BinaryTree* class to return the leftmost data in the binary tree, count the number of nodes in the tree, count the number of leaves in the tree, calculate the height of the tree, and traverse the tree in level order.

Instructions

Copy the source files in the Programming Activity 1 folder for this chapter to a folder on your computer. Note that all files should be in the same folder.

Inside the *BinaryTree* class, you need to modify and code the following methods (the binary tree stores integer values):

1. A method that returns the leftmost data in the binary tree; this method throws an exception if the binary tree is empty
2. A method that returns the number of nodes in the binary tree
3. A method that returns the number of leaves in the binary tree
4. A method that returns the height of the binary tree
5. A method that returns a *String* listing all the values stored in the binary tree using a level traversal of the binary tree

Note: The data returned by these methods must **not** be kept and maintained using an instance variable (for example, we do not keep track of the number of items in the tree).

Hint: You can use a queue in method # 5. The *ArrayList* class includes methods that you can use to provide the functionality of a queue.

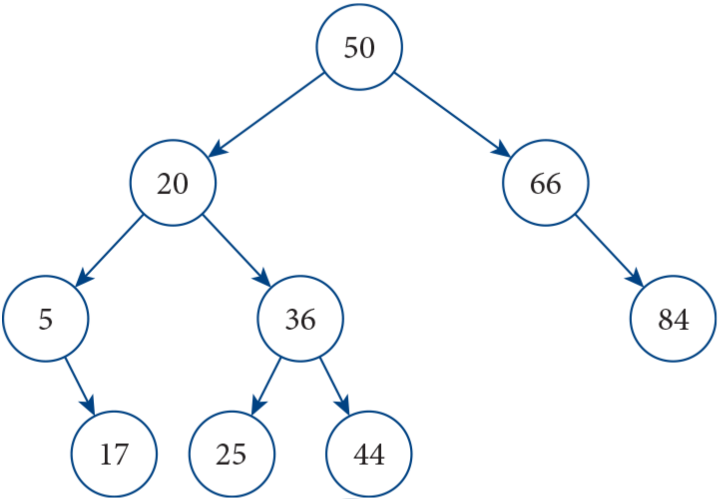
In the client of the class, build a tree storing at least eight values and test all the methods.

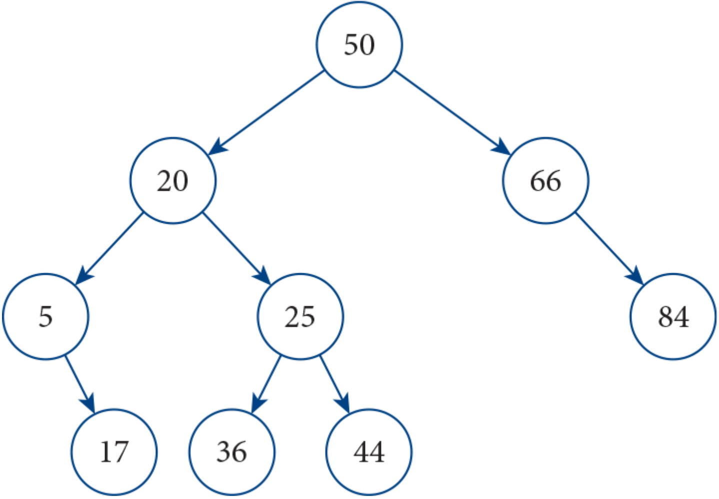
Troubleshooting

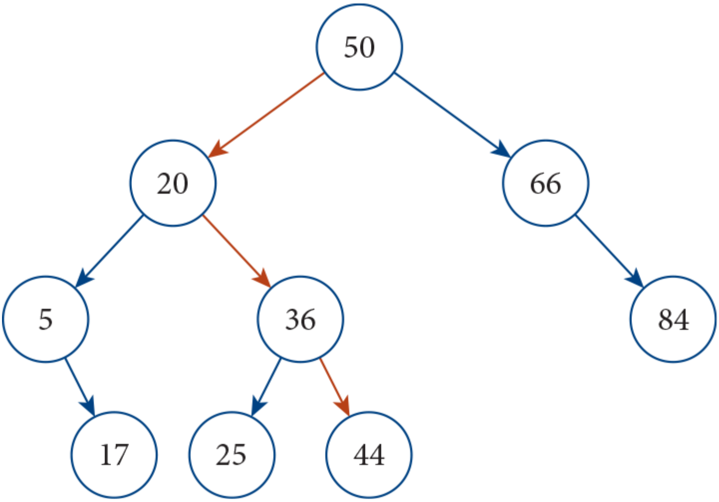
- Code one method at a time and test your results.
- Draw the tree on a piece of paper and check all your results.
- If one of your methods shows a stackoverflow error at run time, check that you have properly coded the base case.

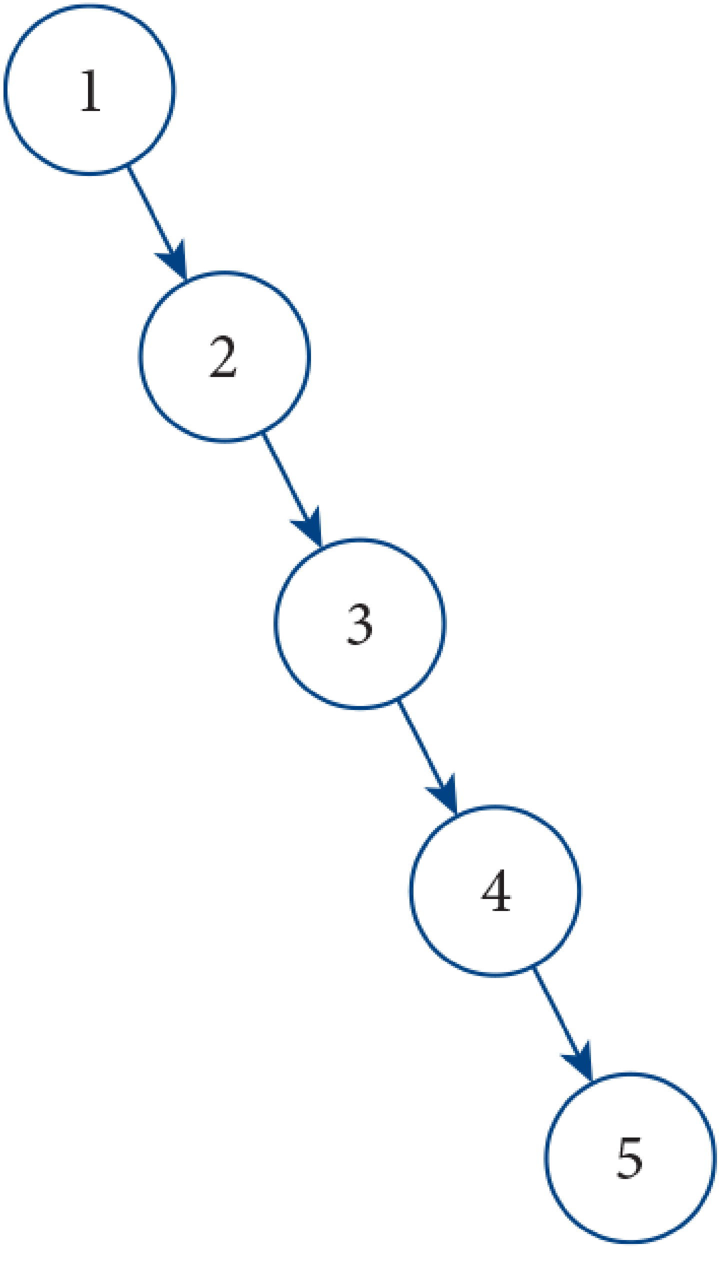
DISCUSSION QUESTIONS

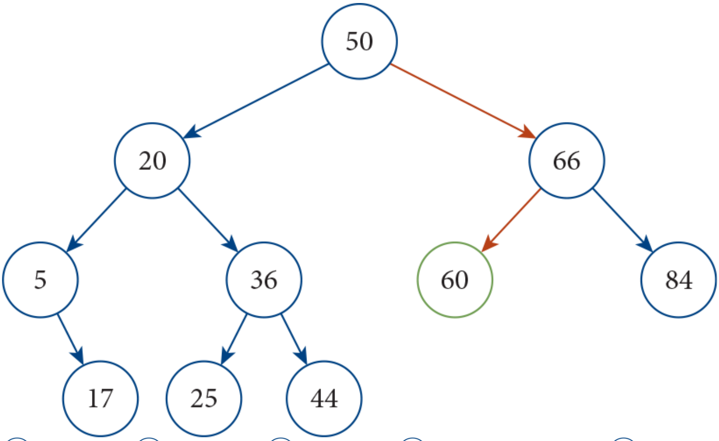
1. **Which methods did you implement recursively? Why did you choose to implement recursively?**
2. **How is the level traversal implementation different from the pre order, in order, and post order implementations?**

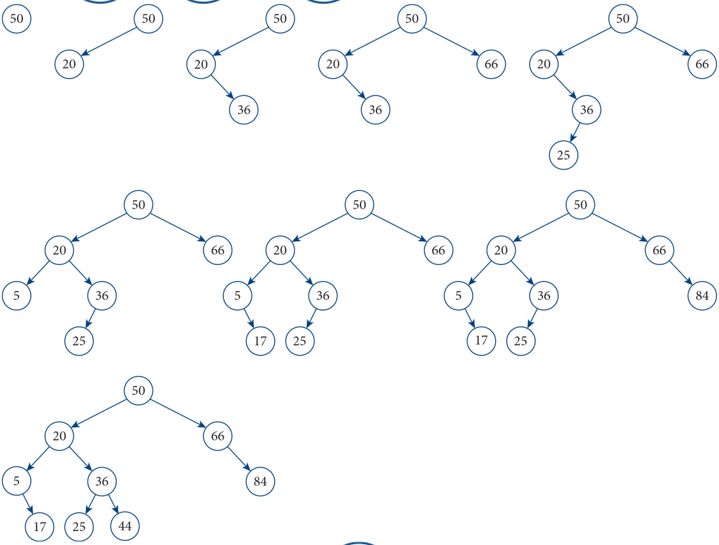


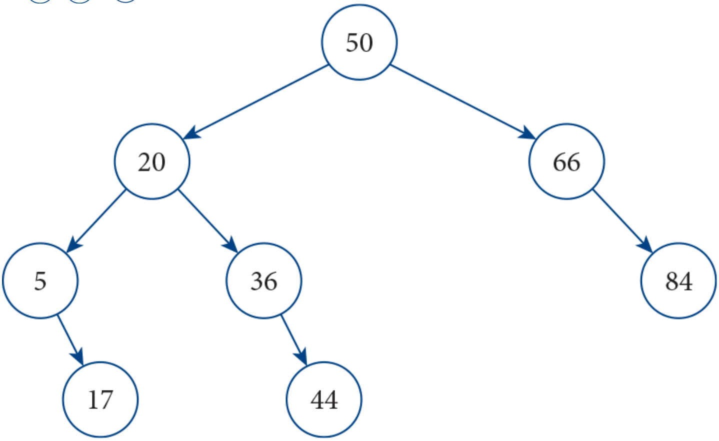


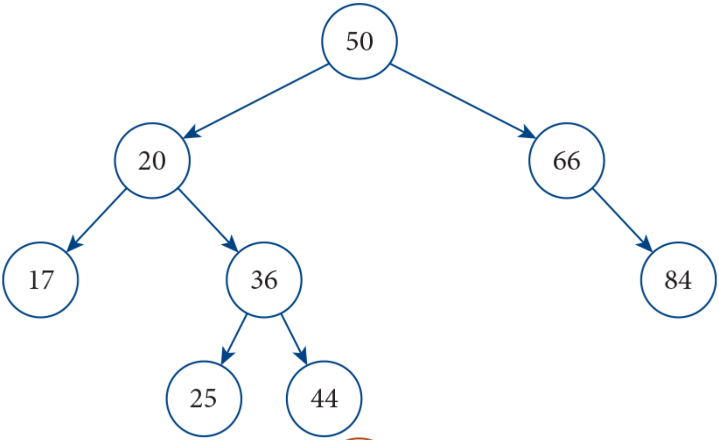


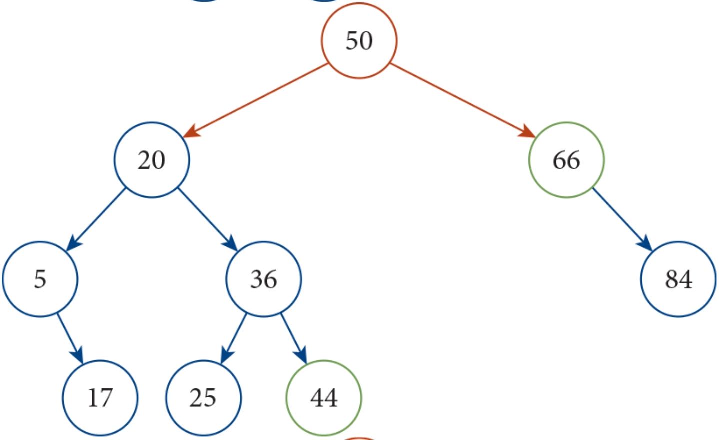


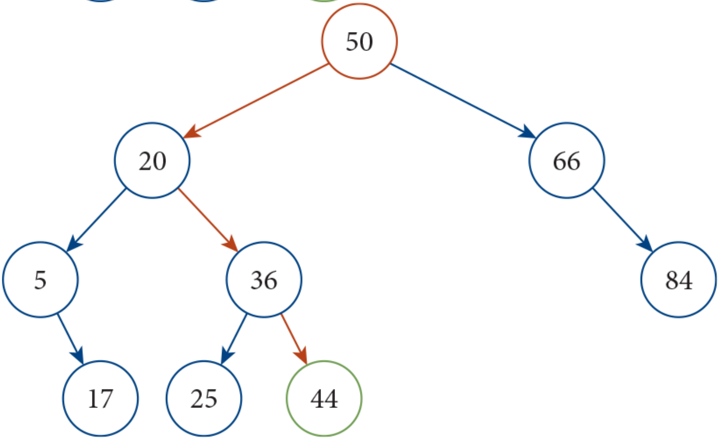


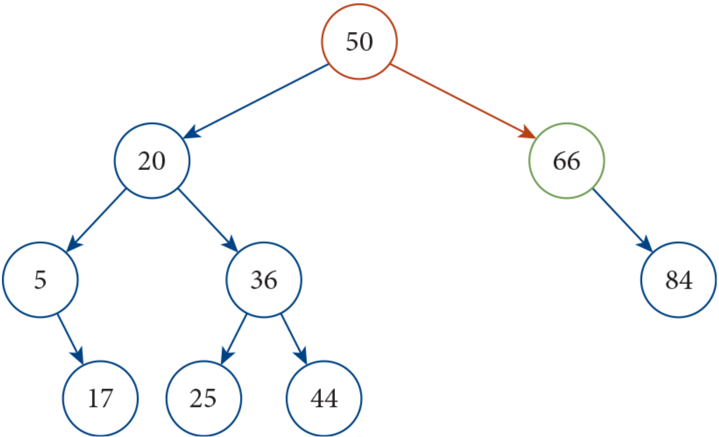


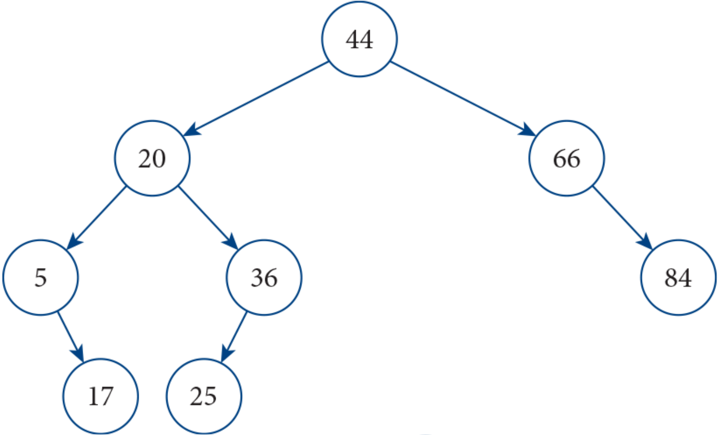


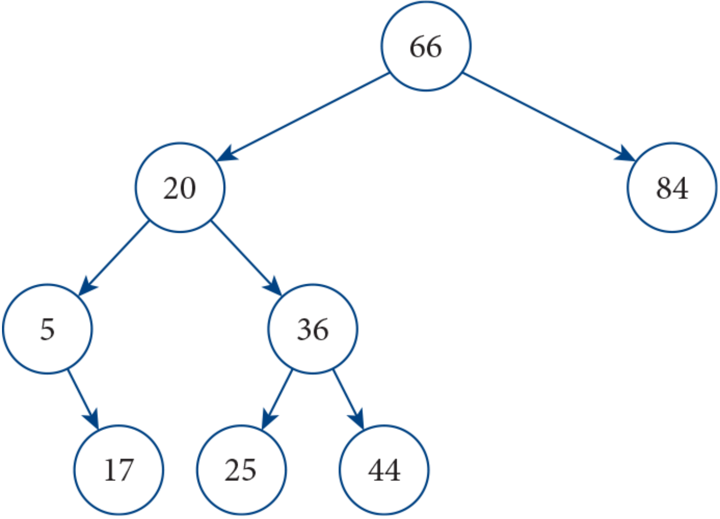












15.5 Binary Search Trees

As we learned earlier, binary trees can be very compact structures. However, without any ordering, binary trees are not suited for searching; we typically need to traverse the whole tree when looking for a particular value. Binary search trees provide a solution to the inefficient searching of a binary tree.

A *binary search tree,* a special type of binary tree, is defined as follows:

- All the elements to the left of the root have a value smaller than the root's value,
- All the elements to the right of the root have a value larger than the root's value,
- The left subtree of a binary search tree is a binary search tree itself, and
- The right subtree of a binary search tree is a binary search tree itself.
- An empty binary tree is a binary search tree.

As we can see, the above definition is recursive (points 1, 2, 3, and 4 define the general case; point 5 defines the base case). **Figure 15.13** shows an example of a binary search tree. Look at the left subtree in which the "root" value is 20; it is a binary search tree itself. The values on its left are all smaller than 20, and the values on its right are all larger than 20. Then, its left and right subtrees are also binary search trees. The left subtree, the "root" value of which is 5, is a binary search tree: its left subtree is empty, 17 is larger than 5, and its right subtree is made up of just one element and is a binary search tree, ...

Figure 15.13 A Binary Search Tree: The values on the left are smaller than 50; the values on the right are larger than 50; both the left and right subtrees are binary search trees themselves.

Description

If we switch 36 and 25 (**Figure 15.14**), we no longer have a binary search tree. Although the values on the left of the root are all smaller than 50, the subtree rooted at the node that contains 25 is not a binary search tree itself, because 36 is on the left of 25 and should be on the right of 25.

Figure 15.14 A Binary Tree That Is NOT a Binary Search Tree: 36 is on the left of 25, a binary search tree property violation.

Description

COMMON ERROR TRAP

If you think you are building a binary search tree and the values do not come out in ascending order when doing an in order traversal of the tree, then the tree is not a binary search tree.

A remarkable property of binary search trees is that values come out in ascending order when doing an in order traversal. For the binary search tree in Figure 15.13, the in order traversal is: 5 17 20 25 36 44 50 66 84.

15.5.1 Searching in a Binary Search Tree

Searching in a binary search tree is similar to doing a binary search. At each comparison, we eliminate one side of the tree. **Figure 15.15** shows how we can search for 44 in our binary search tree. 44 is smaller than 50, so we search left; 44 cannot be found on the right subtree because all the elements on the right of 50 are larger than 50 and therefore larger than 44. Then we look at 20 and since 44 is larger than 20, we search to the right of 20; 44 is larger than 36, so we search right of 36. The next node contains 44. If we search for 43, we follow the same strategy. We first look at 50 and go left; we then look at 20 and go right. We look at 36 and go right, then look at 44 and go left. The node containing 44 does not have a left child, so we conclude that we will not find 43 in the binary search tree of Figure 15.13.

Figure 15.15 Searching for 44 in a Binary Search Tree

Description

Let's make the assumption that a binary search tree is complete. In the worst-case scenario, whether we find the value we are looking for in a leaf or do not find it, we go from the root to a leaf using a path whose length is the height of the tree. Since the height of a complete binary tree is log(*n* +1) − 1 where *n* is the number of nodes in the tree, searching takes O(log *n*). Thus, if we store all the Facebook users and order them using their emails in a complete binary search tree, it will only take us 30 or 31 comparisons in the worst case to find the user we are looking for when we search for an email value.

However, the binary search tree may not be complete; in fact, in the worst-case scenario, it could look like a linked list, as shown in **Figure 15.16**. In this case, searching can take up to *n* steps if we are searching for the largest value in the tree or a value larger than the largest value in the tree. Thus, it is very desirable to keep the binary search tree height-balanced. Later in this chapter, we discuss how we can rebalance a binary search tree so that it is height-balanced.

Figure 15.16 A Binary Search Tree That Looks Like a Linked List

Description

15.5.2 Inserting in a Binary Search Tree

A binary search tree must also support insert and delete operations. After inserting or deleting, the tree must still be a binary search tree afterwards. We also need to keep those operations relatively simple so that they can be easily coded and have an efficient running time.

We typically insert "as a leaf" in a binary search tree. In terms of resetting the links between nodes, it keeps things very simple. There is only one place to insert "as a leaf" in a binary search tree. Furthermore, if we insert in a height-balanced binary search tree, insert takes O(log *n*). Let's insert 60 in the binary search tree of Figure 15.13. In order to find the place to insert, we follow the same strategy as for searching. Since 60 is larger than 50, it will be on the right of 50. Since it is smaller than 66, it will be on the left of 66. The node containing 66 does not have a left child, so we just found the place to insert 60, and that place is unique within the tree (assuming we insert "as a leaf"). **Figure 15.17** visualizes the insertion of 60 in our binary search tree. We can easily see that after 60 is inserted, the tree is still a binary search tree. Other than creating a node and attaching it to the tree, the process is identical to the search process and takes O(log *n*) time for a height-balanced complete binary search tree. Note that if the tree is complete before the insertion, it is probably not complete after the insertion. If the tree "looks like" a linked list, it is likely that the insertion will take O(*n*) running time. Once again, it is very desirable that a binary search tree is height-balanced.

Figure 15.17 Inserting 60 in the Binary Search Tree of Figure 15.13

Description

Figure 15.18 shows a sequence of insertions, starting from an empty binary search tree: 50, 20, 36, 66, 25, 5, 17, 84, and 44 are successively inserted.

Figure 15.18 A Sequence of Insertions in a Binary Search Tree

Description

15.5.3 Deleting from a Binary Search Tree

Deleting a value from a binary search tree can be more complex; indeed, we could be deleting a value in the middle of the tree. In order to delete a value, that value must be in the tree to begin with. Thus, we start by searching for the value. Assuming we find it, we have three different scenarios:

- The value is stored in a leaf,
- The value is stored in a node that has only one child, or
- The value is stored in a node that has two children.

Once again, we want the binary search tree to still be a binary search tree after the deletion. Also, we want the delete operation to be efficient, i.e., O(log *n*) for a height-balanced tree.

If the value we are deleting is stored in a leaf, we simply delete that leaf from the tree, i.e., the leaf's parent's child becomes *null.* **Figure 15.19** shows the resulting tree if we delete 25 from the tree in Figure 15.13. Obviously, it is still a binary search tree.

Figure 15.19 The Resulting Tree After Deleting 25 from the Tree in Figure 15.13

Description

If the value we are deleting is stored in a node that has only one child, the child of that node takes its place. Note that it could be either the left child or the right child. **Figure 15.20** shows the resulting tree if we delete 5 from the tree in Figure 15.13. Again, the resulting tree is a binary search tree. Note also that there could be a whole subtree underneath that child. If there is a whole subtree below the node containing 17, that whole subtree is a binary search tree itself, and although it is to the right of 5, it is to the left of 20; thus, every element in that subtree is smaller than 20. After the deletion takes place, that subtree is still to the left of 20.

Figure 15.20 The Resulting Tree After Deleting 5 from the Tree in Figure 15.13

Description

A more complex situation arises when we delete a value, for example 50, stored in a node that has two children. The general strategy is to replace that value with an existing value below it so that we keep the binary search tree property. We have two possible choices:

- Replace it with the largest value in the left subtree underneath the node containing the value we are deleting (for the tree in Figure 15.13, that is 44)
- Replace it with the smallest value in the right subtree underneath the node containing the value we are deleting (for the tree in Figure 15.13, that is 66)

Figure 15.21 shows the two such values of the tree in Figure

15.13 when we delete 50. The largest value on the left of 50 is 44, and the smallest value on the right of 50 is 66.

Figure 15.21 The Two Candidate Replacement Values When We Delete 50 from the Binary Search Tree in Figure 15.13

Description

The largest value in the left subtree is larger than all the other values in the left subtree and smaller than all the values in the right subtree (because it is in the left subtree, it is smaller than the value we are deleting, and therefore smaller than all the values in the right subtree).

The smallest value in the right subtree is smaller than all the other values in the right subtree and larger than all the values in the left subtree (because it is in the right subtree, it is larger than the value we are deleting, and therefore larger than all the values in the left subtree).

In order to find the largest value in the left subtree, we go left once and then go right as far as we can. **Figure 15.22** shows the path to find such value. The node containing 44 has no right child. In order to find the smallest value in the right subtree, we go right once and then go left as far as we can. **Figure 15.23** shows the path to find such value. The node containing 66 has no left child.

Figure 15.22 Finding the Largest Value (44) Left of 50 in the Tree of Figure 15.13

Description

Figure 15.23 Finding the Smallest Value (66) Right of 50 in the Tree of Figure 15.13

Description

When we write the code to delete a value, we simply pick one of the two choices and implement it. We do not implement both choices.

The value that is selected could be inside a leaf or inside a node that has one child. It is not possible that such a node has two children (otherwise, the value would not be the largest on the left side or the smallest on the right side; we would need to continue searching for such a value). Note that if it is inside a node that has one child, there could be a whole subtree underneath that child.

Either way, after we have placed that value inside the node containing the value that we are deleting, we simply delete that value from the tree. After the deletion, the resulting tree is a binary search tree. **Figures 15.24** and **15.25** show the resulting tree if we delete 50 from the tree in Figure 15.13. Figure 15.24 is based on the first scenario, and Figure 15.25 is based on the second scenario.

Figure 15.24 Using the First Scenario, the Resulting Tree After Deleting 50 from the Tree in Figure 15.13

Description

Figure 15.25 Using the Second Scenario, the Resulting Tree After Deleting 50 from the Tree in Figure 15.13

Description

If the binary search tree is height-balanced, *delete,* like *search* and *insert,* takes O(log *n*). We first go down the tree in order to find the value to delete, then keep going down the tree to find its replacement value, and finally replace the deleted value and reset some links. Overall, we take a path from the root to either a leaf or a node with one child, “measuring” the height of the tree or less. Like *search* and *insert,* if the tree “looks like” a linked list, *delete* can take O(*n*).

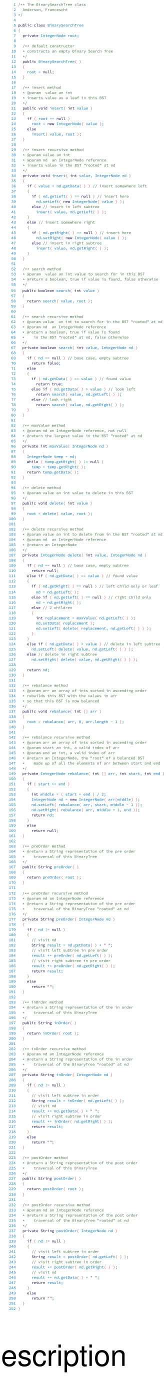
15.6 Binary Search Tree Implementation

Again, to keep things simple and focus on the functionality of a binary search tree, we store integers in *IntegerNode* objects. We use the same *IntegerNode* class as the one in Example 15.3. **Example 15.6** shows the *BinarySearchTree* class.

Example 15.6 The *BinarySearchTree* Class



```java
/** The BinarySearchTree class
  Anderson, Franceschi
*/

public class BinarySearchTree
{
  private IntegerNode root;

  /** default constructor
  * constructs an empty Binary Search Tree
  */
  public BinarySearchTree( )
  {
    root = null;
  }

  /** insert method
  * @param  value an int
  * inserts value as a leaf in this BST
  */
  public void insert( int value )
  {
    if ( root == null )
      root = new IntegerNode( value );
    else
      insert( value, root );
  }

  /** insert recursive method
  * @param value an int
  * @param nd  an IntegerNode reference
  * inserts value in the BST "rooted" at nd
  */
  private void insert( int value, IntegerNode nd )
  {
    if ( value < nd.getData( ) ) // insert somewhere left
    {
      if ( nd.getLeft( ) == null ) // insert here
        nd.setLeft( new IntegerNode( value ) );
      else // insert in left subtree
        insert( value, nd.getLeft( ) );
    }
    else // insert somewhere right
    {
      if ( nd.getRight( ) == null ) // insert here
        nd.setRight( new IntegerNode( value ) );
      else // insert in right subtree
        insert( value, nd.getRight( ) );
    }
  }

  /** search method
  * @param  value an int value to search for in this BST
  * @return a boolean, true if value is found, false otherwise
  */
  public boolean search( int value )
  {
    return search( value, root );
  }

  /** search recursive method
  * @param value  an int to search for in the BST "rooted" at nd
  * @param nd  an IntegerNode reference
  * @return a boolean, true if value is found
  *    in the BST "rooted" at nd, false otherwise
  */
  private boolean search( int value, IntegerNode nd )
  {
    if ( nd == null ) // base case, empty subtree
      return false;
    else
    {
      if ( nd.getData( ) == value ) // found value
        return true;
      else if ( nd.getData( ) > value ) // look left
        return search( value, nd.getLeft( ) );
      else // look right
        return search( value, nd.getRight( ) );
    }
  }

  /** maxValue method
  * @param nd an IntegerNode reference, not null
  * @return the largest value in the BST "rooted" at nd
  */
  private int maxValue( IntegerNode nd )
  {
    IntegerNode temp = nd;
    while ( temp.getRight( ) != null )
      temp = temp.getRight( );
    return temp.getData( );
  }

  /** delete method
  * @param value an int value to delete in this BST
  */
  public void delete( int value )
  {
    root = delete( value, root );
  }

  /** delete recursive method
  * @param value an int to delete from in the BST "rooted" at nd
  * @param nd  an IntegerNode reference
  * @return an IntegerNode
  */
  private IntegerNode delete( int value, IntegerNode nd )
  {
    if ( nd == null ) // base case, empty subtree
      return null;
    else if ( nd.getData( ) == value ) // found value
    {
      if ( nd.getRight( ) == null ) // left child only or leaf
        nd = nd.getLeft( );
      else if ( nd.getLeft( ) == null ) // right child only
        nd = nd.getRight( );
      else // 2 children
      {
        int replacement = maxValue( nd.getLeft( ) );
        nd.setData( replacement );
        nd.setLeft( delete( replacement, nd.getLeft( ) ) );
      }
    }
    else if ( nd.getData( ) > value ) // delete in left subtree
      nd.setLeft( delete( value, nd.getLeft( ) ) );
    else // delete in right subtree
      nd.setRight( delete( value, nd.getRight( ) ) );

    return nd;
  }

  /** rebalance method
  * @param arr an array of ints sorted in ascending order
  * rebuilds this BST with the values in arr
  * so that this BST is now balanced
  */
  public void rebalance( int [] arr )
  {
    root = rebalance( arr, 0, arr.length - 1 );
  }

  /** rebalance recursive method
  * @param arr an array of ints sorted in ascending order
  * @param start an int, a valid index of arr
  * @param end an int, a valid index of arr
  * @return an IntegerNode, the "root" of a balanced BST
  *    made up of all the elements of arr between start and end
  */
  private IntegerNode rebalance( int [] arr, int start, int end )
  {
    if ( start <= end )
    {
      int middle = ( start + end ) / 2;
      IntegerNode nd = new IntegerNode( arr[middle] );
      nd.setLeft( rebalance( arr, start, middle - 1 ));
      nd.setRight( rebalance( arr, middle + 1, end ));
      return nd;
    }
    else
      return null;
  }

  /** preOrder method
  * @return a String representation of the pre order
  *    traversal of this BinaryTree
  */
  public String preOrder( )
  {
    return preOrder( root );
  }

  /** preOrder recursive method
  * @param nd an IntegerNode reference
  * @return a String representation of the pre order
  *    traversal of the BinaryTree "rooted" at nd
  */
  private String preOrder( IntegerNode nd )
  {
    if ( nd != null )
    {
      // visit nd
      String result = nd.getData( ) + " ";
      // visit left subtree in pre order
      result += preOrder( nd.getLeft( ) );
      // visit right subtree in pre order
      result += preOrder( nd.getRight( ) );
      return result;
    }
    else
      return "";
  }

  /** inOrder method
  * @return a String representation of the in order
  *    traversal of this BinaryTree
  */
  public String inOrder( )
  {
    return inOrder( root );
  }

  /** inOrder recursive method
  * @param nd an IntegerNode reference
  * @return a String representation of the in order
  *    traversal of the BinaryTree "rooted" at nd
  */
  private String inOrder( IntegerNode nd )
  {
    if ( nd != null )
    {
      // visit left subtree in order
      String result = inOrder( nd.getLeft( ) );
      // visit nd
      result += nd.getData( ) + " ";
      // visit right subtree in order
      result += inOrder( nd.getRight( ) );
      return result;
    }
    else
      return "";
  }

  /** postOrder method
  * @return a String representation of the post order
  *    traversal of this BinaryTree
  */
  public String postOrder( )
  {
    return postOrder( root );
  }

  /** postOrder recursive method
  * @param nd an IntegerNode reference
  * @return a String representation of the post order
  *    traversal of the BinaryTree "rooted" at nd
  */
  private String postOrder( IntegerNode nd )
  {
    if ( nd != null )
    {
      // visit left subtree in order
      String result = postOrder( nd.getLeft( ) );
      // visit right subtree in order
      result += postOrder( nd.getRight( ) );
      // visit nd
      result += nd.getData( ) + " ";
      return result;
    }
    else
      return "";
  }
}
```

Description

Like we did for the traversal methods in the *BinaryTree* class, we use recursion to code the *insert* method. The *private* recursive method is at lines 29–50 and the *public* wrapper method is at lines 17–27. The recursive method inserts *value,* an *int,* its first parameter, in a binary search tree rooted at *nd,* an *IntegerNode,* its second parameter (line 34). At line 36, we test if *value* is smaller than the value stored inside *nd*. If it is, we insert in the left subtree of nd. If *nd* has no left child (line 38), we have found the point of insertion. We instantiate a node containing *value* and set it as the left child of *nd* (line 39). If *nd* has a left child, we make a recursive call to insert in the left subtree of *nd* (line 41). If *value* is larger than the value stored inside *nd* (line 43), we insert as the right child of *nd* if *nd* does not have a right child (lines 45–46), or we insert in the right subtree of *nd* if *nd* has a right child by making a recursive call (line 48).

The wrapper method instantiates *root* with *value* (line 24) if the tree is empty (line 23). Otherwise, it calls the recursive method to insert *value* in the subtree rooted at *root,* i.e., the whole tree (line 26).

We also use recursion to code the *search* method. The *private* recursive method is at lines 61–80 and the *public* wrapper method is at lines 52–59. The recursive method searches for *value,* an *int,* in a subtree rooted at a node *nd,* both parameters of the method (line 67). The wrapper method searches for *value* in the subtree rooted at *root,* i.e., the whole tree. Both methods return *true* if we find *value, false* if we do not. If *nd* is *null* (line 69), then the subtree rooted at *nd* is empty and we will not find *value* inside it; we return *false* at line 70. If *nd* is not *null,* we test if it contains *value* at line 73 and return *true* in that case (line 74). Otherwise, we compare *value* to the value inside *nd* in order to determine whether we search the left subtree (line 76) or the right subtree (line 78) and return whatever the recusive call to the *search* method returns.

At lines 163–251, we include methods to traverse the tree in pre order, in order, and in post order; they are identical to the ones in Example 15.4. These methods are very useful to check that the resulting tree is correct after calling the *insert* and *delete* methods in a client class.

We also use recursion to delete a value from the tree. The *private* recursive method (lines 102–130) deletes *value,* its first parameter, from the subtree rooted at node *nd,* its second parameter (line 107). It returns an *IntegerNode* because we want to use the returned value as the left or right child of a node, i.e., use it as the argument passed to either the *setLeft* or *setRight* methods (lines 121, 125, and 127).

At line 111, we test if the current node, *nd*, contains the value we are looking to delete. If it does, there are three scenarios: *nd* does not have a right child, i.e., is either a leaf or has a left child only (line 113), has a right child only (line 115), or has two children (line 117). If it is a leaf or only has a left child, we simply assign that left child to *nd* (line 114). That converts a grandparent-grandchild relationship between the parent of *nd* and the left child of *nd* to a parent-child relationship; note that the left child of *nd* could be *null*. We do something similar if *nd* has only a right child (line 116). If *nd* has two children, we first call the *maxValue* method in order to find the largest value, *replacement,* in the left subtree of *nd* (line 119); *maxValue,* a *private* utility method, is coded at lines 82–92. Starting at its node parameter *nd*, it finds and returns the largest value within the tree rooted at *nd*. Note that when that method is called, *nd* is guaranteed to have two children. Thus, *temp,* which is assigned *nd.getLeft( )* at line 88, is guaranteed not to be *null,* and there is no risk of a *NullPointerException* at line 89. The value returned by *maxValue* is the value we want to place inside *nd*; we do that at line 120. Then, we make a recursive call to the *delete* method in order to delete that replacement value in the tree rooted at the left child of *nd* (line 121). As part of the same statement making the recursive call (line 121), we also attach the *IntegerNode* returned by the method as the left child of *nd*. Most of the time, that attachment will not change anything in the tree as we attach *nd* to its child. Eventually, a base case is reached, and the deleting actually takes place. Note that because the replacement value is the largest value in the left subtree under *nd,* it is guaranteed not to have a right child (it may or may not have a left child). Thus, when we call the *delete* method to delete, we are guaranteed to fall either in the “delete a leaf” or “delete a node with one child” scenario. These steps are illustrated in **Figure 15.26**.

Figure 15.26 Steps in Deleting a Value (50) Stored in a Node with Two Children

Description

At line 124, we test if the value inside *nd* is greater than *value.* If it is, we make a recursive call to delete *value* within the subtree rooted at the left child of *nd* (line 125). We also set the node returned by the recursive call to the *delete* method to be the left child of *nd*. The process is similar if the value inside *nd* is smaller than *value* (lines 126–127). Again, most of the time, that attachment will not change anything in the tree as we attach *nd* to its child. Eventually, a base case is reached, and the deleting actually takes place.

At line 129, we return *nd*. **Figure 15.27** shows the links that are being reset (in red) when we call *delete* with argument 5.

Figure 15.27 In Red, the Links Reset When Deleting 5

Description

Table 15.4 lists what happens when we call the *delete* method with argument 5. The notation "node*(x)"* represents the node that contains the value *x.* As recursive calls are made, the first argument of *delete* is always 5, while its second argument starts with *root* and goes through every node in the path between *root* and the node containing 5 (node(5)) as the method searches for and finds that node. When *delete* is called (call # 1) with argument node(50), line 125 executes and eventually the method returns node(50) at line 129. The argument passed to *setLeft* at line 125 is the node returned by the call to *delete* with argument node(20), the left child of node(50). When *delete* is called (call # 2) with argument node(20), line 125 executes again and eventually the method returns node(20). Thus, node(20) is the argument passed to *setLeft* above; that does nothing since the left child of node(50) is already node(20). During call # 2, we set the left child of node(20) to be the node returned by *delete* when called with argument node(5). When *delete* is called (call # 3) with argument node(5), lines 116 and 120 evaluate to *true,* and line 121 executes. It changes the value of *nd* to be node(17), which is then returned at line 129. Thus, the left child of node(20) becomes node(17) and node(5) is no longer reachable, and therefore marked for garbage collection. Tracing what happens when we delete a value stored in a leaf, for example 84, or a value stored in a node that has two children, for example 50, are left as exercises.

The Recursive Calls of the *delete* Method When Deleting 5 (Node Has One Child)

"Method call"	Argument (nd)	Returned Node	Setting Children	Line
1: delete(5, root)	node(50)	node(50)	node(50).setLeft(node(20))	125
2: delete(5, node(20))	node(20)	node(20)	node(20).setLeft(node(17))	125
3: delete(5, node(5))	node(5)	node(17)		

Description

Example 15.7 shows how to build the tree in Figure 15.13, looping through an array of values and calling the *insert* method (lines 10–12). At lines 14–16, we call the three traversal methods to check that the tree is the one in Figure 15.13. At line 18, we declare an array of values to be deleted from the tree, including *9* and *8*, two values that are not in the tree. At lines 19–29, we loop through the array, testing many situations, including a value (*9*) not in the tree and trying to delete (*8*) from an empty tree.

Example 15.7 The *BinarySearchTreeClient* Class

```
 1 /** The BinarySearchTreeClient class
 2   Anderson, Franceschi
 3 */
 4
 5 public class BinarySearchTreeClient
 6 {
 7   public static void main( String [] args )
 8   {
 9     BinarySearchTree bst = new BinarySearchTree( );
10     int [] insertions = { 50, 20, 36, 66, 25, 5, 17, 84, 44 };
11     for( int value : insertions )
12       bst.insert( value );
13
14     System.out.println( "Pre order: " + bst.preOrder( ) );
15     System.out.println( "In order: " + bst.inOrder( ) );
16     System.out.println( "Post order: " + bst.postOrder( ) );
17
18     int [] deletions = { 50, 20, 36, 66, 9, 84, 17, 25, 5, 44, 8 };
19     for( int value : deletions )
20     {
21       System.out.println( "\nDeleting " + value );
22       bst.delete( value );
23       System.out.println( "Pre order: " + bst.preOrder( ) );
24       System.out.println( "In order: " + bst.inOrder( ) );
25       System.out.println( "Post order: " + bst.postOrder( ) );
26     }
27   }
28 }
```

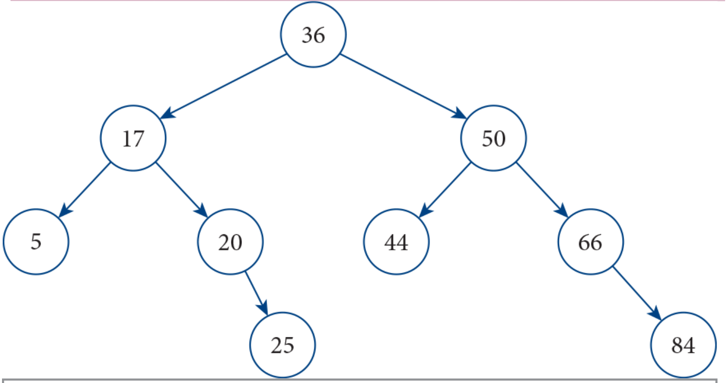
Description

At lines 23–25, we call the three traversal methods after each deletion to check the correctness of the deletion. The output is shown in **Figure 15.28**.

Figure 15.28 The Output of Example 15.7

Description

Index	0	1	2	3	4	5	6	7	8
Value	5	17	20	25	36	44	50	66	84



```
Pre order: 5 17 20 25 36 44 50 66 84
In order: 5 17 20 25 36 44 50 66 84
Post order: 84 66 50 44 36 25 20 17 5

After rebuilding the tree
Pre order: 36 17 5 20 25 50 44 66 84
In order: 5 17 20 25 36 44 50 66 84
Post order: 5 25 20 17 44 84 66 50 36
```

15.7 Rebalancing a Binary Search Tree

We have seen that if a binary search tree is height-balanced, *search, insert,* and *delete* are O(log *n*) and therefore very efficient. However, after many *insert* operations, it is very likely that the binary search tree is no longer height-balanced. In fact, it could degenerate into something that looks like a linked list. Inserting successively 1, 2, 3, 4, and 5 results in the binary search tree in Figure 15.16.

We can rebalance any binary search tree so that it is either complete or almost complete. We do this in two steps:

- Traverse the binary search tree in order and unload it into an array (the array will be automatically sorted in ascending order).
- From the sorted array, build a binary search tree that is height-balanced.

For the first step, if we keep track of the number of elements inserted in the tree, we can size the array appropriately. If we do not, we can build an *ArrayList* as we traverse the tree in order, then unload the *ArrayList* elements into an array. This part is left as an exercise. We focus on how to rebuild a balanced binary search tree from a sorted array.

If we traverse in order and unload the binary search tree in Figure 15.13 into an array, we get the array shown in **Figure 15.29**.

Figure 15.29 The Array Resulting from Traversing In Order the Tree in Figure 15.13

Description

Our algorithm to build a balanced binary search tree is as follows:

- Define *root* as holding the value in the middle of the array, here 36.
- Construct a height-balanced binary search tree with the array elements on the left half of the array (5, 17, 20, 25) and attach its root as the left child of *root.*
- Construct a height-balanced binary search tree with the array elements on the right half of the array (44, 50, 66, 84) and attach its root as the right child of *root.*

This algorithm is recursive and steps 2 and 3 are recursive calls, building smaller balanced binary search trees. Let’s apply the algorithm to the array in Figure 15.29. The root of the tree contains 36, the middle element. Its left child contains the middle element of the left half of the array, 17(0+3)/2 = 1 is the middle index of the left half of the array). Its right child contains the middle element of the right half of the array, 50((5+8)/2 = 6 is the middle index of the right half of the array). The left child of the node containing 17 contains 5, the only element left on the left side of the array. The right child of the node containing 17 contains the middle element of the slice of the array that contains 20 and 25, i.e., 20((2+3)/2 = 2). As the algorithm ends, we get the tree shown in **Figure 15.30**. Every level is completely filled except the last level. We can see that the tree is height-balanced.

Figure 15.30 The Balanced Binary Search Tree Built from the Array in Figure 15.29

Description

As for our three traversals, *insert, search,* and *delete* methods, we use a *public* wrapper method and a *private* recursive method to build a balanced binary search tree from a sorted array. Our recursive *rebalance* method builds a balanced binary search tree from a slice of a sorted array. We can define a slice of an array with three things: the array itself, the starting index, and the ending index. Thus, our recursive method accepts those three as parameters (line 149). It returns the root of the tree that it is building, so that it can be attached as the left or right child of another root from a bigger tree as we make the recursive calls. In the general case, it does the following:

- Create a node (*nd*) with the middle element of the array slice (lines 153–154); that node is the root of the subtree that the method is building,
- Make a recursive call to build a balanced binary search tree with the left half of the subarray (line 155). That recursive call returns a node, the root of the subtree that the method is building; attach that node as the left child of *nd* (line 155), and
- Make another recursive call to build a balanced binary search tree with the right half of the subarray (line 156). That recursive call returns a node, the root of the subtree that the method is building; attach that node as the right child of *nd* (line 156).

If the array slice is empty, the method "builds" an empty tree and returns *null* (lines 159–160); that is the base case.

Our *public* wrapper method only needs to accept one parameter, an array of *ints* (line 137). It calls the recursive method to build a balanced binary search tree for the array slice whose starting index is 0 and ending index is the last array index (line 139), i.e., the whole array.

Example 15.8 shows how to use the *rebalance* method of Example 15.6 to rebuild a height-balanced binary search tree. We first build a binary search tree that looks like a linked list, inserting successively all the values of a sorted array (lines 10–12). At line 18, we rebuild the tree so that it is a height-balanced binary search tree. At lines 21–23, we call the three traversal methods to check that the tree is the one in Figure 15.30. The output is shown in **Figure 15.31**.

Example 15.8 The *BinarySearchTreeClient2* Class

```
 1 /** The BinarySearchTreeClient2 class
 2   Anderson, Franceschi
 3 */
 4
 5 public class BinarySearchTreeClient2
 6 {
 7   public static void main( String [] args )
 8   {
 9     BinarySearchTree bst = new BinarySearchTree( );
10     int [] insertions = { 5, 17, 20, 25, 36, 44, 50, 66, 84 };
11     for( int value : insertions )
12       bst.insert( value );
13
14     System.out.println( "Pre order: " + bst.preOrder( ) );
15     System.out.println( "In order: " + bst.inOrder( ) );
16     System.out.println( "Post order: " + bst.postOrder( ) );
17
18     bst.rebalance( insertions );
19
20     System.out.println( "\nAfter rebuilding the tree" );
21     System.out.println( "Pre order: " + bst.preOrder( ) );
22     System.out.println( "In order: " + bst.inOrder( ) );
23     System.out.println( "Post order: " + bst.postOrder( ) );
24   }
25 }
```

Description

Figure 15.31 The Output of Example 15.8

Description

15.8 Programming Activity 2: Working with Binary Search Trees

In this activity, you will simulate and test the running time of the *insert* method. In order to do this, you will modify the *insert* method of the *BinarySearchTree* class and keep track of the number of steps it takes to insert.

Instructions

Copy the source files in the Programming Activity 2 folder for this chapter to a folder on your computer. Note that all files should be in the same folder.

Inside the *BinarySearchTree* class, you need to modify and code the following methods (the binary tree stores integer values):

Modify the *insert* method so that it keeps track of the number of steps it took to insert (the number of steps is defined as the number of edges from the root to the newly inserted node). You can code the *insert* method so that it returns the number of steps. Alternatively, you can use a *static* instance variable in the class and update it; if you use a *static* instance variable, you need to provide methods to access it from outside the class and reset it to 0.

Code a method that returns an array of integers representing all the values, in ascending order, stored in the binary search tree.

Inside a client class, build a binary search tree storing integers as follows:

- Generate 100000 random integers with values from 0 to 1000000 (to keep it simple, duplicates are accepted) and insert them all in the binary search tree.
- Then, generate 1000 random integers with values from 0 to 1000000 (again, duplicates are accepted) and insert them in the binary search tree, and calculate and output the

average number of steps it took to insert a value.

- Restore the binary search tree to a height-balanced state. Then, generate 1000 random integers with values from 0 to 1000000 (again, duplicates are accepted) and insert them in the binary search tree, and calculate and output the average number of steps it took to insert a value.
- The values 1000, 100000, and 1000000 should be constants (and you should use those constants).

On a separate Word document (1 page max), report your results (first average number of steps to insert, and second average number of steps to insert). In both cases, how does the average number of steps relate to the number of elements in the binary search tree?

Troubleshooting

- Code one method at a time and test your results.
- Check that your results correlate with the math computations in this chapter.

DISCUSSION QUESTIONS

1. **How do your results compare to the math calculations in this chapter?**
2. **Did it help with the running time of insert to reconstruct a height-balanced binary search tree? How much?**

© Lois GoBe/Shutterstock

CHAPTER REVIEW

15.9 Chapter Summary

- A tree is a data structure simulating the hierarchical nature of a tree, including a root and its descendants.
- Nodes in a tree are connected using parent-child relationships.
- The degree of a node is its number of children.
- Sibling nodes are nodes that share the same parent node.
- A leaf is a node that has no child.
- The depth of a node is the number of edges on the path from the root to that node.
- The level of a node is also the number of edges on the path from the root to that node.
- The height of a node is the largest number of edges on the path from the node to a leaf.
- The height of a tree is the height of its root.
- A binary tree is a tree where all the nodes have degree 0, 1, or 2.
- We can traverse a tree in level order, pre order, in order, or post order.
- Traversing the tree in level order, we list the elements level by level, left to right for each level.
- Traversing in pre order, in order, and post order involve

walking around the tree counterclockwise.

- Traversing in pre order, we list each element the first time we see it.
- Traversing in order, we list each element the second time we see it.
- Traversing in post order, we list each element the last time we see it.
- Pre order, in order, and post order traversals are easy to implement using recursion.
- A complete binary tree is a binary tree where every level is full except the last one; the last level is filled left to right.
- A full binary tree is a complete binary tree where the last level is also full.
- In a full binary tree of height h, we have $n = 2^h - 1$ elements.
- A binary search tree is a binary tree such that:
    - All the elements to the left of the root have a value smaller than the root's value.
    - All the elements to the right of the root have a value larger than the root's value.
    - The left subtree of a binary search tree is a binary search tree itself.
    - The right subtree of a binary search tree is a binary search tree itself.
- An empty binary tree is a binary search tree.
- If we traverse a binary search tree in order, the values come out in ascending order.
- In a binary search tree, we insert as a leaf and maintain the binary search tree property.
- In a binary search tree, we maintain the binary search tree property when we delete.
- If a binary search tree is height-balanced, *insert, delete,* and *search* take O(log n) running time, where n is the

number of values stored in the tree.

- We can build a height-balanced binary search tree from an array sorted in ascending order.

15.10 Exercises, Problems, and Projects

15.10.1 Multiple Choice Exercises

1. The node at the “top” of the tree hierarchy is called the
    - head
    - tail
    - root
5. The degree of a node is
    - its number of parents
    - its number of children
    - its number of siblings
    - its stored value
10. A leaf is a node of degree
    - −1
    - 0
    - 1
    - 2
15. The level of a node and the depth of a node have equal values
    - True
    - False
18. The height of a tree is equal to
    - the depth of its left most leaf
    - the depth of its root

- the number of children of its root
- the height of its root

23. The pre order, in order, and post order traversals involve walking around the tree

    - level by level
    - clockwise
    - counterclockwise

27. In a binary tree, every node has

    - no child
    - exactly 1 child
    - 0, 1, or 2 children
    - 1 or 2 children

32. When traversing a binary tree in order, we list each node’s element

    - the first time we see it
    - the second time we see it
    - the third time we see it
    - the fourth time we see it

37. When traversing a binary search tree in order, the elements come out

    - in descending order
    - in no particular order
    - in ascending order

41. If a binary search tree is complete, the worst-case running time of *insert, search,* and *delete* is

    - O(l)
    - O(log *n*)

- O(*n*)
- O(*n* log *n*)

46. If we loop through all the elements of a sorted array from the first to the last index, and insert the elements in a binary search tree in that order, we will get

    - A balanced binary search tree
    - A complete binary search tree
    - A full binary search tree
    - A binary search tree that looks like a linked list

51. Check all that apply: We want to build a balanced binary search tree from an array sorted in ascending order.

    - The middle array element will be stored in the root.
    - The left half of the array (minus the middle element) will make up the left subtree.
    - The right half of the array (minus the middle element) will make up the right subtree.
    - The balanced binary search tree will always be full.

15.10.2 Reading and Understanding Code

1. Within the binary tree of Figure 15.3, the *IntegerNode nd* is a reference to the node containing 33:

   Redraw the tree after the following code is executed:

   ```
   nd.setRight( nd.getRight( ).getRight( ) );
   ```

   Description

2. Within the binary tree of Figure 15.3, the *IntegerNode nd* is a reference to the node containing 33:

   Redraw the tree after the following code is executed:

   ```
   IntegerNode temp = nd.getLeft( ).getRight( );
   nd.getLeft( ).setRight( temp.getRight( ) );
   ```

Description

3. The pre order and in order traversals of a binary tree are as follows:

```
In order:   55 17 74 100 54 22 30  8 12
Pre order: 100 17 55  74 22 54  8 30 12
```

Description

What value is stored inside the root?
What values are stored in the left subtree?
What values are stored in the right subtree?

4. The traversals of a binary tree are as follows:

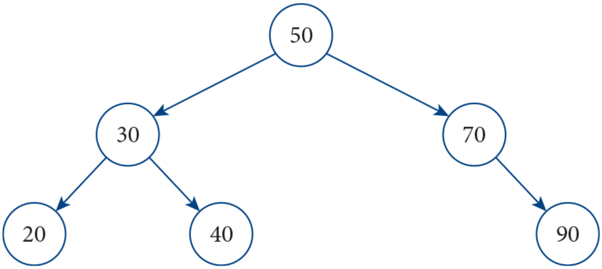
```
Pre order:  88 44 60 25  10 33  40 100
In order:   60 44 10 25  88 33 100  40
Post order: 60 10 25 44 100 40  33  88
```

Description

Draw the tree.

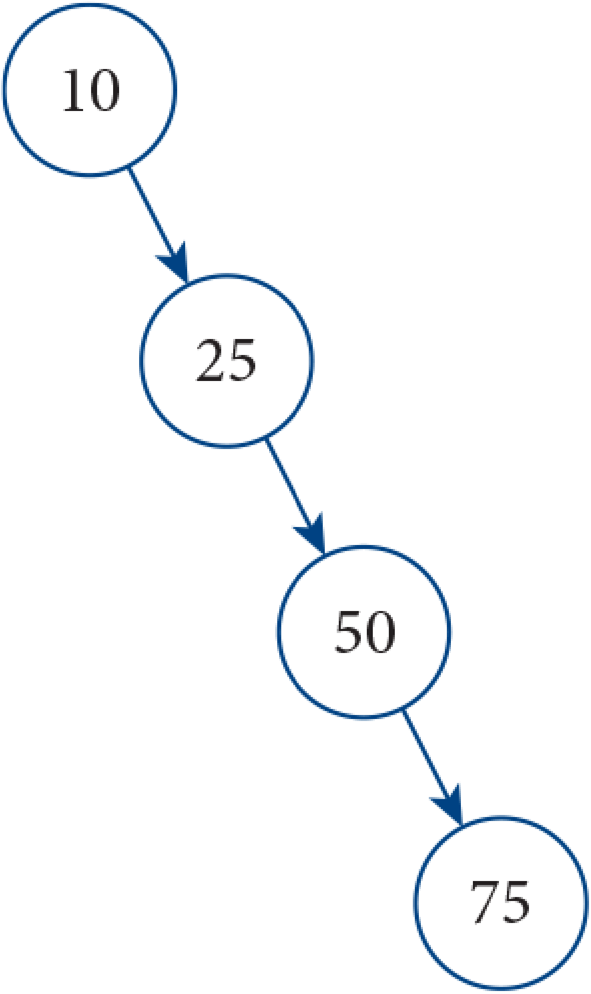
5. We successively insert 100, 125, 75, 87, 50, 150, 175, and 25 in a binary search tree; draw the tree.

6. What succession of inserts would result in the binary search tree below?



Description

7. What succession of inserts would result in the binary search tree below?



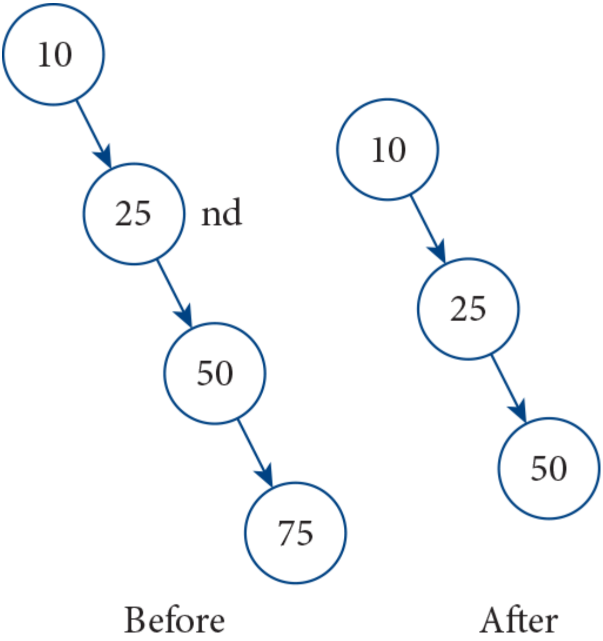
Description

8. Build a table similar to Table 15.4 when deleting 84 from the binary search tree in Figure 15.13.
9. Build a table similar to Table 15.4 when deleting 50 from the binary search tree in Figure 15.13.

15.10.3 Fill In the Code

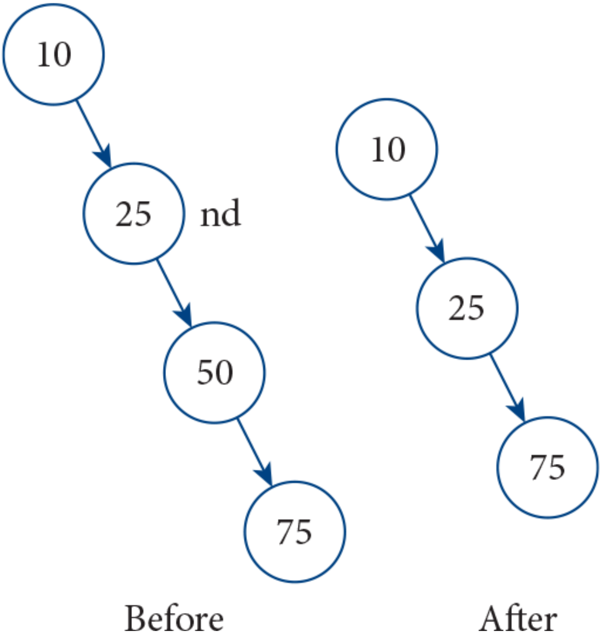
1. Assume that you are coding somewhere inside the

BinaryTree class and that *nd* is a reference to the node containing 25. Write the code to go from the Before to the After picture.



Description

2. Assume that you are coding somewhere inside the *BinaryTree* class and that *nd* is a reference to the node containing 25. Write the code to go from the Before to the After picture.



Description

3. This method of the *BinaryTree* class returns *true* if a binary tree is empty, *false* otherwise.

```
public boolean isEmpty( )
{
   // Your code goes here
}
```

Description

4. This method of the *BinaryTree* class returns *true* if a binary tree has exactly one element, *false* otherwise.

```
public boolean hasExactlyOne( )
{
   // Your code goes here
}
```

Description

5. This method of the *BinaryTree* class returns *true* if a binary tree has at least one element and if the root has 2 children, *false* otherwise.

```
public boolean rootHas2Children( )
{
  // Your code goes here

}
```

Description

6. This method of the *BinaryTree* class returns *true* if a binary tree stores at least three values, *false* otherwise.

```
public boolean storesAtLeast3Values( )
{

   // Your code goes here

 }
```

Description

7. The *public* method of the *BinaryTree* class returns the number of elements in a binary tree that are odd (assume that we store integer values in the binary tree).

```
public int numberOfOddValues( )
{
  // Your code goes here

}

private int numberOfOddValues( IntegerNode nd )
{
  // Your code goes here

}
```

Description

15.10.4 Identifying Errors in Code

1. Where could an error be generated with the following code? How would you fix it?

   ```
   public String preOrder( )
   {
     return preOrder( root );
   }
   private String preOrder( IntegerNode nd )
   {
     String result = nd.getData( ) + " ";
     result += preOrder( nd.getLeft( ) );
     result += preOrder( nd.getRight( ) );
     return result;
   }
   ```

   Description

2. Instead of the *attachLeft* method of the *BinaryTree* class of the chapter, we code this *attachLeft* method instead. What is the error?

   ```
   public void attachLeft( BinaryTree bt )
   {
     root = root.getLeft( bt.root );
   }
   ```

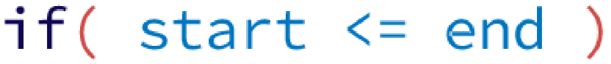
   Description

3. Instead of the *public delete* wrapper method of the *BinarySearchTree* class of the chapter, we code this *delete* method instead, which returns *true or false.* When we try to delete a value that is not found, it returns *true;* explain why.

   ```
   public boolean delete( int value )
   {
     return delete( value, root ) != null;
   }
   ```

   Description

4. In the *rebalance* recursive method of the *BinarySearchTree* class of the chapter, we change:



```
if( start <= end )
```

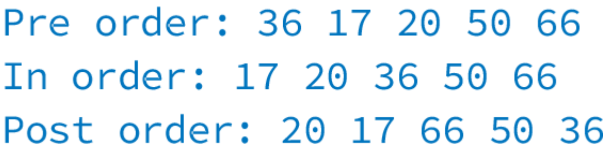
Description

to

```
if( start < end )
```

Description

With the same client as in the chapter, the output is now:



```
Pre order: 36 17 20 50 66
In order: 17 20 36 50 66
Post order: 20 17 66 50 36
```

Description

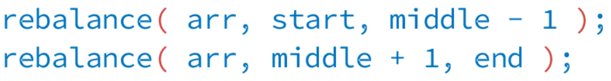
What happened to the missing numbers (5, 25, 44, 84)?

5. In the *rebalance* recursive method of the *BinarySearchTree* class of the chapter, we change:

```
nd.setLeft( rebalance( arr, start, middle - 1 ) );
nd.setRight( rebalance( arr, middle + 1, end ) );
```

Description

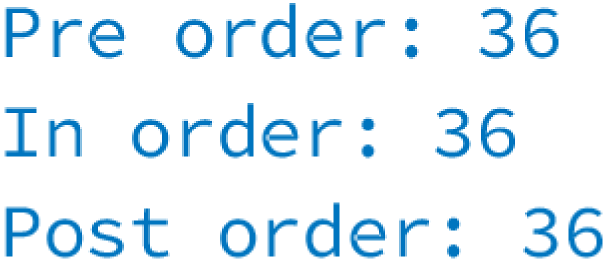
to



```
rebalance( arr, start, middle - 1 );
rebalance( arr, middle + 1, end );
```

Description

With the same client as in the chapter, the output is now:



```
Pre order: 36
In order: 36
Post order: 36
```

Description

It seems that there is only one value, 36, in the binary search tree. How did this happen?

15.10.5 Debugging Area—Using Messages from the Java Compiler and Java JVM

1. In the *BinaryTree* class of the chapter, we add these methods:

```
public void preOrder2( )
{
  preOrder2( root );
}

private void preOrder2( IntegerNode nd )
{
  System.out.print( nd.getData( ) + " " );
  preOrder2( nd.getLeft( ) );
  preOrder2( nd.getRight( ) );
}
```

Description

When we call *preOrder2* from the client, we get a runtime exception as shown below; explain what the problem is (i.e., what is *null)* and how to fix it.

```
Exception in thread "main" java.lang.NullPointerException;
Cannot invoke "IntegerNode.getData()" because "<parameter1>" is null
   at BinaryTree.preOrder2(BinaryTree.java:125)
   ...
```

Description

2. In the *attachLeft* of the *BinaryTree* class of the chapter, we

change:

```
root.setLeft( bt.root );
```

Description

to

```
root.setLeft( bt );
```

Description

At compile time, we get the following error:

```
BinaryTree.java:24: error: incompatible types: BinaryTree
cannot be converted to IntegerNode
    root.setLeft( bt );
```

Description

Explain what the problem is and how to fix it.

3. Instead of the *public insert* wrapper method of the *BinarySearchTree* class of the chapter, we code this *insert* method instead.

```
public void insert( int value )
{
     insert( value, root );
}
```

Description

When we call it from the client, we get a runtime exception as shown below; explain what the problem is (i.e., what is *null)* and how to fix it.

```
Exception in thread "main" java.lang.NullPointerException;
Cannot invoke "IntegerNode.getData()" because "<parameter2>" is null
    at BinarySearchTree.insert(BinarySearchTree.java:32)
    at BinarySearchTree.insert(BinarySearchTree.java:26)
    at BinarySearchTreeClient.main(BinarySearchTreeClient.java:11)
```

Description

15.10.6 Write a Short Program

1. Inside the *BinaryTree* class, write a method that calculates the number of nodes that have exactly 1 child.
2. Inside the *BinaryTree* class, write a method that returns all the nodes in the binary tree that have exactly 2 children; you can return that list as an *ArrayList.*
3. Inside the *BinaryTree* class, write a method that returns the rightmost data stored in the binary tree; the method should throw an exception if the binary tree is empty.
4. Inside the *BinaryTree* class, write a method that returns all the values stored in the binary tree that are multiples of 10; you can return that list as an *ArrayList.*
5. Inside the *BinaryTree* class, write a method that returns *true* if the binary tree is a full binary tree, *false* otherwise.
6. Inside the *BinaryTree* class, write a method that returns *true* if the binary tree is a complete binary tree, *false* otherwise.
7. Inside the *BinaryTree* class, write a method that returns *true* if the binary tree is height-balanced, *false* otherwise.
8. Inside the *BinaryTree* class, write a method that returns the maximum sum of all the paths from the root to a leaf.
9. Inside the *BinarySearchTree* class, write a method that returns all the values stored in the binary search tree in ascending order; you can return that list as an *ArrayList.*
10. Inside the *BinarySearchTree* class, modify the *delete* method so that when we delete a node that has two children, we use the other scenario instead.

15.10.7 Programming Projects

1. Write a modified *BinaryTree* class so that we insert in such a way that the binary tree is always complete.

2. Same as 47 and also include a *delete* method so that we delete the last element that was inserted in the binary tree.
3. Same as 48 and also include another *delete* method so that we delete any element and replace it with the deepest/ rightmost ("last") element.
4. Write a modified *BinaryTree* class so that it includes a method to build a complete binary tree from a linked list.
5. Write a program that includes a *BinaryTree* class that stores *chars;* each *char* can be a digit (0 to 9) or an arithmetic operator (+ , –, *, /). In the client, build a binary tree such that, when traversing the tree in order, correct arithmetic expressions, such as 3 + 5 * 6, are returned.
6. Write a program that is the same as #51 but add parentheses around each operation (for example, an in order traversal would return

   $$((3 + 5) * 6), \text{or} (((6 * 7) - 8) + (9 * 4))$$

7. Write a program that includes a *BinaryTree* class that stores *Strings;* each *String* can be either AND, OR, a, b, or c. A binary tree stores a valid boolean expression (a and b are *boolean* variables). In the client, build a binary tree such that, when traversing the tree in order, correct boolean expressions, such as a AND b OR a, are returned.
8. Same as #53 but add parenthesis around each operation (for example, an in order traversal would return ((a AND b) OR b), or (((a OR b) AND b) AND (c OR a)).
9. Write a program that includes a *BinaryTree* class that stores *Strings;* each *String* is the name of a directory, for example bin, home, or / (the root in Linux). In the client, build a binary tree such that, when searching for a *String* (directory or file name) in the tree, the correct path is

returned (for example /bin/java, or /home/user/msmith). Include code in the client to build a tree of at least 10 elements and enable the user to search for a file path.

10. Write a program that includes a *BinaryTree* class that stores *chars;* each *char* is either a . (dot) or a - (hyphen). The binary tree stores letters coded using Morse code. The Morse code representation of a letter in the tree is its path from the root to that letter (for example, a is .-, b is - ..., c is -.-., d is -.., e is ., ...). Only consider letters from a to z. Add a method in the *BinaryTree* class that returns the Morse code of a letter. In the client, build a binary tree that stores all the letters from a to z. Ask the user to input a letter and return its Morse code representation by searching the tree.
11. Write a program that includes a *BinaryTree* class that stores pairs of *Strings;* that tree will be used as a family tree. The pair of *Strings* is meant to be one person of the family and his or her spouse (or *null* if that person is not married). Assume that people can only have two children. Each *String* is the name of a person, for example *Jill* or *Adam.* Add methods to do the following: based on somebody's name, return *true* if that person is in the tree and is married; based on one name, return the name of that person's sibling (it may have a *null* value); based on somebody's name, return the list of all the descendants. In the client, build a binary tree and test those methods based on user input. Include code in the client to build a tree of at least 10 elements.
12. Write a program that includes a *BinarySearchTree* class that stores information about employees. An *Employee* is defined as having an email, a job title, and a salary. Order the binary search tree based on the email. Add methods to

search based on the email and the job title. For these two methods, return an *Employee* object reference. Add methods to return a list of *Employees* who have a salary greater than or equal to a certain value and a list of *Employees* who have an email that ends with *edu.* In the client, build a binary search tree and test all those methods based on user input. Include code in the client to build a tree of at least 10 elements.

13. Same as #58 and include a method that returns an *ArrayList* of *Employees* sorted in ascending order based on email. In the *Employee* class, include two *static* methods: one that accepts an *ArrayList* of *Employees* and return it in ascending order based on salary; another one that accepts an *ArrayList* of *Employees* and return an array of *Employees.* In the *BinarySearchTree* class, also include a method to rebalance the tree based on salary ordering. In the client, build a binary search tree and test all those methods. Include code in the client to build a tree of at least 10 elements.
14. Write a program that includes a *BinarySearchTree* class that stores information about television channels. A *Channel* is defined as having a number, a description, and whether it is a cable channel or not. Order the binary search tree based on the channel number. Add a method to search based on the channel number and return a *Channel* object reference. Add a method that returns the first *Channel* object you find that matches a certain description. Add methods to return a list of *Channels* that are cable channels and a list of *Channels* whose description contains a certain keyword. In the client, build a binary search tree and test all those methods. Include code in the client to build a tree of at least 10 elements.

15. Write a program that includes a *BinarySearchTree* class that stores information about people. A *Person* is defined as having an email, an age, and a country of origin. Order the binary search tree based on the email of people. Add a method to search based on email. Add methods to search based on age or country of origin and return an *ArrayList* of *Person* object references. Add another method to return a list of *Persons* who are younger than a certain age. In the client, build a binary search tree and test all those methods based on user input. Include code in the client to build a tree of at least 10 elements.

15.10.8 Technical Writing

1. Consider the two search methods in exercise #60 that return a single *Channel* object reference; discuss their respective running times and the impact on deciding the ordering criteria on those running times.
2. A *heap* is a special type of complete binary tree. Research what a heap is, give a description of it, and give an example (i.e., draw it) of a heap with at least 10 elements. Research how to insert into a heap, and insert successively two elements (i.e., redraw the heap after each insertion) in your heap of 10 elements.

15.10.9 Group Project (for a group of 1,2, or 3 students)

1. A composite number is an integer that has exactly two factors, both of them prime. For example, 91(13 times 7) and 85 (17 times 5) are composite numbers. The RSA encryption algorithm is based on the fact that factoring is difficult; in particular, composite numbers are difficult to

factor (when they are large). Build a *BinarySearchTree* class that stores composite numbers and their two factors. The ordering of the tree should be based on the number (not the two factors). Include the appropriate methods to rebalance such a binary search tree so that it is height-balanced. Since you will store composite numbers, you should have a class encapsulating a composite number. Inside that class, provide a method to return a composite number object, including the two factors, based on the value of a number. In the client, build a very large binary search tree (you will need to use looping to build it). Note that you do not need to factor any composite number to fill the tree. For example, with 13 and 7, you can create the composite number 91 and store it along with its two factors, 13 and 7. Additionally, test the two ways to factor a composite number: one by using the binary search tree to retrieve its two factors, the other by factoring the composite number (you will need to create an algorithm for that). For a very large number, compare the actual running time of those two ways to factor.

2. You need to encode a word input by the user into a binary *String* (made of 0s and 1s) that is minimal in length. You need to implement the following algorithm:

    - Create an *ArrayList* of objects for that *String:* each object has two attributes: a character (that is found in the *String)* and its frequency within the *String.* For example, if the user input is JAVA, there will be three objects in the list: J:1, A:2, and V:1 (Note: character:frequency is simply a *String* representation of such an object).
    - Order that *ArrayList* in ascending order by frequency. If the user input is JAVA, the ordered list of objects is J:1, V:1, A:2.
    - From that ordered *ArrayList,* create a parallel *ArrayList* of binary trees. Each binary tree contains only one object.

- Loop to combine the binary trees in that list two at a time until there is only one binary tree left in the *ArrayList.* At each iteration of the loop, the two binary trees with the lowest frequency are combined. When combining two binary trees, the frequency of the resulting binary tree is the sum of the frequencies of the two binary trees. If the user input is JAVA, there are two iterations. At the first iteration, the binary trees containing J:l and VI are combined, resulting in a binary tree with frequency 2 (its root can store an object containing a character of your choice, for example ?, and 2). At the second iteration, that binary tree is combined with the binary tree containing A:2, resulting in a binary tree with frequency 4 (again, its root can store an object containing a character of your choice, for example ?, and 4).
- The resulting/final binary tree contains the codes for each character in the original *String.* The characters are stored in the leaves. Each edge in the tree can be labeled 0 or 1; for example, an edge from a node to its left child can be labeled with a 0, and an edge from a node to its right child can be labeled with a 1. The *String of* 0s and Is that make up the path to a leaf is the encoding of the character stored in that leaf. If the user input is JAVA, a possible resulting binary tree is shown below; the encoding for J is 00, the encoding for V is 01, and the encoding for A is 1. Traverse the tree in order to find the encoding for each character in the *String.*
- Use the encoding scheme above to output the encoding for the word input by the user. Using the encoding above for J, V, and A, the encoded *String* for

JAVA is 001011. Note that the encoding is not unique (for example if you flip the 0s and the 1s, you have another solution).

- Advice: test your code at every step. Draw the tree on paper and check your result against your drawing. Be sure to test your code with many user inputs.

Introduction

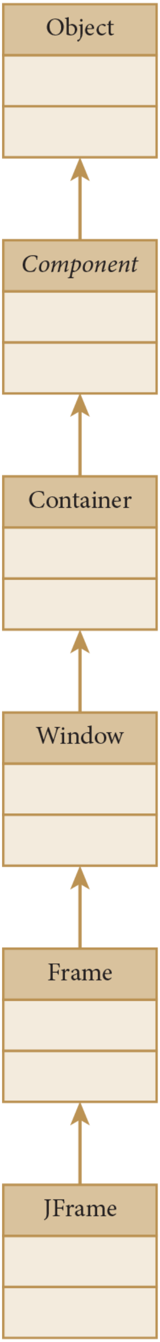
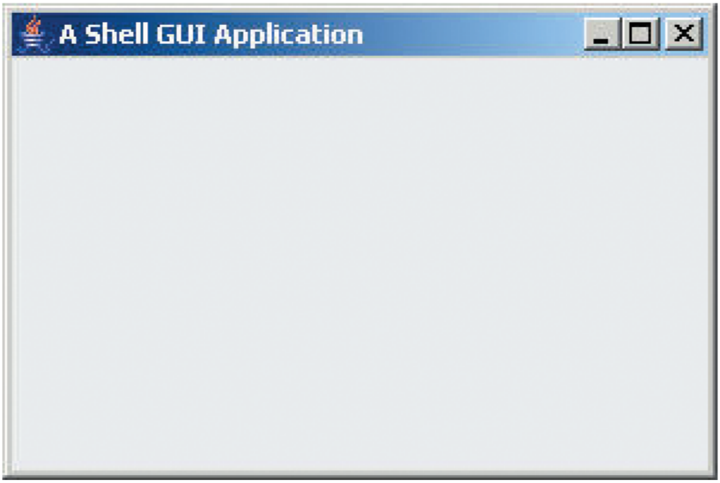
Many applications we use every day have a graphical user interface, or GUI (pronounced goo-ey), which allows us to control the operation of the program visually. For example, web browsers, such as Microsoft Internet Explorer, provide menus, buttons, drop-down lists, and other visual input and output devices to allow the user to communicate with the program through mouse clicks, mouse movements, and by typing text into boxes.

GUIs enable the user to select the next function to be performed, to enter data, and to set program preferences, such as colors or fonts. GUIs also make a program easier to use because a GUI is a familiar interface to users. If you design your program's GUI well, users can quickly learn to operate your program, in many cases, without consulting documentation or requiring extensive training.

Java is very rich in GUI classes. In this chapter, we will present some of those classes, along with the main concepts associated with developing a GUI application.



Object
Component
Container
Window
Frame
JFrame



16.1 GUI Applications Using *JFrame*

The first step in developing a GUI application is to create a window. We will use the *JFrame* class in the *javax.swing* package to create a window for our GUI applications. The inheritance hierarchy for the *JFrame* class is shown in **Figure 16.1**.

Figure 16.1 Inheritance Hierarchy for *JFrame*

Description

Inheriting directly from *Object* is the *Component* class, which represents a graphical object that can be displayed. Inheriting from the *Component* class is the *Container* class, which, as its name indicates, can hold other objects. This is good because we will want to add GUI components to our window. The *Window* class, which inherits from the *Container* class, can be used to create a basic window. The *Frame* class, which inherits from the *Window* class, adds a title bar and a border to the window. The title bar contains icons that allow the user to minimize, maximize, resize, and close the window. This is the type of window we are accustomed to seeing.

We need to step down one more level of inheritance, however, to the *JFrame* class before we are ready to create our

GUI application. A *JFrame* object is a *swing* component. Thus, the *JFrame* class provides the functionality of *Frame*, as well as support for the *swing* architecture. We'll explain more about the *swing* components later in this chapter. For now, Figure 16.1 shows us that a *JFrame* object is a *Component*, a *Container*, a *Window*, and a *Frame* by inheritance, so we can use a *JFrame* object to display a window that will hold our GUI components, and thus present our GUI to the user. Our typical GUI application class will be a subclass of *JFrame*, inheriting its functionality as a window and a container. Thus, the class header for our GUI applications will follow this pattern:

```
public class ClassName extends JFrame
```

Description

Table 16.1 shows two constructors and some important methods of the *JFrame* class, some of which are inherited from its superclasses. Because our GUI applications extend the *JFrame* class, our applications inherit these methods also.

Useful *JFrame* Constructors and Methods

Constructors

Class	Constructor
`JFrame`	`JFrame( )`
constructs a *JFrame* object, initially invisible, with no text in the title bar	
`JFrame`	`JFrame( String titleBarText )`
constructs a *JFrame* object, initially invisible, with *titleBarText* displayed in the window's title bar	

Methods

Return value	Method name and argument list
`Container`	`getContentPane( )`
returns the content pane object for this window	
`void`	`setDefaultCloseOperation( int operation )`
sets the default operation when the user closes this window, that is,	

when the user clicks on the X icon in the top-right corner of the window	
`void`	`setSize( int width, int height )`
sizes the window to the specified *width* and *height* in pixels	
`void`	`setVisible( boolean mode )`
displays this window if *mode* is *true*; hides the window if *mode* is *false*	

Description

Example 16.1 shows a shell GUI application class. This class demonstrates the general format for building GUI applications, but has no components.

Example 16.1 A Shell GUI Application Using *JFrame*

```
 1 /*  A Shell GUI Application
 2     Anderson, Franceschi
 3 */
 4
 5 import javax.swing.JFrame;
 6 import java.awt.Container;
 7 // other import statements here as needed
 8
 9 public class ShellGUIApplication extends JFrame
10 {
11    private Container contents;
12    // declare other instance variables
13
14    // constructor
15    public ShellGUIApplication ( )
16    {
17      // call JFrame constructor with title bar text
18      super( "A Shell GUI Application" );
19
20      // get container for components
21      contents = getContentPane ( );
22
23      // set the layout manager

24
25      // instantiate GUI components and other instance variables
26
27      // add GUI components to the content pane
28
29      // set original size of window
30      setSize( 300, 200 );
31
32      // make window visible
33      setVisible( true );
34   }
35
36   public static void main( String [ ] args )
37   {
38     ShellGUIApplication basicGui = new ShellGUIApplication( );
39     basicGui.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
40   }
41 }
```

Description

We have defined one instance variable, *contents*, which is a *Container* object reference (line 11). Our subsequent GUI applications will define instance variables for the components to be placed in the window, as well as instance variables to hold the data of the application as primitive data types or objects.

The *main* method is coded at lines 36–40. We start by instantiating an object of this application class (line 38), which invokes the constructor (lines 14–34).

At line 39, we call the *setDefaultCloseOperation* method. The *EXIT_ON_CLOSE* argument is a useful *static* constant of the *JFrame* class, which specifies to the *setDefaultCloseOperation* method that the GUI application should terminate when the user closes the window.

A constructor in a GUI application has several tasks to perform:

- Call the constructor of the *JFrame* superclass.
- Get an object reference to the content pane container. We will add our GUI components to the content pane.
- Set the layout manager. Layout managers arrange the GUI components in the window.
- Instantiate each component.
- Add each component to the content pane.
- Set the size of the window.
- Display the window.

In our constructor, at line 18, we call the *JFrame* constructor, passing as an argument, a *String* representing the text that we want to be displayed in the title bar of the window. As in any subclass, this must be the first statement in the constructor.

At line 21, we call the *getContentPane* method, inherited from the *JFrame* class, and assign its return value to *contents*. The *getContentPane* method returns a *Container* object reference; subsequent applications will add our GUI components to this container.

Although this shell application does not have any GUI components, we have inserted comments to indicate where the component-related operations should be performed. Later in this chapter, we show you how to perform these actions.

COMMON ERROR TRAP

Be sure to call the *setSize* method to set the initial dimensions of the window and call the *setVisible* method to display the window and its contents. Omitting the call to the *setSize* method will create a default *JFrame* consisting of a title bar only, although it will be resizable by the user. If you omit the call to the *setVisible* method, the window will not open when the application begins.

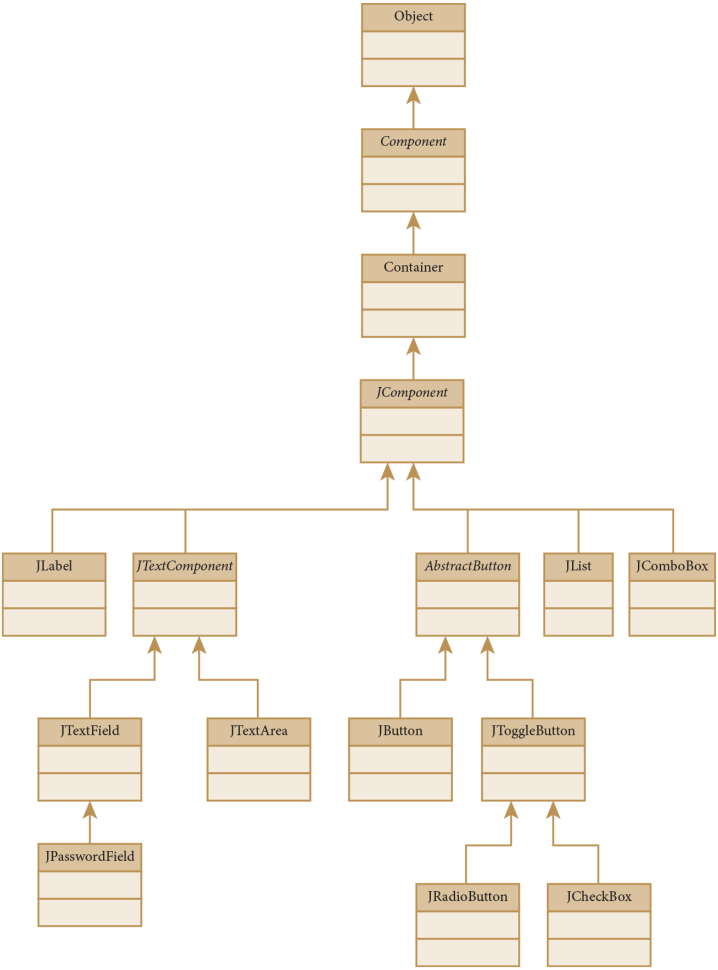
We then set the initial size of the window to a width of 300 pixels and a height of 200 pixels by calling the *setSize* method (line 30). Finally, we call the *setVisible* method (line 33) so that the window will be displayed when the constructor finishes executing. Calling the *setSize* and *setVisible* methods is not required, but if you omit either method call, you will get unfavorable results. If you omit the call to *setSize*, the window will consist of just the title bar. If you omit the call to *setVisible*, the window will not be displayed when the application begins.

The window generated by running Example 16.1 is shown in **Figure 16.2**. Note the text in the title bar, which was set by calling the *JFrame* constructor. When you run the program, try minimizing, maximizing, moving, resizing, and closing the window.

Figure 16.2 The Window Generated by Example 16.1

Description

We have opened a window successfully, but an empty window is not very impressive. In the next section, we will show you how to start adding GUI components to the window.



Object
Component
Container
JComponent
JLabel
JTextComponent
AbstractButton
JList
JComboBox
JTextField
JTextArea
JButton
JToggleButton
JPasswordField
JRadioButton
JCheckBox

16.2 GUI Components

We have already said that a **component** is an object having a graphical representation. Labels, text fields, buttons, radio buttons, checkboxes, and drop-down lists are examples of components. A component performs at least one of these functions:

- displays information
- collects data from the user

- allows the user to initiate program functions

Java provides an extensive set of classes that can be used to add a GUI to your applications. **Table 16.2** lists some GUI components and the Java classes that encapsulate them. All classes listed in Table 16.2 belong to the *javax.swing* package.

Selected GUI Components and Java Classes

Component	**Purpose**	**Java Class**
Label	Displays an image or read-only text. Labels are often paired with text fields and are used to identify the contents of the text field.	*JLabel*
Text field	A single-line text box for displaying information and accepting user input.	*JTextField*
Text area	Multiple-line text field for data entry or display.	*JTextArea*
Password field	Single-line text field for accepting passwords without displaying the characters typed.	*JPasswordField*
Button	Command button that the user clicks to signal that an operation should be performed.	*JButton*
Radio button	Toggle button that the user clicks to select one option in the group. Clicking on a radio button deselects any previously selected option.	*JRadioButton*
Checkbox	Toggle button that the user clicks to select 0, 1, or more options in a group.	*JCheckBox*

Drop-down list	Drop-down list of items that the user clicks to select one item.	*JComboBox*

Description

Java supports two implementations of GUI components: AWT (Abstract Window Toolkit) and *swing*.

The AWT components are the original implementation of Java components and hand off some of the display and behavior of the component to the native windowing system. In other words, on a PC, AWT components, such as buttons and frames, are rendered by the Windows windowing system; on a Macintosh computer, AWT components are rendered by the MacOS windowing system; on a Unix computer, AWT components are rendered by the X-Window system. As a result, the AWT GUI components automatically take on the appearance and behavior (commonly called the **look and feel**) of the windowing system on which the application is running. One disadvantage of AWT components, however, is that because of the inconsistencies in the look and feel among the various windowing systems, an application may behave slightly differently from one platform to another. Because AWT components rely on the native windowing system, they are often called **heavyweight** components.

The *swing* components are the second generation of GUI components, developed entirely in Java to provide a consistent look and feel from platform to platform. As such, they are often referred to as **lightweight** components. Some of the benefits of *swing* components are:

- Applications run consistently across platforms, which makes maintenance easier.
- The *swing* architecture has its roots in the model-view-controller paradigm, which facilitates programming:
    - the model represents the data for the application
    - the view is the visual representation of that data
    - the controller takes user input on the view and updates the model accordingly

- The *swing* components can be rendered in multiple windowing system styles, so your application can take on the look and feel of the platform on which it is running, if desired.

Given the advantages of *swing* over AWT, we will build our GUI applications using *swing* components exclusively. You can recognize a *swing* component because its class name begins with *J*. Thus, *JFrame* is a *swing* component. *Swing* components are found in the *javax.swing* package.

A summary of the inheritance hierarchy for selected *swing* components is shown in **Figure 16.3**. *JComponent* is the base class for all swing components, except for top-level containers such as *JFrame*. Notice that the *JFrame* class does not inherit from the *JComponent* class. However, the *JFrame* class and the *JComponents* shown in Table 16.2 do share some common superclasses: *Component* and *Container*. Thus, the *JComponents* are *Containers*, and as such, can contain other *JComponents* or other *Container* objects. This means that we can nest GUI components, which will help us organize the layout of our windows. We will show you how to do that later in the chapter.

Figure 16.3 The Inheritance Hierarchy for Some GUI Classes

Description

Table 16.3 lists some important methods of *JComponent*. Because these methods are *public*, the GUI components shown in Figure 16.3 inherit these methods.

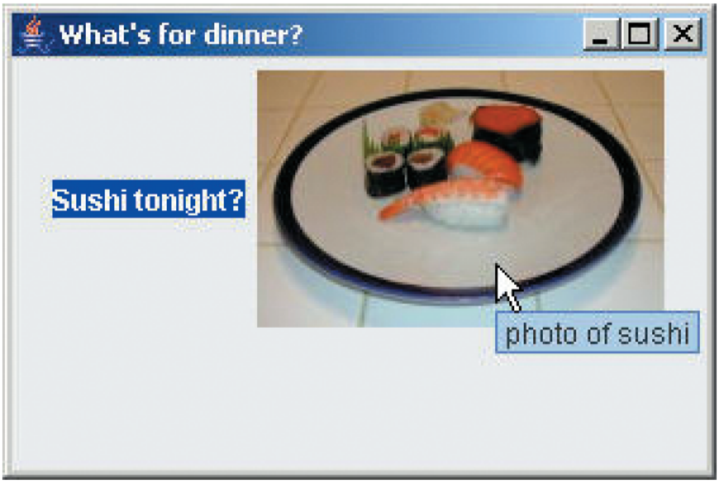
Some Useful *JComponent* Methods

Methods of the JComponent Class	
Return value	**Method name and argument list**
`void`	`setVisible (boolean mode )`

makes the component visible if *mode* is *true*; hides the component if *mode* is *false*. The default is visible.

`void`	`setToolTipText( String toolTip )`	sets the tool tip text to *toolTip*. When the mouse lingers over the component, the tool tip text will be displayed.
`void`	`setForeground ( Color foreColor )`	sets the foreground color of the component to *foreColor*.
`void`	`setBackground( Color backColor )`	sets the background color of the component to *backColor*.
`void`	`setOpaque ( boolean mode )`	sets the component's background to opaque if *mode* is *true*; sets the component's background to transparent if *mode* is *false*. If opaque, the component's background is filled with the component's background color; if transparent, the component's background is filled with the background color of the container on which it is placed. The default is transparent.
`void`	`setEnabled( boolean mode )`	enables the component if *mode* is *true*; disables the component if *mode* is *false*. An enabled component can respond to user input.

Description



16.3 A Simple Component: *JLabel*

Now it's time to place a component into the window. We will start with a simple component, a label, encapsulated by the *JLabel* class. A user does not interact with a label; the label just displays some information, such as a title, an identifier for another component, or an image.

Example 16.2 creates a window containing two labels, one that displays text and one that displays an image. **Figure 16.4** shows the window when the application is run.

Example 16.2 A Simple GUI Component: *JLabel*

```java
/*  Using JLabels to display text and images
    Anderson, Franceschi
*/

import java.awt.Container;
import javax.swing.JFrame;
import javax.swing.ImageIcon;
import javax.swing.JLabel;
import java.awt.FlowLayout;
import java.awt.Color;

public class Dinner extends JFrame
{
  private Container contents;
  private JLabel labelText;
  private JLabel labelImage;

  // Constructor
  public Dinner( )
  {
    super( "What's for dinner?" );       // call JFrame constructor

    contents = getContentPane( );        // get content pane

    contents.setLayout( new FlowLayout( ) ); // set layout manager

    // use the JLabel constructor with a String argument
    labelText = new JLabel( "Sushi tonight?" );

    // set label properties
    labelText.setForeground( Color.WHITE );
    labelText.setBackground( Color.BLUE );
    labelText.setOpaque( true );

    // use the JLabel constructor with an ImageIcon argument
    labelImage = new JLabel( new ImageIcon( "sushi.jpg" ) );

    // set tool tip text
    labelImage.setToolTipText( "photo of sushi" );

    // add the two labels to the content pane
    contents.add( labelText );
    contents.add( labelImage );

    setSize( 300, 200 );
    setVisible( true );
  }

  public static void main( String [ ] args )
  {
    Dinner dinner = new Dinner( );
    dinner.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
  }
}
```

Description

Figure 16.4 Running Example 16.2

Description

Java provides classes to help us organize window contents. These classes are called layout managers. They implement the *LayoutManager* interface and determine the size and position of the components within a container. We will use the simple *FlowLayout* layout manager for the next few examples; later in the chapter, we will look into two other, more sophisticated layout managers: *BorderLayout* and *GridLayout*.

The *FlowLayout* layout manager arranges components in rows from left to right in the order in which the components are added to the container. Whenever a newly added component does not fit into the current row, the *FlowLayout* layout manager starts a new row. With *FlowLayout*, if the user resizes the window, the components may be rearranged into fewer or more rows. We will use the default constructor of the *FlowLayout* class, which centers the components within each row.

To add components to a window, we use two methods of the *Container* class, shown in **Table 16.4**, to set the layout manager and add components to the window. Remember that we obtain the content pane of the *JFrame* window as a *Container* object. We call these methods using the content pane object reference.

Useful Methods of the *Container* Class

Methods of the Container Class

Return value	**Method name and argument list**
`void`	`setLayout( LayoutManager mgr )`
sets the layout manager of the window to *mgr*.	
`Component`	`add( Component component )`
adds the *component* to the container, using the rules of the layout manager. Returns the argument.	
`void`	`removeAll( )`
removes all components from the window.	

Description

In Example 16.2, we declare two *JLabel* instance variables at lines 15–16. At line 25, we set *FlowLayout* as the layout manager.

Next, we instantiate our *JLabel* objects. **Table 16.5** shows several constructors of the *JLabel* class.

Useful Constructors of the *JLabel* Class

Constructors of the JLabel Class

Class	Constructor
`JLabel`	`JLabel( String text )`
creates a *JLabel* object that displays the specified text.	
`JLabel`	`JLabel( String text, int alignment )`
creates a *JLabel* object that displays the specified text. The *alignment* argument specifies the alignment of the text within the label component. The *alignment* value can be any of the following *static int* constants from the *SwingConstants* interface: LEFT, CENTER, RIGHT, LEADING, or TRAILING. By default, the label text is left-adjusted.	
`JLabel`	`JLabel( Icon image )`
creates a *JLabel* object that displays the *image*.	

Description

The *SwingConstants* interface, which is implemented by many *JComponents* that display text, such as labels, text fields, and buttons, provides a collection of *static int* constants that can be used for positioning and orientation of the text within a component.

REFERENCE POINT

More information about the *SwingConstants* interface can be found on the Oracle Java website: *www.oracle.com/technetwork/java*.

The first *JLabel* object reference, *labelText*, is instantiated at line 28, using the constructor with a *String* argument.

The second *JLabel* object reference, *labelImage*, is instantiated at line 36, using the constructor that takes an *Icon* argument. The *ImageIcon* class encapsulates an image and implements the *Icon* interface, so an *IconImage* object can be used wherever an *Icon* argument is required. One of the *ImageIcon* constructors takes as a *String* argument the file name where the image is stored. Its API is:

```
public ImageIcon( String filename )
```

Description

Lines 31–33 call the *setForeground*, *setBackground*, and *setOpaque* methods inherited from the *JComponent* class to set some properties of *labelText*. On line 39, we set up a tool tip that will pop up the message “photo of sushi” when the user pauses the mouse pointer over the image. You can see this tool tip displayed in Figure 16.4.

COMMON ERROR TRAP

As for any object reference, it is mandatory to instantiate a component before using it. Forgetting to instantiate a component before adding it to the content pane will result in a *NullPointerException* at run time.

In lines 42–43, we add the two labels to the window. Because we are using the *FlowLayout* layout manager, the labels appear in the order we added them to the component, first *labelText*, then *labelImage*, centered left to right in the window. If the user resizes the window to be about the same width as the *JLabel* *labelText*, the layout manager will arrange the display so that the image appears under the text (as a second row).

Note that the last statement of the constructor (line 46) is a call to the *setVisible* method to make the window visible.

16.4 Event Handling

Now we know how to open a window in an application, and we know how to display labels and images. But the user can't interact with our application yet, except to display a tool tip. We need to add some interactive GUI components, like buttons or text fields or lists. By interacting with these components the user will control which operations of the program will take place, and in what order.

GUI programming uses an **event-driven model** of programming, as opposed to the procedural model of programming we have been using thus far. By that, we mean that by using a GUI, we put the user in interactive control. For example, we might display some text fields, a few buttons, and a selectable list of items. Then our program will “sit back” and wait for the user to do something. When the user enters data into a text field, presses a button, or selects an item from the list, our program will respond, perform the function that the user has requested, then sit back again and wait for the user to do something else. These user actions generate **events**. Thus, the processing of our program will consist of responding to events caused by the user interacting with GUI components.

When the user interacts with a GUI component, the component **fires an event**. Java provides interfaces, classes, and methods to handle these events. Using these Java tools, we can register our application’s interest in being notified when an event occurs for a particular component, and we can specify the code we want to be executed when that event occurs.

To allow a user to interact with our application through a GUI component, we need to perform the following functions:

1. write an event handler class (called a **listener**)
2. instantiate an object of that class
3. register that listener on one or more components

A typical event handler class *implements* a listener interface. The listener interfaces, which inherit from the *EventListener* interface, are supplied in the *java.awt.event* and *javax.swing.event* packages. A listener interface specifies one or more abstract methods that an event handler class needs to implement. The listener methods receive as a parameter an event object, which represents the event that was fired.

An application can instantiate multiple event handlers, and a single event handler can be the listener for multiple components.

Event classes are subclasses of the *EventObject* class, as shown in **Figure 16.5**, and are in the *java.awt.event* and *javax.swing.event* packages. From the *EventObject* class, the event classes inherit the *getSource* method, which returns the object reference of the component that fired the event. Its API is shown in **Table 16.6**.

Figure 16.5 Event Class Hierarchy

Description

The *getSource* Method Inherited by Event Classes

Return Value	**Method Name and Argument List**
`Object`	`getSource( )`
returns the object reference of the component that fired the event	

Description

Thus, with some simple *if/else* statements, an event handler that is registered as the listener for more than one component can identify which of the components fired the event and decide on the appropriate action.

The types of listeners that we can register on a component depend on the types of events that the component fires. **Table 16.7** shows some user activities that generate events, the type of event object created, and the appropriate listener interface for the event handler to implement. Some of these components can fire other events, as well.

Component Events and Listeners

JComponent	**User Interaction That Generates an Event**	**The Event Object Created**	**Listener Interface the Event Handler Should Implement**
JTextField	Pressing Enter	*ActionEvent*	*ActionListener*
JButton	Pressing the button	*ActionEvent*	*ActionListener*
JRadioButton	Selecting a radio button	*ItemEvent*	*ItemListener*
JCheckBox	Selecting or deselecting a checkbox	*ItemEvent*	*ItemListener*
JList	Selecting an item	*ListSelectionEvent*	*ListSelectionListener*
JComboBox	Selecting an item	*ItemEvent*	*ItemListener*
Any component	Pressing or releasing mouse buttons	*MouseEvent*	*MouseListener*
Any component	Moving or dragging the mouse	*MouseEvent*	*MouseMotionListener*

Description

To add event handling to our *ShellGUIApplication* class, we will follow the following pattern. The code we need to add is shown in bold.

```
// import statements as needed

public class ClassName1 extends JFrame
{
  // declare components and other instance variables

  // constructor
  public ClassName1( )
  {
     // call JFrame constructor
     // get content pane
     // set the layout manager
     // instantiate components and other instance variables
     // add components to the content pane
     // declare and instantiate event handler objects
     // register event handlers on components

     // set window size
     // make window visible
  }

  // private event handler class
  private class EventHandlerName implements ListenerName
  {
     // implement the methods of the listener interface
     // to process the events
  }

  public static void main( String [ ] args )
  {
     // instantiate application object
  }
}
```

Description

Although we can define an event handler class as *public* in its own source file, we usually declare an event handler as a ***private* inner class** within the GUI application class. A *private* inner class is defined within the *public* class and has access to all the members of the *public* class. Thus, declaring our event handler as a *private* inner class simplifies our code by giving the event handler direct access to our application’s GUI components.

In the constructor, we instantiate an object of our event handler class. Then we register that event handler on a component by calling an *add…Listener* method. **Table 16.8** shows a few of these methods. We call the *add…Listener* method using the object reference of the component on which we want to register the listener and passing as an argument the event handler object we instantiated.

Some *add…Listener* Methods

***add…Listener* Method APIs**

```
void addActionListener( ActionListener
handler )
void addItemListener( ItemListener handler
)
void addListSelectionListener(
ListSelectionListener handler )
void addMouseListener( MouseListener
handler )
void addMouseMotionListener(
MouseMotionListener handler )
```

Enter id open

Enter password ??????

Welcome!

Warning: Any attempt to illegally
log in to this server is punishable by law.
This corporation will not tolerate hacking,
virus attacks, or other malicious acts.

16.5 Text Fields

Now we are ready for our first GUI program with user interaction. For this first example, we will build a GUI that takes an ID and a password from a user. If the ID is “open” and the password is “sesame”, we display “Welcome!” Otherwise, we display “Sorry: wrong login”.

We will use a *JTextField* for the ID and a *JPasswordField* for the password. For confidentiality of passwords, the *JPasswordField* does not display the characters typed by the user. Instead, as each character is typed, the *JPasswordField* displays an echo character. The default echo character is *, but we can specify a different character, if desired. We will also use a *JTextArea* to display a legal warning to potential hackers. Both *JTextField* and *JTextArea* are direct subclasses of *JTextComponent*, which encapsulates text entry from the user. *JTextField* displays a single-line field, and *JTextArea* displays a multiline field.

Table 16.9 lists some useful constructors and methods of these text classes.

Useful Constructors and Methods of *JTextField*, *JTextArea*, and *JPasswordField*

Constructors and Methods of the *JTextField*, *JTextArea*, and *JPasswordField* Classes

Constructors

Class	Constructor
`JTextField`	`JTextField( String text, int numColumns )`
constructs a text field initially filled with *text*, with the specified number of columns.	
`JTextField`	`JTextField( int numberColumns )`
constructs an empty text field with the specified number of columns.	
`JTextArea`	`JTextArea( String`

`text )`

constructs a text area initially filled with *text.*

`JTextArea` `JTextArea( int numRows, int numColumns )`

constructs an empty text area with the number of rows and columns specified by *numRows* and *numColumns.*

`JTextArea` `JTextArea( String text, int numRows, int numColumns )`

constructs a text area initially filled with text, and with the number of rows and columns specified by *numRows* and *numColumns.*

`JPasswordField` `JPasswordField( int numberColumns )`

constructs an empty password field with the specified number of columns.

Methods Common to *JTextField*, *JTextArea*, and *JPasswordField* Classes

Return value **Method name and argument list**

`void` `setEditable( boolean mode )`

sets the properties of the text component as editable or noneditable, depending on whether *mode* is *true* or *false*. The default is editable.

`void` `setText( String newText )`

sets the text of the text component to *newText*.

`String` `getText( )`

returns the text contained in the text component.

Additional Methods of the *JPasswordField* Class

Return value **Method name and argument list**

`void` `setEchoChar( char c )`

sets the echo character of the password field to *c*.

`char [ ]` `getPassword( )`

returns the text entered in this password field as an array of *chars*. Note: This method is preferred over the *getText* method for getting the password typed by the user.

Description

Example 16.3 implements our login application, and **Figure 16.6** shows the application in action.

Example 16.3 The *Login* Class

```java
/* Using JTextFields, JTextArea, and JPasswordField
   Anderson, Franceschi
*/

import javax.swing.JFrame;
import javax.swing.JLabel;
import javax.swing.JTextField;
import javax.swing.JPasswordField;
import javax.swing.JTextArea;
import java.awt.Container;
import java.awt.FlowLayout;
import java.awt.Color;
import java.awt.event.ActionListener;
import java.awt.event.ActionEvent;

public class Login extends JFrame
{
 private Container contents;
 private JLabel idLabel, passwordLabel, message;
 private JTextField id;
 private JPasswordField password;
 private JTextArea legal;

 // Constructor
 public Login( )
 {
  super( "Login Screen" );
  contents = getContentPane( );
  contents.setLayout( new FlowLayout( ) );

  idLabel = new JLabel( "Enter id" ); // label for ID
  id = new JTextField( "", 12 );      // instantiate ID text field

  passwordLabel = new JLabel( "Enter password" ); // password label
  password = new JPasswordField( 8 ); // instantiate password field
  password.setEchoChar( '?' );        // set echo character to '?'

  message = new JLabel( "Log in above" );  // label to hold messages

  // instantiate JTextArea with legal warning
  legal = new JTextArea( "Warning: Any attempt to illegally\n"
           + "log in to this server is punishable by law.\n"
           + "This corporation will not tolerate hacking,\n"
           + "virus attacks, or other malicious acts." );
  legal.setEditable( false );        // disable typing in this field

  // add all components to the window
  contents.add( idLabel );
  contents.add( id );
  contents.add( passwordLabel );
  contents.add( password );
  contents.add( message );
  contents.add( legal );

  // instantiate event handler for the text fields
  TextFieldHandler tfh = new TextFieldHandler( );

  // add event handler as listener for ID and password fields
  id.addActionListener( tfh );
  password.addActionListener( tfh );

  setSize( 250, 200 );
  setVisible( true );
 }

 // private inner class event handler
 private class TextFieldHandler implements ActionListener
 {
  public void actionPerformed( ActionEvent e )
  {
   if ( id.getText( ).equals( "open" )
    && ( new String( password.getPassword( ) ) ).equals( "sesame" ) )
   {
    message.setForeground( Color.BLACK );
    message.setText( "Welcome!" );
   }
   else
   {
    message.setForeground( Color.RED );
    message.setText( "Sorry: wrong login" );
   }
  }
 }

 public static void main( String [ ] args )
 {
  Login login = new Login( );
  login.setDefaultCloseOperation( JFrame.EXIT_ON_CLOSE );
 }
}
```

Description

Figure 16.6 Running Example 16.3

Description

Lines 5–14 import the various classes that we use in this program. Line 16 declares the class, which we name *Login*, as a subclass of *JFrame*.

We declare our instance variables at lines 18–22. In addition to our three components (the *JTextField id*, the *JPasswordField password*, and the *JTextArea legal*), we also have three *JLabel* components (*idLabel, passwordLabel*, and *message*). The *idLabel* and *passwordLabel* components provide descriptions for the corresponding text fields. We will use the *message* label to display feedback to the user on whether the login was successful.

At line 32, we instantiate the *JTextField id* using the constructor that takes an initial value and the size of the text field. The initial value is blank, and we want the text field to accommodate 12 characters. At line 35, we instantiate the *JPasswordField password* and set its length to 8 characters. At line 36, we call the *setEchoChar* method to reset the echo character from its default of * to ?. Thus, when the user types characters into the password field, a ? will be displayed for each character typed.

At lines 40–44, we instantiate the *JTextArea legal*. By default, a user can enter data into a text area. However, since we are using this text area only to display a legal warning, we turn off the ability of the user to type into the text area by calling the *setEditable* method with the argument *false* (line 45).

At lines 47–53, we add all the components to the content pane. As Figure 16.6 shows, the components will be displayed in the window in the order we added them to the container.

After the window is displayed, our application will wait for the user to interact with the components. When the user enters a value into either the *id* or the *password* field, we want to check whether the values the user entered are correct. This will be the job of the event handler for those fields.

Pressing the *Enter key* in a text field generates an *ActionEvent*; therefore, at lines 66–83, we coded our event handler as the *private* inner class, *TextFieldHandler*, which *implements* the *ActionListener* interface. As shown in **Table 16.10**, the *ActionListener* interface has only one *abstract* method, *actionPerformed*, which receives an *ActionEvent* parameter.

ActionListener Method API

`public void actionPerformed( ActionEvent event )`

An event handler that implements the *ActionListener* interface writes code in this method to respond to the *ActionEvent* fired by any registered components.

Description

Be sure that you code the *actionPerformed* method correctly, as shown in Table 16.10. Failure to code the header properly causes a compiler error. For example, misspelling the method name generates the following compiler error:

```
Login.TextFieldHandler is not abstract and does not override
abstract method actionPerformed(ActionEvent) in ActionListener
private class TextFieldHandler implements ActionListener
        ^
1 error
```

Description

COMMON ERROR TRAP

Be sure that the header of the *actionPerformed* method is coded correctly. Otherwise, your method will not override the *abstract actionPerformed* method, as required by the *ActionListener* interface.

In the constructor, we declare and instantiate a *TextFieldHandler* object reference, *tfh* (line 55–56). Then at lines 58–60, we register *tfh* as the listener on the *id* and *password* components. When either *id* or *password* is in focus (that is, if the mouse was last clicked on the component) and the user presses the *Enter* key, the component that is in focus will fire an action event and our *actionPerformed* method will be executed.

We implement the *actionPerformed* method at lines 69–82. Because we defined this event handler as a *private* inner class, the *actionPerformed* method can directly access the *id* and *password* fields. At lines 71–72, we test if the *id* and *password* entered by the user are correct.

As shown in Table 16.9, the *getPassword* method of the *JPasswordField* class returns an array of *chars*. At line 72, to convert that array of *chars* to a *String*, we use a constructor of the *String* class with the following API, which takes an array of *chars* as an argument:

```
public String ( char [ ] charArray )
```

Description

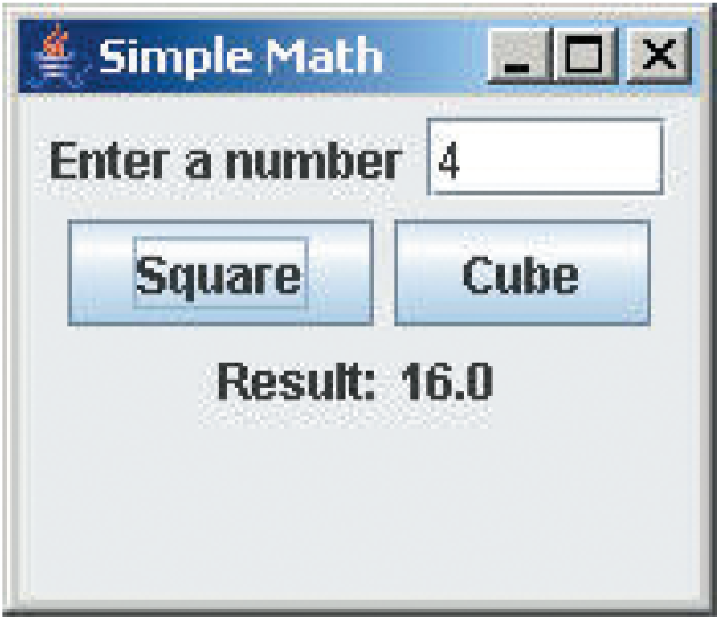
If the user has typed correct values into both the *id* and *password* fields, our event handler sets the foreground color to black and sets the text of *message* to “Welcome!” (lines 74–75). If either the id or the password is incorrect, we set the foreground color to red and set the text of *message* to “Sorry: wrong login” (lines 79–80).

COMMON ERROR TRAP

If you do not register a listener on a component, the component will not fire an event. Thus, the event handler will not execute when the user interacts with the component.

Note that we did not register our event handler for the *JTextArea*. We have disabled typing into that field, so the user cannot enter new text into that field. Also, if we did not register a listener on the *id* and *password* components, the user could still type characters into these two fields and press the *Enter* key, but no events would fire, and therefore, our application would not respond to the user’s actions.

Figure 16.6 shows the application when the window first opens, after the user enters incorrect login values, and after the user enters correct login values. We suggest you become familiar with this application. First run the application as it is written. Then, delete either line 59 or 60, which registers the listeners on the components, and test the application again. Finally, change the echo character and test the application again.



16.6 Command Buttons

Handling an event associated with a button follows the same pattern as Example 16.3. We instantiate an event handler and add that event handler as a listener for the button. Clicking on a button generates an *ActionEvent*, so our listener needs to implement the *ActionListener* interface.
